Optically pumped atoms lose their polarization by various relaxation mechanisms. The relaxation is slowest for spin-polarized nuclei of atoms with no electronic angular momentum in their ground states (e.g., He^3, Xe^{129}, Hg^{199}). Relaxation times ranging from many seconds to hours have been observed for such species, and much of the relaxation is due to hyperfine interactions of atoms adsorbed on the container walls. For atoms with electronic spin angular momentum but no orbital angular momentum (e.g., H, Na, N), relaxation times as long as several seconds are observed. The relaxation is due to weak, collisionally induced spin-orbit couplings in gas-phase collisions, in weakly bound van der Waals molecules, or while the atoms are adsorbed on the container walls. For atoms with nonzero orbital angular momentum nearly every collision causes substantial changes in the polarization, and relaxation rates are comparable to gas kinetic collision rates.

Not all slowly relaxing atoms can be polarized easily by optical pumping. An important example is atomic hydrogen. Since the resonance line of atomic hydrogen is in the vacuum ultraviolet region of the spectrum, and since the fine structure interaction which transfers the polarization from the photon to the spin is small, it is very difficult to pump hydrogen directly. However, hydrogen atoms can be readily polarized by spin exchange with optically pumped rubidium according to the reaction

$$\mathrm{Rb}(\uparrow) + \mathrm{H}(\downarrow) \rightarrow \mathrm{Rb}(\downarrow) + \mathrm{H}(\uparrow)$$

Thus, spin exchange can be used to extend the usefulness of optical pumping to many species (e.g., H, N, e^-) for which direct optical pumping is impractical.

Optical pumping can also produce coherence between the energy sublevels of matter. The coherence ρ_{ij} between a pair of energy levels i and j is defined to be the average value of the product of the quantum mechanical amplitude a_i for one sublevel with the complex conjugate amplitude a_j^* of the other sublevel, i.e., $\rho_{ij} = \langle a_i a_j^* \rangle$ where the average is taken over all components (e.g., atoms) in the system. An example of a physical quantity described by coherence is the transverse component of the spin of an atom. Coherence will ordinarily oscillate at the difference frequency $\omega_{ij} = (E_i - E_j)/\hbar$ of the energy levels, and light modulated at the difference frequency, or unmodulated light in conjunction with radiofrequency or other radiation tuned to the difference frequency, is often used to generate coherence. Transient coherence can also be produced whenever there is a sudden change in the optical pumping conditions. Coherence is conveniently detected by observing the intensity or polarization modulation of the transmitted or scattered light in an optically pumped system.

Optical pumping of gallium arsenide is used to produce intense sources of spin-polarized electrons. The conduction band of gallium arsenide is S-like in character, while the top of the valence band has $P_{3/2}$ character. Thus conduction electrons generated by the absorption of circularly polarized light near the band edge of GaAs are highly polarized in analogy to the polarization of the photon-excited atoms of Fig. 2. By appropriate treatment of the semiconductor surface, the electron affinity of the GaAs conduction electrons can be made negative and the spin-polarized, photogenerated electrons can be efficiently extracted from the semiconductor into a vacuum.

Atoms polarized by optical pumping (Rb, Cs) are used as precise frequency standards and magnetometers. Optically pumped mercury and xenon have been used in experimental nuclear magnetic resonance gyroscopes. Optical pumping is used to provide population inversions for many masers and lasers, and optical pumping by starlight may drive some celestial masers. Finally, optical pumping and closely related techniques have been an extremely effective spectroscopic tool for investigating the fine structures, hyperfine structures, lifetimes, and other properties of molecules, atoms, ions, and optical centers in solids.

OPTICS, GEOMETRICAL

The radiant energy emitted from a point of a luminous source situated in a homogeneous medium free from obstacles travels through the medium as a spherical wave front whose velocity of advance is a characteristic of the medium. A radius of this wave front is a light ray. If a ray experiences a change of medium or encounters an obstacle, it will, in general, deviate from the rectilinear path defined by the radius. The science of geometrical optics is concerned with controlled deviations.

The Law of Reflection (a) The directions of incidence and reflection and of the normal to the reflecting surface are coplanar.

(b) The angle of reflection is equal to the angle of incidence, both angles being taken with respect to the normal (see Fig. 1(a)).

The Law of Refraction (a) The directions of incidence and refraction and of the normal to the refracting surface are coplanar.

(b) The ratio of the sines of the angles of incidence and refraction, both angles being taken with respect to the normal, is a constant whose magnitude is a function of the properties of the two media on either side of the refracting surface (see Fig. 1(b)). The function is

$$\sin \theta_1 / \sin \theta_2 = \mu_{12}$$

The constant μ_{12} is the index of refraction for the two media when light travels from medium 1 to medium 2. If the direction of the ray is reversed, as in Fig. 1(c), it traverses exactly the same path so that

$$\sin \theta_2 / \sin \theta_1 = \mu_{21}, \quad \therefore \mu_{21} = 1/\mu_{12}$$

If the first medium is air, it is usual to drop the suffixes and to replace μ_{12} by n. If the first medium is a vacuum then μ_{12} is the absolute refractive index of the second. For air at NTP the value is 1.00028 so that, for most practical purposes the distinction between μ_{12} and n, with air as the first medium, is negligible for substances, such as glass, commonly used for light control. The value of n depends on the wavelength of the light. For sodium yellow of 5890.6Å, the values of n for a number of media are:

Crown glass	1.517
Flint glass	1.650
Quartz	1.544
Fused silica	1.459
Water at 20°C	1.333
Diamond	2.42

For a mathematically plane surface, the coefficient of reflection for normal incidence is dependent on the value of μ_{12}. Fresnel's law gives for this coefficient

$$\rho = [(\mu_{12} - 1)/(\mu_{12} + 1)]^2$$

Clean polished surfaces give results largely in accord with Fresnel's law. Films of grease or slight roughness appreciably reduce the value of ρ.

(a) REFLECTION (b) REFRACTION (c) REFRACTION

FIG. 1. Reflection and refraction at plane surfaces.

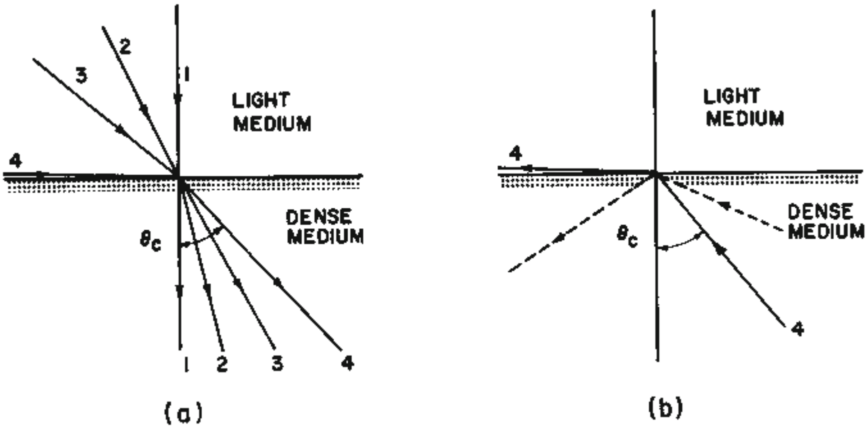

FIG. 2. Illustrating total reflections.

Total Reflection Figure 2(a) shows a series of rays passing from air into a denser medium. Ray No. 1 experiences no deviation. The others experience progressively increasing deviations until, with the tangential ray, No. 4, the angle of refraction θ_c is the greatest possible for that particular medium. Since the angle of incidence is 90°

$$1/\sin \theta_c = n, \quad \therefore \sin \theta_c = 1/n$$

By reversing the directions of the rays, we see that an angle of incidence θ_c is the maximum possible angle for emergence into the air. For angles $> \theta_c$ there is internal reflection, as in Fig. 2(b), governed by the law of reflection. The angle θ_c is called the critical angle for the particular combination of media. Figure 3 shows a number of practical applications of total reflection.

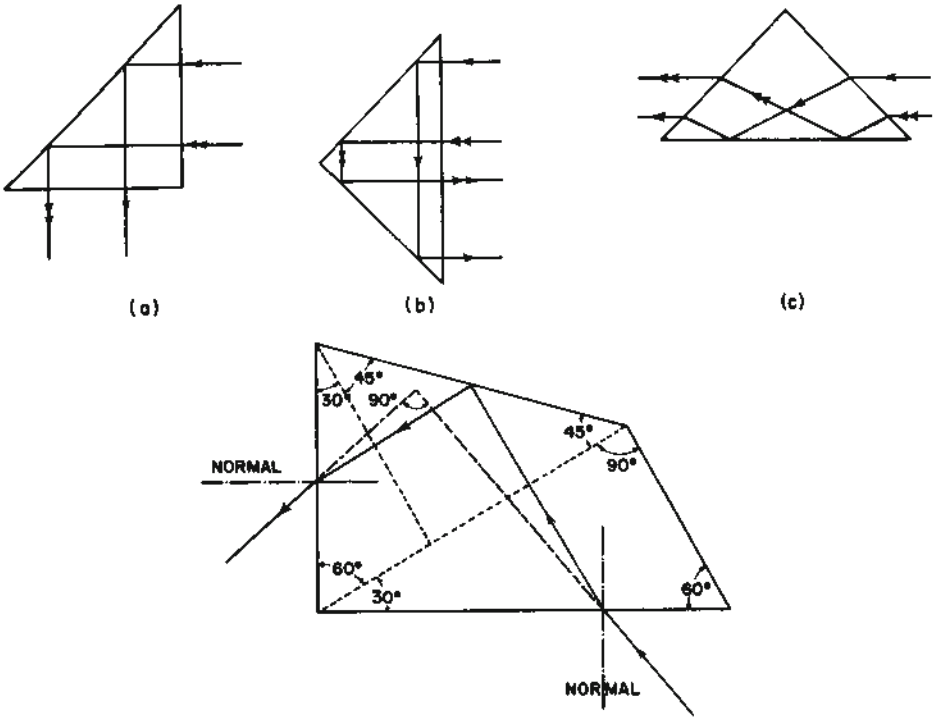

FIG. 3. (a), (b) and (c) show three methods of using the 45° prism. (d) is a constant deviation prism as used in spectrometers.

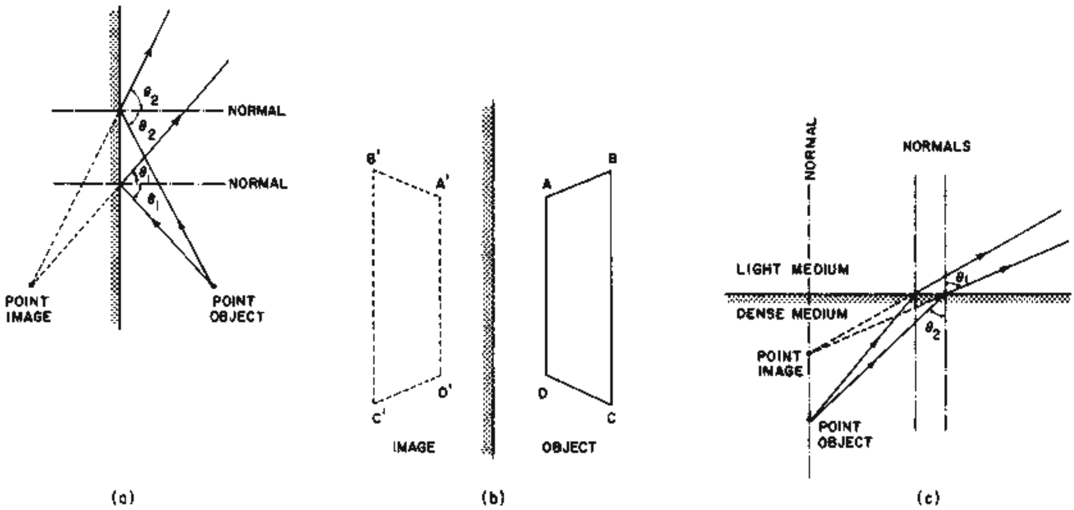

FIG. 4. Image formation by plane surfaces: (a) point object, (b) extended object, (c) image by diffraction of a point object.

Image Formation The geometry of Fig. 4(a) shows that the image in a plane mirror of a point in front of it is another point which lies behind the mirror along the normal from the object point, and is as far behind the mirror as the object is in front. The image of an extended object is identical in size and shape but experiences lateral inversion (see Fig. 4(b)). The image is virtual in the sense that it cannot be received on a screen.

The geometry of Fig. 4(c) shows that the image of a point in a dense medium is another point situated on the same normal to the surface and at a distance from the surface of $1/n$ of the distance of the object point. For large viewing angles, this relationship does not apply, the rays forming the envelope of a caustic as in Fig. 5(a). If the object is extended, a straight line for example, the image is curved and concave towards the surface as in Fig. 5(b).

Refraction by Prism Figure (6a) shows the general case, the incident angle θ_1 being different from the emergent angle $\theta_1{}'$. The deviation D is given by

$$D = \theta_1 + \theta_1{}' - A$$

Figure 6(b) shows the conditions for minimum deviation. $\theta_1 = \theta_2 = \theta$, say. The deviation is now given by

$$n = \sin \frac{A + D_{\text{min}}}{2} \Big/ \sin \frac{A}{2}$$

Thus for a 60° prism for which $n = 1.517$

$$\sin \frac{A + D_{\text{min}}}{2} = n \sin A/2 = 1.517 \times 0.5 = 0.7585$$

$$\therefore A + D_{\text{min}} = 2 \times 49°20'; \quad D_{\text{min}} = 38°40'$$

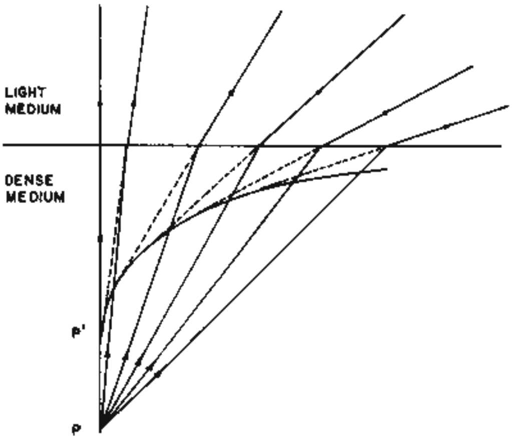

FIG. 5(a). Formation of caustic by refraction. P, point-object. P′, position of point-image for small angles of incidence.

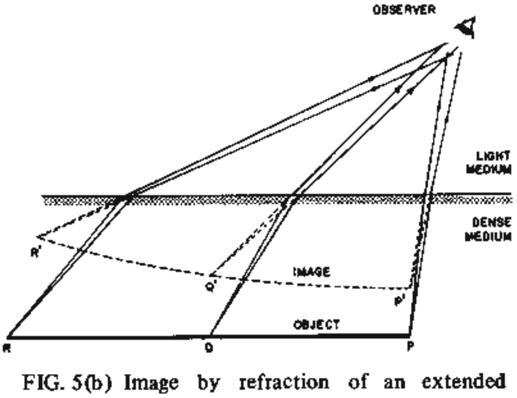

FIG. 5(b) Image by refraction of an extended object.

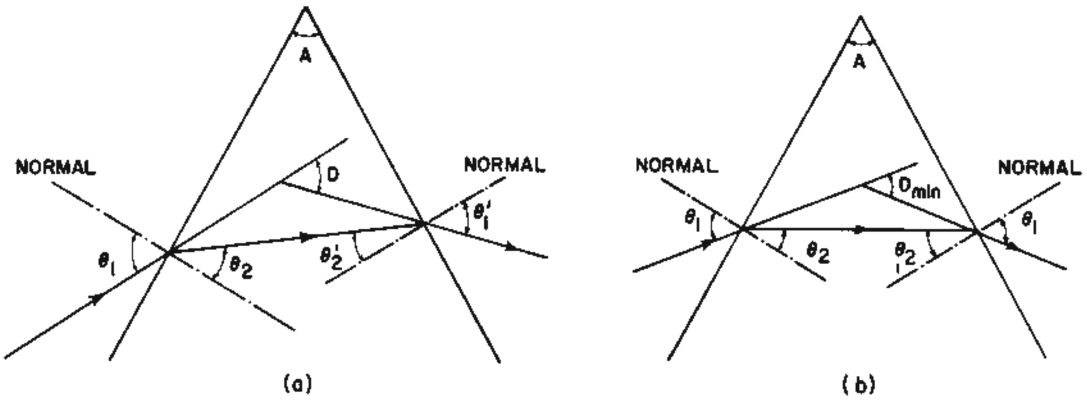

FIG. 6. Deviation by prism: (a) General case, (b) condition for minimum deviation.

A "thin" prism is one for which $A \ngtr 15^\circ$, so that θ(radians) $\simeq \sin\theta$. This gives

$$D_{\min} \simeq (n-1)A$$

Only if the incident ray is monochromatic will the emergent ray be monochromatic. If the incident ray is heterochromatic, then the various components in the emergent beam will have different deviations according to their wavelengths. Deviation without dispersion can be achieved by using a compound prism. The main prism, of apex angle A, is of crown glass of refractive index n, and the correcting prism is of flint-glass, of apex angle A' and refractive index n'. Denote the light of minimum wavelength by the suffix b and that of maximum wavelength by r, then for the main prism

$$D_b - D_r = (n_b - n_r)A,$$

and for the correcting prism

$$D_b' - D_r' = (n_b' - n_r')A'.$$

For zero dispersion we must have

$$(D_b - D_r) = (D_b' - D_r'),$$

$$(n_b - n_r)A = (n_b' - n_r')A',$$

therefore

$$\frac{A}{A'} = \frac{n_b' - n_r'}{n_b - n_r}.$$

If the deviation is to be zero, $D = D'$. Now

$$D - D' = (n-1)A - (n'-1)A',$$

$$(n-1)A = (n'-1)A'$$

since $D - D' = 0$; therefore

$$\frac{A}{A'} = \frac{n'-1}{n-1}.$$

Reflection at Curved Surfaces The element of area round a point on the surface is regarded as part of the tangent plane at that point. First consider a spherical surface, Figs. (7a) and (b), and let the aperture be small compared with the radius of curvature. In each Figure, O is the center of curvature, OP is a radius, and O' is the "pole" of the mirror. A ray parallel to the axis is reflected to a point F, the focus. In Fig. 7(a), F is in front of the mirror; in Fig. 7(b) it is

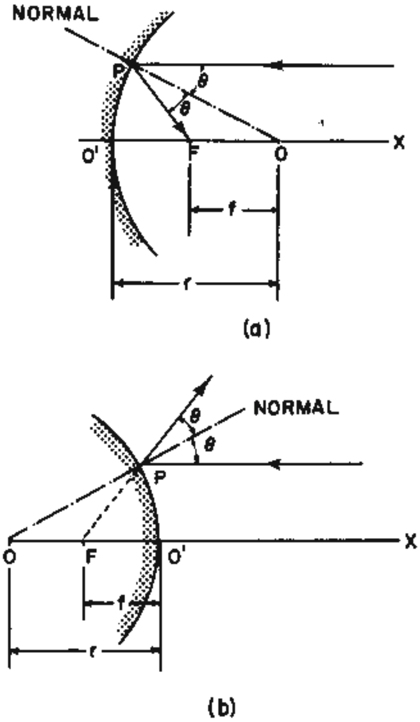

FIG. 7. Reflection at spherical mirrors. (a) Concave, (b) convex.

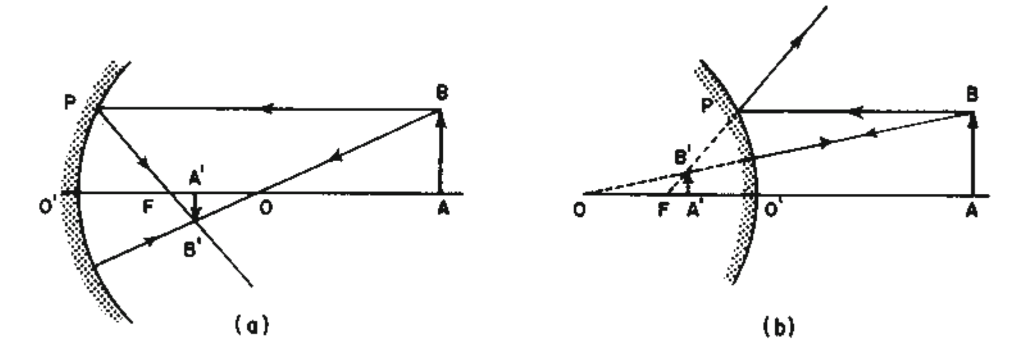

FIG. 8. Image formation in spherical mirrors. (a) Concave, (b) convex.

Concave Mirror	Convex Mirror
u and r negative	u negative and r positive
$u = -8, r = -6, f = -3$	$u = -8, r = +6, f = +3$
$\therefore \frac{1}{v} = -\frac{1}{3} - \left(-\frac{1}{8}\right) = -\frac{1}{4.8}$	$\therefore \frac{1}{v} = \frac{1}{3} - \left(-\frac{1}{8}\right) = \frac{11}{24}$
$v = -4.8$	$v = +2.18m$

behind, so that the reflected ray *appears* to come from F. For small apertures O′F ≈ PF and the position of F is independent of O within this limitation. This gives for O′F, the focal length $f = r/2$.

Image Formation For an object of small dimensions, the image can be obtained by drawing two rays only: (a) a ray through O—this strikes the mirror normally and is returned along the same path; (b) a ray parallel to the axis—this is reflected through the focal point F.

In Fig. 8, AB is the object and A′B′ the image. In Fig. 8(a) the image is real, in Fig. 8(b) it is virtual. An image is real when the reflected rays actually pass through points in it; it is virtual if they have to be traced back, so that they only appear to come from the image.

Conjugate Foci In Fig. 9(a) a point object A produces a point image A′. If A and A′ are interchanged, the rays take identical paths but the arrows are reversed. A and A′ are called conjugate foci. In Fig. 9(b) the image A′ in the convex mirror is virtual. The relationship between the angles is as follows:—

$$\gamma = \theta + \beta,\ \beta = \theta + \alpha;\ \therefore \alpha + \gamma = 2\beta$$

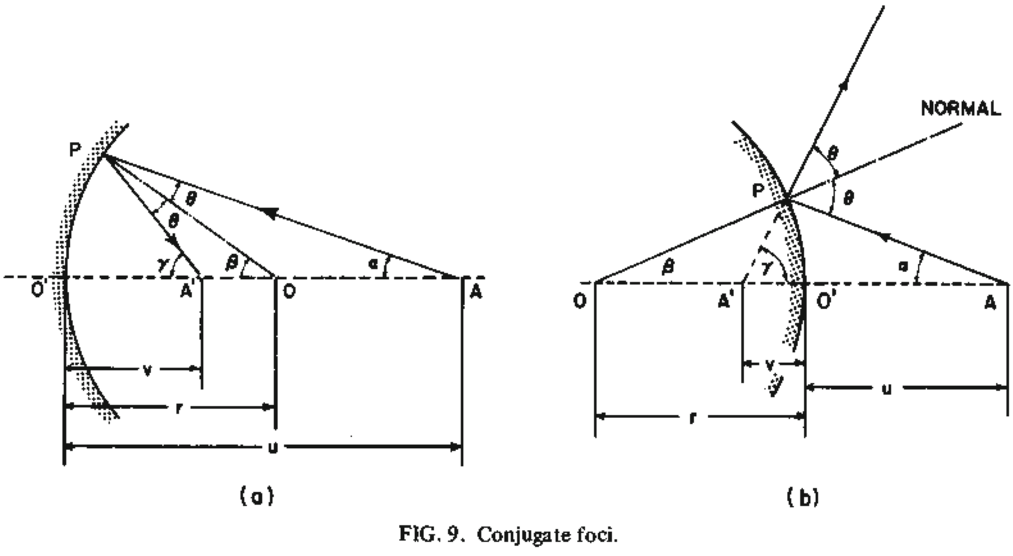

FIG. 9. Conjugate foci.

For small apertures

$$\alpha = PO'/O'A, \quad \beta = PO'/O'O, \quad \gamma = PO'/O'A'$$

$$\therefore \frac{1}{v} + \frac{1}{u} = \frac{2}{r} = \frac{1}{f}$$

This is purely quantitative relationship. For general application it is necessary to adopt a convention regarding signs. Distances are always measured from the mirror, and the direction of the incident light is reckoned positive. As an example let $u = 8$ and $r = 6$. (See calculations under Fig. 8.)

The magnification

$$m = \frac{A'B'}{AB} = \frac{v}{u}$$

This is positive if v and u have the same sign as with the real inverted image of a real object, Fig. 8(a). It is negative if u and v are of opposite sign as with the virtual erect image of a real object, Fig. 8(b).

The axial magnification of an object of finite axial dimension is given by differentiating the above equation.

$$-\frac{dv}{v^2} - \frac{du}{u^2} = 0, \quad \therefore \frac{dv}{du} = -\frac{v^2}{u^2}$$

This shows that if an object is moved towards the mirror a distance du, the image will move $dv = -v^2du/u^2$. Thus the image will move more rapidly when u is small.

Parabolic Mirror For large apertures for which the angle β is not small, the rays of a parallel axial beam are not all brought to a focus at F, but form the envelope of a cusp, as in Fig. 10(a). A parabolic mirror brings all the rays of such a beam to the same focus. [see Fig. 10(b)].

Refraction at Spherical Surfaces The geometry of Fig. 11(a) gives for a surface of small aperture

$$\frac{n-1}{r} = \frac{n}{v} - \frac{1}{u}$$

If we put $v = \infty$, so that the rays are parallel after refraction and put f_1 for the corresponding value of u

$$\frac{n-1}{r} = -\frac{1}{f_1}$$

If we put $u = \infty$, so that the incident rays are parallel, the corresponding value of v (call it f_2) is given by

$$\frac{n-1}{r} = +\frac{n}{f_2}, \quad \therefore \frac{n}{f_2} + \frac{1}{f_1} = 0$$

For an object AB, Fig. 11(b), we obtain the position of the image by drawing two rays from B; the first parallel to the axis, thereby passing through F_2 after refraction; the second passing through F_1, thereby becoming parallel to the axis after refraction.

$$m = \frac{f_1}{u - f_1} \quad \text{or} \quad \frac{v - f_2}{f_2}$$

Lenses Figure 12 shows three media separated by spherical surfaces. Considering each surface in turn

$$\frac{n_2}{n_1} \cdot \frac{1}{w} - \frac{1}{u} = \left(\frac{n_2}{n_1} - 1\right) / r_1$$

$$\therefore \frac{n_2}{w} - \frac{n_1}{u} = \frac{n_2 - n_1}{r_1}$$

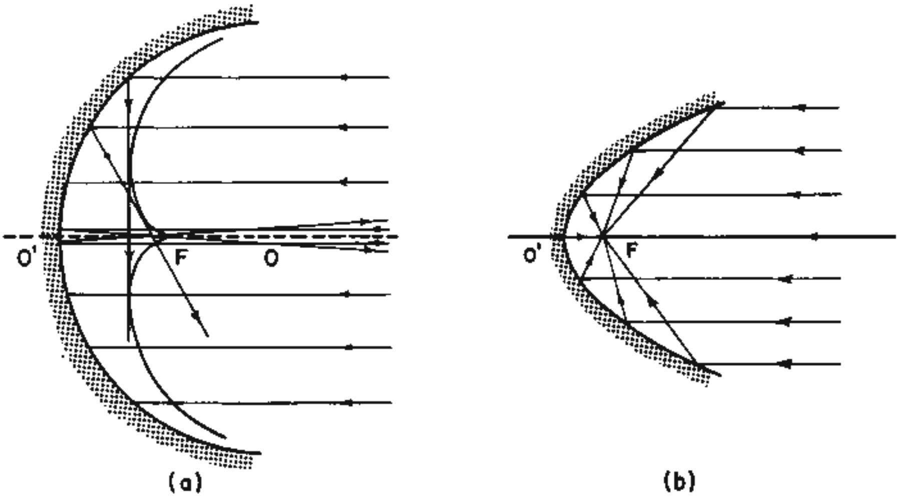

FIG. 10. Reflection by mirrors of wide aperture. (a) Spherical, (b) parabolic.

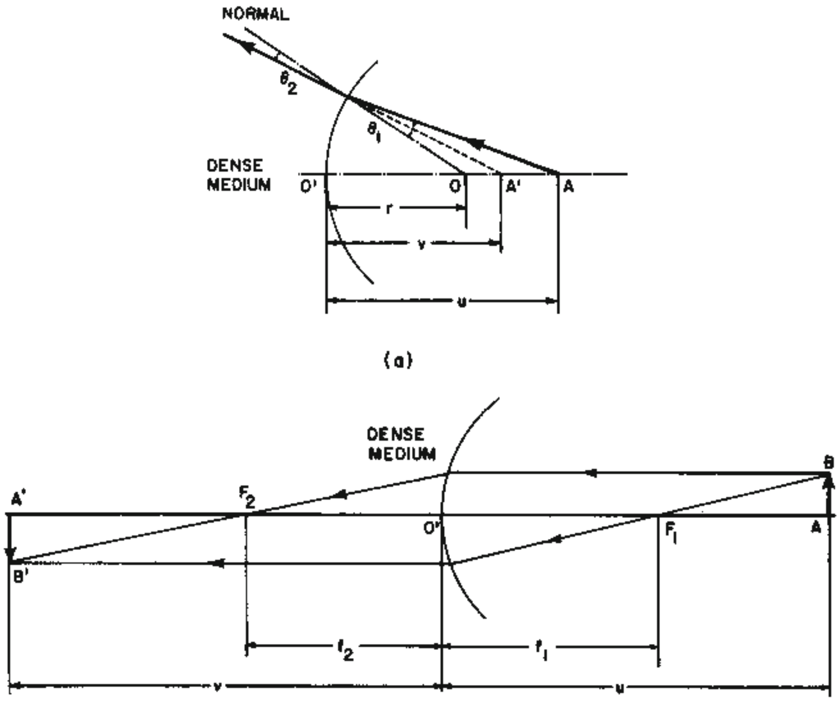

(a)

(b)

FIG. 11. Refraction at spherical surface of separation between two media.

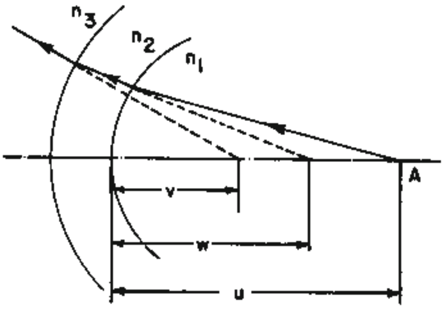

FIG. 12. Lens.

Similarly

$$\frac{n_3}{v}-\frac{n_2}{w}=\frac{n_3-n_2}{r_2}$$

adding,

$$\frac{n_3}{v}-\frac{n_1}{u}=\frac{n_3-n_2}{r_2}+\frac{n_2-n_1}{r_1}$$

In the case of a lens, $n_3 = n_1$, giving

$$\frac{1}{v}-\frac{1}{u}=\left(\frac{n_2}{n_1}-1\right)\left(\frac{1}{r_1}-\frac{1}{r_2}\right)$$

with air on either side of the central section, $n_1 = n_3 = 1$, and we can put $n_2 = n$.

$$\therefore \frac{1}{v}-\frac{1}{u}=(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right)$$

If we put $u = \infty$ then $v = f$, the focal length,

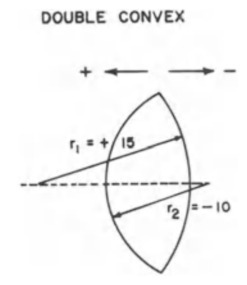
$$\therefore \frac{1}{f}=(u-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right)^{*};\quad f=\frac{r_1 r_2}{(n-1)(r_2-r_1)}$$

Lateral magnification $m = \dfrac{v}{u}$ or $\dfrac{f}{u-f}$

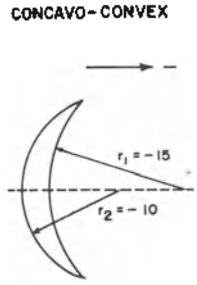
Axial magnification $\dfrac{dv}{du} = -\dfrac{v^2}{u^2}$

*Some authors give this equation with a + sign in the second bracket. In such a case it is necessary to use different signs for convex and concave surfaces, a confusion which is avoided by the simple convention adopted in this article.

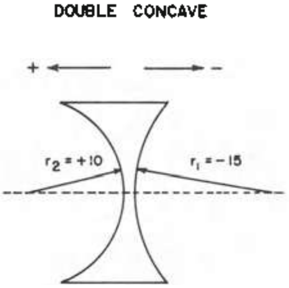
Example $r_1 = 10$, $r_2 = 15$, $\mu = 1.6$



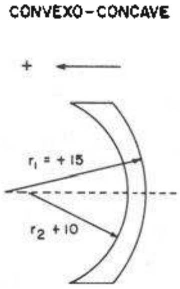
$$f = \frac{15 \times (-10)}{0.6(-10 - 15)} = +10$$



$$f = \frac{-15 \times (-10)}{0.6(-10 + 15)} = +50$$



$$f = \frac{-15 \times (+10)}{0.6(10 - (-15))} = -10$$



$$f = \frac{15 \times 10}{0.6(10 - 15)} = -15$$

With the convex lenses the focus is on the far side of the lens from the source; with the concave lenses it is on the same side as the source. With plano-convex and plano-concave lenses, $1/r$ for the plane surface is zero.

Defects in Mirrors and Lenses An aperture which is large compared with the focal length introduces errors in both mirrors and lenses. One of these is the axial spread of the focus as shown in Fig. 10(a). The amount of spread for a mirror of aperture 2θ is

$$\frac{r}{2}\left(\frac{1}{\cos\theta} - 1\right)$$

Astigmatism results when the object is situated off the axis. The reflected pencil is brought to a focus at a point I, also off the axis, and is spread into an axial line Q_1Q_2, as in Fig. 13(a). If the mirror is turned through a small angle, the point I describes a line called the first focal line. Q_1Q_2 is the second focal line and is perpendicular to the other. In between there is a region where the reflected pencil is the nearest approach to a circle; this is called the circle of least confusion.

Figure 13(b) shows longitudinal spherical aberration in a lens; rays very close to the axis pass through the focal point as defined for a thin lens, while increasing divergence brings the focus nearer to the lens. Figure 13(c) shows chromatic aberration—the focal length, even for a thin lens, being a function of the wavelength. This is because n varies with the wavelength and increases as the wavelength decreases. Thus the focal length for violet is less than for red.

Curvature of the Field The image of a plane object lies, in general, on a slightly curved field (Fig. 14), and this combines with the effects of astigmatism. Pincushion distortion results when a lens is used as a magnifying glass; barrel distortion results when an object is viewed through a lens at some distance from the eye.

Correction of Spherical Aberration (1) *Spherical mirror.* The distortion due to a spherical concave mirror can be corrected by imposing a similar distortion, but in the opposite direction, on the incident light. An elegant solution, used in the Schmidt telescope, is to place at the center of curvature of a mirror—and therefore between the incident light and the mirror—a transparent plate having one surface aspherical. The contours of this plate are such that the beam transmitted by the plate is distorted from true parallelism by the required amount. The paths of the extreme rays are indicated in Fig. 15. The cone of rays reflected by the mirror is, by this device without distortion; thereby form-

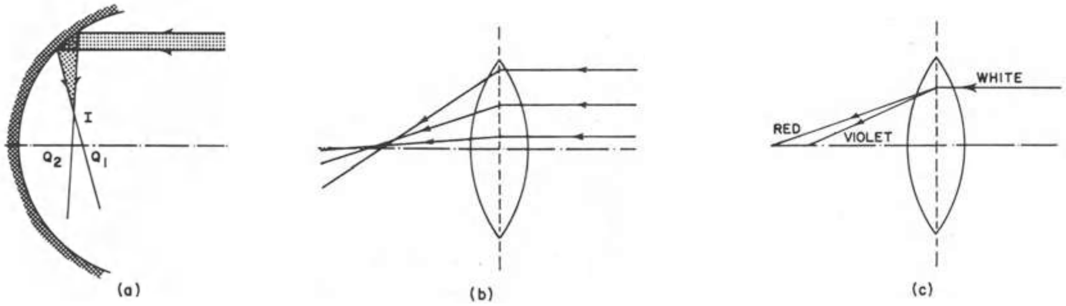


FIG. 13. Image defects. (a) Astigmatism, (b) longitudinal spherical aberration, (c) chromatic aberration.

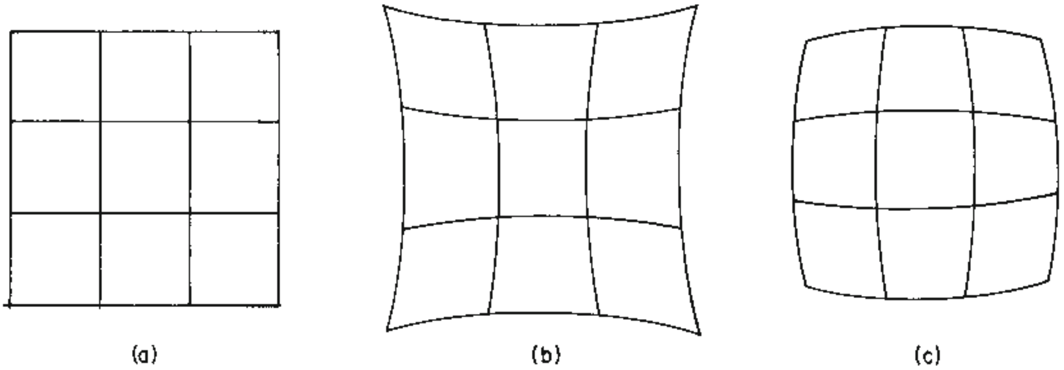

FIG. 14. Image distortion. (a) Object, (b) pincushion distortion, (c) barrel distortion.

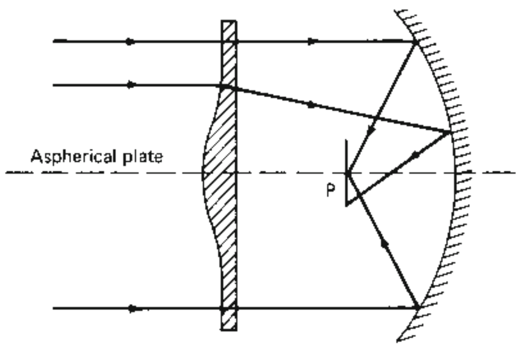

FIG. 15. Ray diagram for Schmidt Telescope.

ing a very sharp image on the photographic plate P.

In conventional reflecting telescopes of the Newtonian kind, uncorrected aberration limits the permissible inclination of rays to axis to a few degrees. In the Schmidt telescope the absence of aberration means that the angular diameter of the effective field is proportional to the ratio of the aperature to the focal length of the mirror.

(2) *Thick Lens.* Close to the axis the two opposite faces of the lens have only a small inclination to one another, whereas away from the axis this inclination is greater. This increase with distance from the axis brings the transmitted rays to a focus progressively nearer to the lens, as shown in Fig. 13(b). With large diameter lenses the aberration is corrected by means of a stepped construction in which the lens consists of a series of concentric zones. Figure 16(a) shows a single stepped lens and also a double lens in which the second component is inverted. The double lens allows a much greater angle of collection. Cheap lenses can be of moulded glass, but where precision is essential the surfaces must be polished and the cost therefore high. Figure 16(b) shows what is probably the supreme example of light control by refraction and internal reflection; it is a schematic drawing of a lighthouse lens system. In this case every prism has to be optically perfect, and also the refracting surface of each dioptic (stepped) lens. For this reason the various components have to be separate, as indicated in the figure.

Systems of Lenses The inverse of the focal length of a lens is called the power of the lens. If the unit of length is the centimeter, the unit

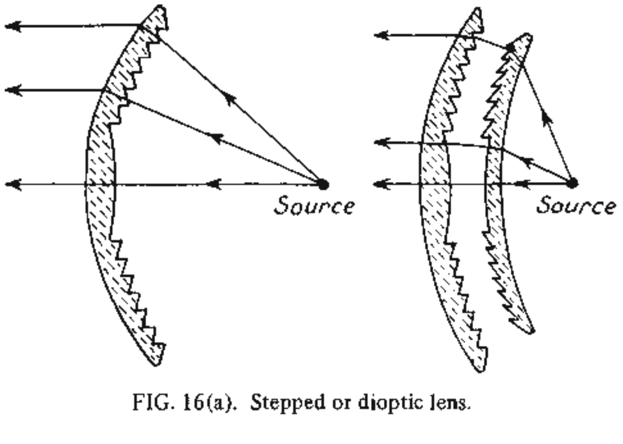

FIG. 16(a). Stepped or dioptic lens.

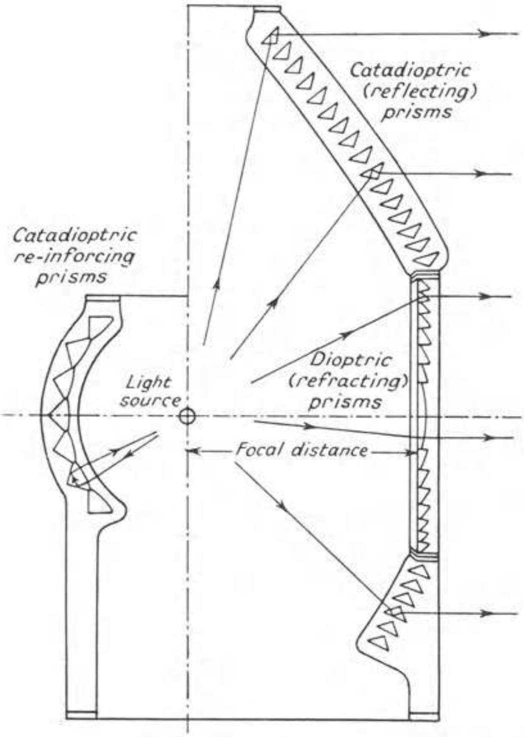

FIG. 16(b). Schematic drawing of a lighthouse lens.

of power is the diopter:

$$D = \frac{1}{f}$$

If a number of thin lenses are in contact, the power of the combination is the *algebraic sum* of the individual powers. As an example, consider two thin lenses for which $f_1 = 10$ and $f_2 = - 15$ cm.

$$D_1 = \frac{1}{10} = 0.1 \text{ diopter;}$$

$$D_2 = - \frac{1}{15} = - 0.0667 \text{ diopter}$$

$$D = 0.1 - 0.0667 = + 0.0333$$

$$\therefore f = + 30 \text{ cm}$$

If two coaxial lenses are separated a distance d, then the focal length of the combination is given by

$$\frac{1}{f} = \frac{1}{f_1} + \frac{1}{f_2} - \frac{d}{f_1 f_2}$$

For a minimum longitudinal spherical aberration, the distance d should be

$$d = f_1 - f_2$$

For minimum spherical aberratior,

$$f_1 - f_2 = d.$$

For minimum achromatism,

$$f'_1 + f'_2 = 2d.$$

Combining these two gives

$$f_1 = \tfrac{3}{2}d \quad \text{and} \quad f_2 = \tfrac{1}{2}d.$$

These are the conditions for the Huygens eyepiece. In this eyepiece the combination is equivalent to a single positive lens. (A single negative lens can also be used as an eyepiece.) Consider the case of the compound microscope. Figure 17(a) gives the ray diagram for a positive eyepiece. The objective forms an image of the object behind the eyepiece, that is, within the instrument tube, and the rays are brought to a focus at what is called the Ramsden circle outside the eyepiece. The magnified image, as seen by the observer is inverted. Figure 17(b) shows that the Ramsden circle is between the eyepiece and the objective and that the image is erect. For the same magnifying power the working distance, that is, the distance between object and objective, is larger with the negative eyepiece. Its disadvantage is that the field of view is smaller so that a smaller portion of the object is visible. In order to ensure the largest possible field of view for given powers of the objective-eyepiece combination the Ramsden circle must exist between the eyepiece and the eye. The Ramsden eyepiece as actually manufactured is a combination of two plano-convex lenses of equal focal lengths. Their distance apart is decided by the requirements and can vary between the focal length of a single lens and two-thirds of this distance. According to the previously determined relationships for two-lens combinations a separation equal to the focal length of a single lens would require that one of the lenses would be at the first principal focus. As this is where the image is formed the separation has to be reduced in order that the focal plane may be removed from the lens surface. The ray diagram for this eyepiece is given in Figure 17(c). If the eyepiece is used as a micrometer, the cross-wires are placed between the two lenses and indicated in the diagram by AB. The image A′B′ is between the lenses and is upright as with a single double-concave lens. The shortening of the lens distance introduces a small decrease in achromatism, but this can be remedied by the use of a combination lens for the eye lens.

Thick Lens Figure 18(a) shows a thick converging lens receiving a parallel beam of light.

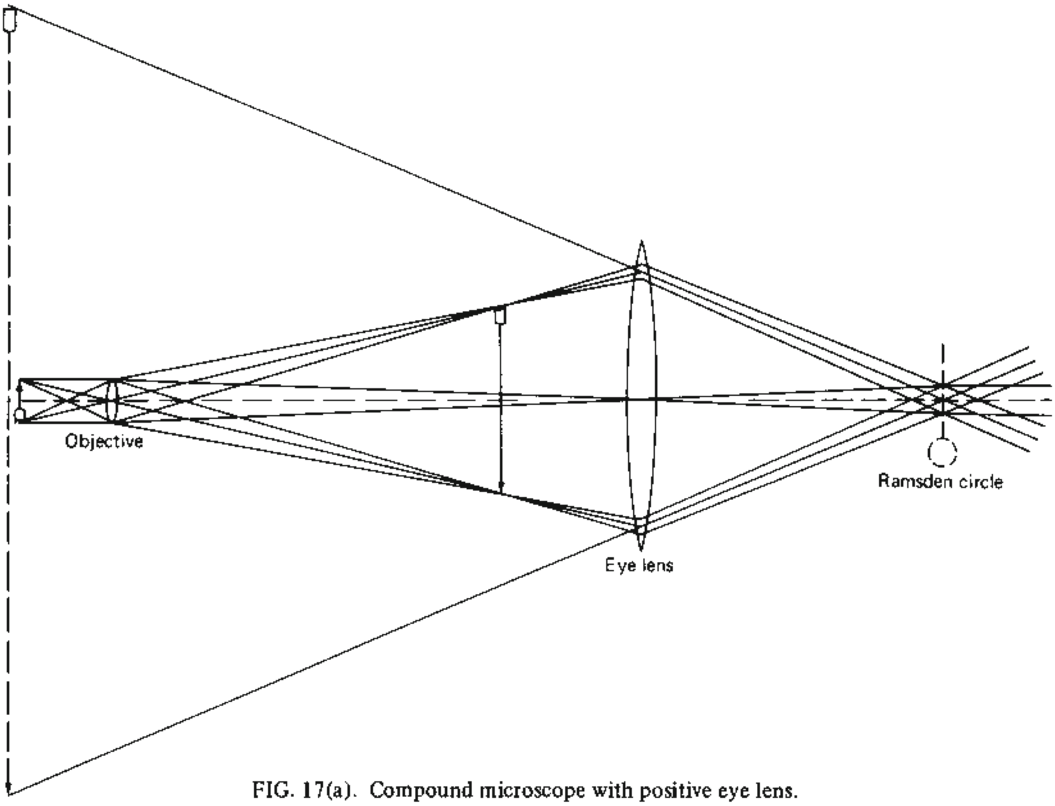

FIG. 17(a). Compound microscope with positive eye lens.

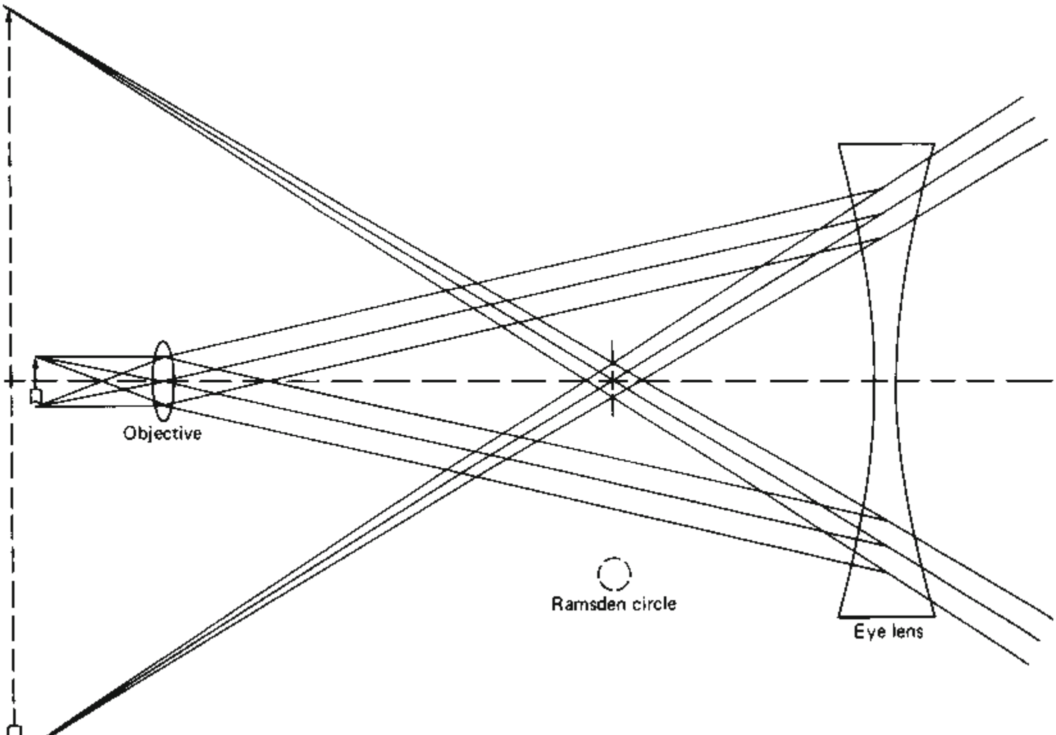

FIG. 17(b). Compound microscope with negative eye lens.

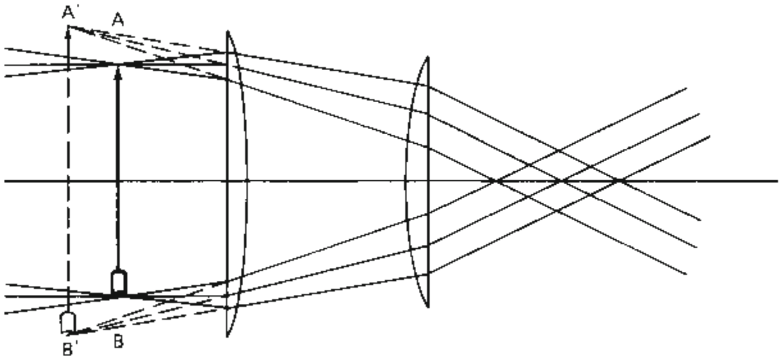

FIG. 17(c). Ramsden eyepeice.

The axial ray 1 passes through the lens without deviation. Any other ray, such as 2, on emerging intersects the axis at some point F'. If we extend the incident ray forward and the emergent ray backwards, as shown by dotted lines, they will intersect at some point P'. The point F' is called the *second focal point* and the plane through P' to which the axis is perpendicular is called the *second principal plane.*

Figure 18(b) shows a system of rays starting from a point F such that the emergent beam is parallel. Then point F is the *first focal point* and the plane through P, determined as before, the first principal plane.

The solution of the thick lens is therefore dependent on the following: The lens behaves as though the deviation of the rays leaving point F all takes place at the plane P; also the deviation of the emergent rays appears to take place at the plane P^1. Image formation is therefore in accordance with Fig. 19.

From the geometry of the figure we see that

$$ff' = xx' \quad \therefore m = -\frac{f}{x} = -\frac{x'}{f'}$$

also

$$\frac{f'}{\ell'} + \frac{f}{\ell} = 1, \quad \therefore m - \frac{f\ell'}{f'\ell}$$

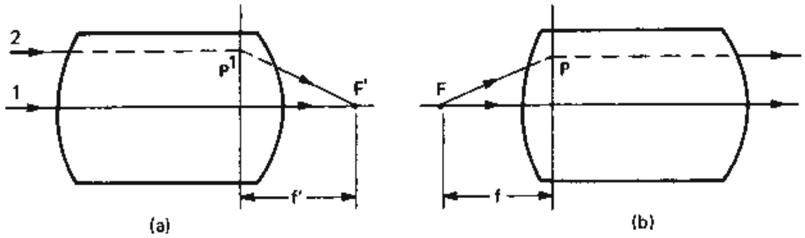

FIG. 18. Thick lens: principal focal points and principal planes.

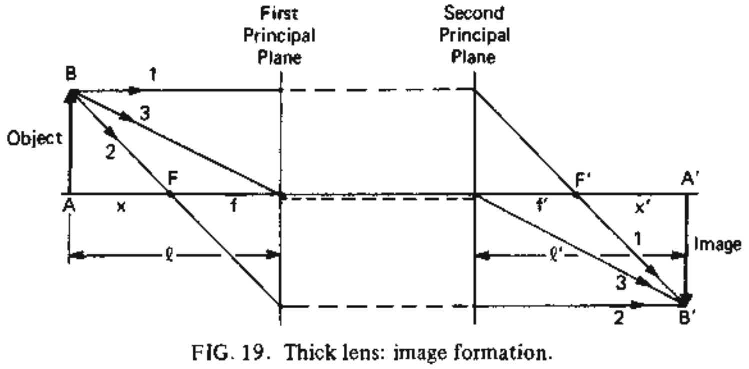

FIG. 19. Thick lens: image formation.

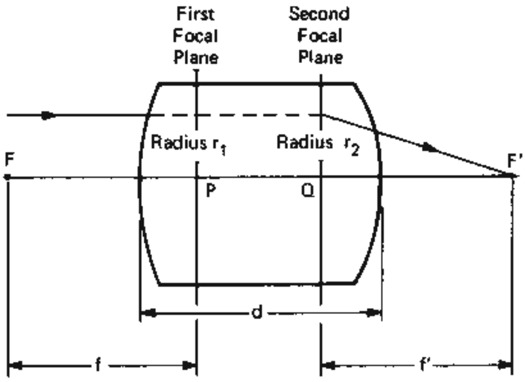

FIG. 20.

The focal length of a thick lens is reckoned from the second focal plane, namely, the distance OF' in Fig. 20. In terms of the radii it is given by

$$f' = (\mu - 1)\left(\frac{1}{r_1} - \frac{1}{r_2} + \frac{\mu - 1}{\mu}\frac{d}{r_1 r_2}\right).$$

It differs from the expression for the focal length of a thin lens by the term

$$\frac{\mu - 1}{\mu}\frac{d}{r_1 r_2},$$

and this, of course, is zero when $d = 0$.

For light traveling from right to left and for which a parallel beam is brought to a focus at F

$$f = (\mu - 1)\left(\frac{1}{r_2} - \frac{1}{r_1} + \frac{\mu - 1}{\mu}\frac{d}{r_1 r_2}\right)$$

$$f = -f'.$$

Optical Distance The optical distance between two points is the minimum possible time required for light to travel from one point to the other. Since a ray of light is the normal to an element of wave front, this concept involves velocity. In a homogeneous medium the optical distance between two points separated by a distance ℓ is $\ell n/c$ where c is the velocity of light in vacuo. Since, in all problems we are concerned with the paths between two given points we can give to c the arbitrary value of unity thus giving ℓn for the optical path. As an example consider again the equation for a thin lens (Fig. 21). For the axial ray we have

$$PS + SQ = PC + CQ + (n - 1)\,MN$$

$$PS = (PC^2 + CS^2) = PC + CS^2/2PC$$

the approximation being relevant to a thin lens. This gives

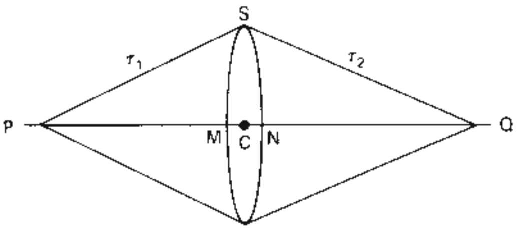

FIG. 21.

$$CS^2/2PC + CS^2/2QC = (n - 1)MN$$

$$\frac{1}{PC} + \frac{1}{QC} = \frac{1}{u} + \frac{1}{v} = 2(n - 1)MN.$$

Considering the points P and Q as the centers of curvature r_1 and r_2 of the two lens faces,

$$\frac{1}{r_1} + \frac{1}{r_2} = 2MN/CS^2,$$

giving

$$\frac{1}{u} + \frac{1}{v} = (n - 1)\left(\frac{1}{r_1} + \frac{1}{r_2}\right).$$

OPTICS, GEOMETRICAL, ADVANCED

Geometrical optics deals with light regarded as rays, an approximation which is valid when the wavelength of the light is much smaller than the dimensions of the optical system. (Otherwise, diffraction effects are significant; see FOURIER OPTICS and DIFFRACTION BY MATTER AND DIFFRACTION GRATINGS.) The other physical principle needed to describe optical systems is *Snell's law*, in the form

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \tag{1}$$

where n_1, n_2 are the indices of refraction of two media separated by a plane interface, and θ_1, θ_2 are the incident and refracted angles, respectively. (See OPTICS, GEOMETRICAL for a more extended treatment.)

Paraxial Matrix Optics An extremely ingenious way of simplifying the mathematics associated with ray tracing is the matrix method proposed by Sampson (1913) and Smith (1945), and extended by Brouwer (1964). Figure 1 shows a ray leaving an arbitrary object point P and striking the first surface of a typical lens at P_1. If the angles α_1, α_1', θ_1, and θ_1' shown are all small (0.1 radian or 5° or less), then Snell's law (1) in *paraxial* form (this term means "close to the axis") becomes

$$n_1\theta_1 = n_2\theta_2. \tag{2}$$

The figure shows that this is

$$n_1(\alpha_1 + \phi) = n_1'(\alpha_1' + \phi). \tag{3}$$

But the paraxial approximation also leads to

$$\sin\phi = \phi = x_1/r_1. \tag{4}$$

Define the *refracting power* of the surface with vertex V_1 as

$$k_1 = (n_1' - n_1)/r_1. \tag{5}$$

Combining (3), (4), and (5) with the identity

$$x_1' = x_1 \tag{6}$$

gives

$$\begin{pmatrix} n_1'\alpha_1' \\ x_1 \end{pmatrix} = \begin{pmatrix} 1 & -k_1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} n_1\alpha_1 \\ x_1 \end{pmatrix} \tag{7}$$

where the 2 X 2 matrix

$$R_1 = \begin{pmatrix} 1 & -k_1 \\ 0 & 1 \end{pmatrix} \tag{8}$$

is the *refraction matrix* for surface 1.

Next, consider the ray P_1P_2. Its position at P_2 is

$$x_2 = x_1' + t_1 \tan\alpha_1' \sim x_1' + t_1'\alpha_1' \tag{9}$$

and combining this with the identity $\alpha_2 = \alpha_1'$ gives

$$\begin{pmatrix} n_2\alpha_2 \\ x_2 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ t_1'/n_1' & 1 \end{pmatrix} \begin{pmatrix} n_1'\alpha_1' \\ x_1' \end{pmatrix} \tag{10}$$

where

$$T_{21} = \begin{pmatrix} 1 & 0 \\ t_1'/n_1' & 1 \end{pmatrix} \tag{11}$$

is the *translation matrix* for the passage from surface 1 to surface 2.

The matrices of (8) and (11) are all that are needed, for the refraction at surface 2 can be expressed by a matrix R_2, the translation to an image plane or a second lens by T_{32}, etc. In addition, the left-hand side of (7) can be substituted into the right-hand side of (10) and the combined translation-refraction process is specified as a matrix product. Thus, we have a simple, virtually automatic procedure for tracing paraxial rays through an optical system of arbitrary complexity. The constants of the

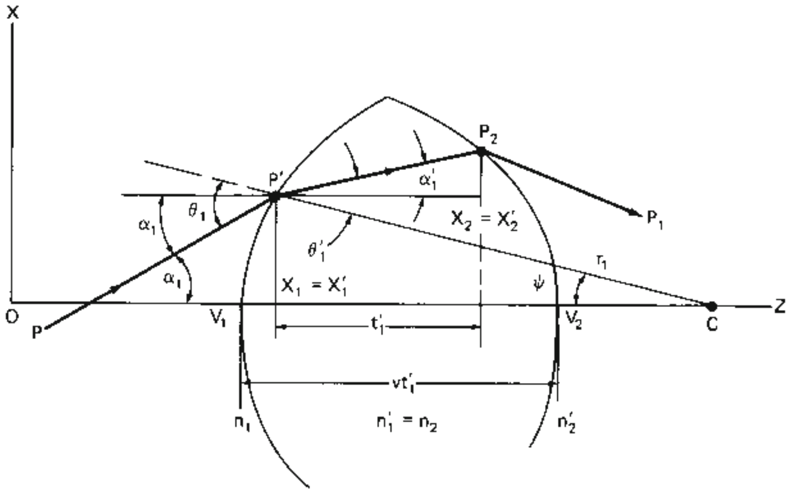

FIG. 1. Refraction matrix.

system which must be specified are the indices n_i, n_i' and the radius r_i of each refracting surface ($i = 1, 2, \ldots$) and the axial distance t_i' between each pair of surfaces. In addition, it is a straightforward matter to derive by matrix multiplication the formulas quoted in GEOMETRICAL OPTICS, and many others which are rather difficult when using ordinary algebra; examples and a more extended discussion of sign conventions will be found in Nussbaum and Phillips (1976).

Meridional Matrices Figure 1 incorporates the usual convention that the symmetry axis of the optical system is taken as OZ. A plane containing this axis is said to be *meridional*, and we consider the problem of ray tracing in such a plane with the paraxial restriction removed. It is not difficult to show [again see Nussbaum and Phillips (1976)] that the matrix approach outlined above is preserved, provided some moderately obvious changes are made. These involve (1) defining a *skew power K* for surface 1 as

$$K_1 = (n_1' \cos\theta_1' - n_1 \cos\theta_1)/r_1 \qquad (12)$$

where θ_1 and θ_1' are the Snell's law angles before and after refraction, respectively; (2) writing (7) in the form

$$\begin{pmatrix} n_1' \sin\alpha_1' \\ x_1 \end{pmatrix} = \begin{pmatrix} 1 & -K_1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} n_1 \sin\alpha_1 \\ x_1 \end{pmatrix}; \qquad (13)$$

and (3) writing (10) as

$$\begin{pmatrix} n_2 \sin\alpha_2 \\ x_2 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ T_1'/n_1' & 1 \end{pmatrix} \begin{pmatrix} n_1' \sin\alpha_1' \\ x_1' \end{pmatrix}, \qquad (14)$$

where T_1' is the actual length of the ray P_1P_2. We note that when the paraxial approximation is valid—i.e., $\sin x = x$—Eqs. (12), (13), and (14) simplify to (5), (7), and (10), respectively, as they should do.

One complication associated with these meridional matrices is that T_1', unlike t_1', is a variable; it may readily be determined from the geometry in the form of an auxiliary formula. We shall refer to a more general form of this formula in a later section. In addition, the angle θ_1 requires an auxiliary formula and θ_1' then follows from Snell's law. Another complication is the fact that the matrices are no longer constants. All these difficulties are surmounted by using numerical, rather than algebraic calculations, and the procedure outlined here is easily programmed on hand-held calculators and computers.

The consequences of the removal of the paraxial approximation for meridional rays is shown in Fig. 2. The rays close to the axis meet at the *paraxial focus* F', those farther out come together at an *intermediate focus* F_I, and the rays passing through the edge of the lens (the *margin*) meet at the *marginal focus* F_M. The situation of Fig. 2 is what the matrix equations would reveal for a double convex lens; the existence of a set of focal points and the resulting blurry image is called a *third-order aberration*, where the designation refers to the fact that the paraxial approximation $\sin x = x$ implies that we had cut off the Taylor series for the sine function at the first-order term and now we are including third-order terms. [There are also fifth-order and higher aberrations which are primarily of interest to lens designers; see Cox (1964).] The significant feature of Fig. 2 is that it indicates that the blurred image is a consequence of the failure of marginal meridional rays to conform to the paraxial approximation; this failure is called

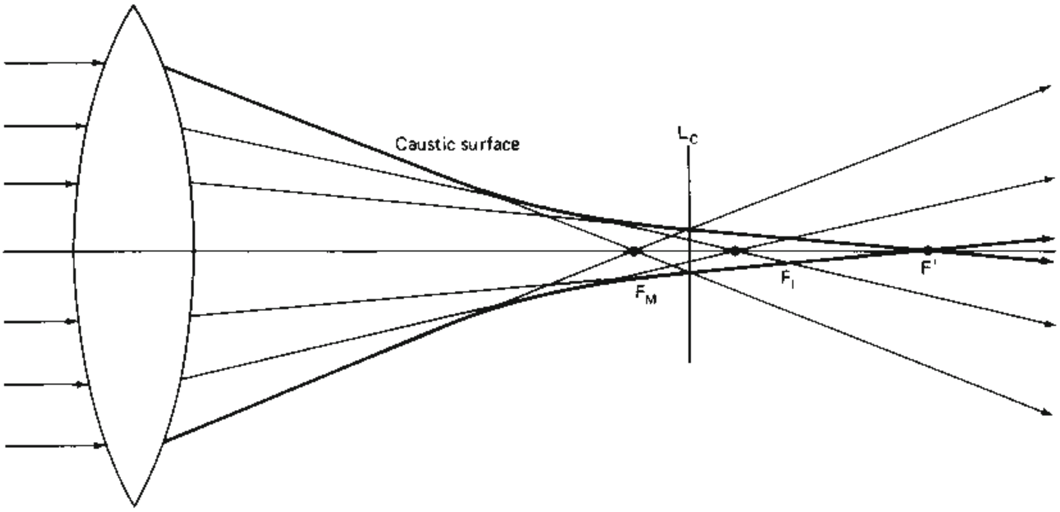

FIG. 2.

spherical aberration. If the object at infinity producing the parallel rays of light is replaced by a point-object on the axis, we still find a similar aberration situation on the image side; hence, spherical aberration is one of three third-order point aberrations; the other two will be introduced immediately below.

Skew Matrices We now remove the meridional restriction and introduce the possibility of *skew rays*—those not confined to the plane of the paper in Fig. 2—leaving an object. We specify such rays in terms of their point of origin (x, y, z) and their direction cosines γ, δ, ϵ with respect to the axes $OXYZ$. This implies that the single equations (13) and (14) must each be generalized to a three-dimensional set of the form

$$\begin{pmatrix} n_1'\gamma_1' \\ x_1' \end{pmatrix} = \begin{pmatrix} 1 & -K_1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} n_1\gamma_1 \\ x_1 \end{pmatrix} \qquad (15)$$

with equations in δ, y and ϵ, z, and

$$\begin{pmatrix} n_2\gamma_2 \\ x_2 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ T_1'/n_1' & 1 \end{pmatrix} \begin{pmatrix} n_1'\gamma_1' \\ x_1' \end{pmatrix} \qquad (16)$$

again with two similar equations.

Using the auxiliary formulas and numerical approach mentioned above, we are now in a position to trace skew rays. Consider the two rays of Fig. 3, generating an intermediate focus. Then incline the rays (Fig. 3b), shifting the focus as shown and rotate the rays through an angle of 180° about a parallel axis halfway between them. All the new rays produced in this fashion are skew, and since the two sets of three matrix equations (15) and (16) will not in general produce the same results as the meridional equations (13) and (14), the location of the focal point is no longer F_1'. What happens, in fact, is that it must move in a closed path on the image, returning to its original position at the end of the 180° rotation, since the rays are

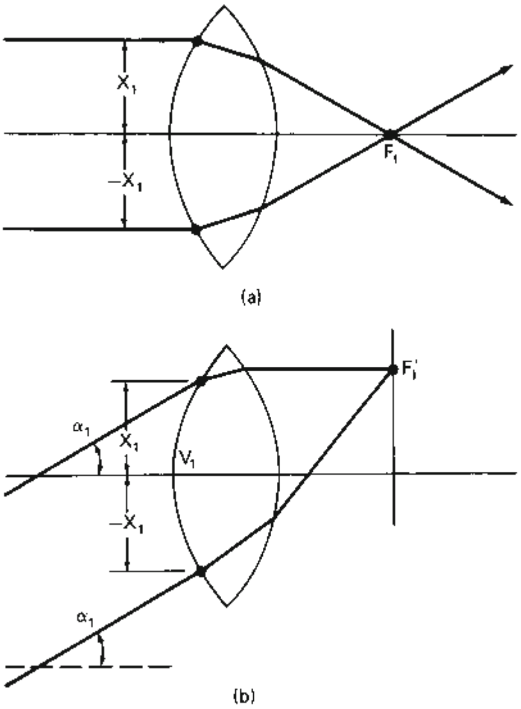

FIG. 3.

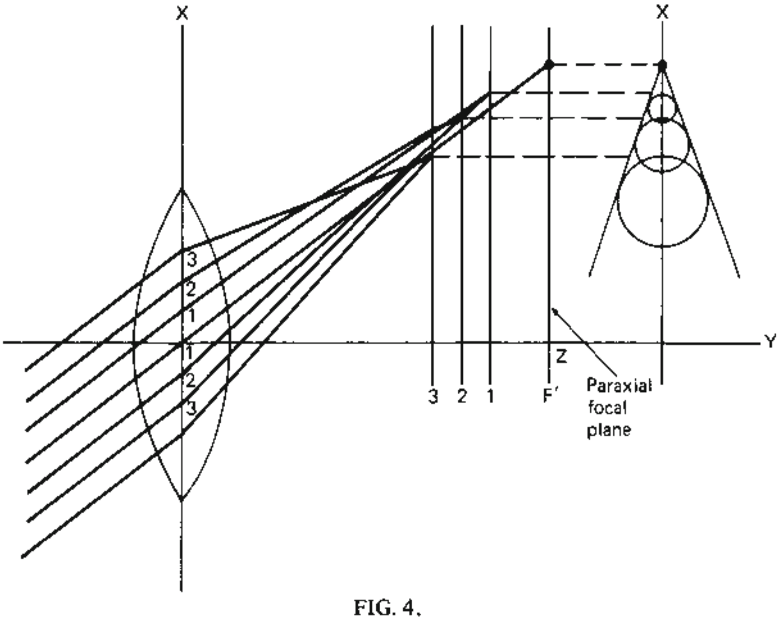

FIG. 4.

once again meridional. This path would be expected to be a circle in the image plane, since the rays generate such a path on the front of the lens, and this is indicated as circle 3 in Fig. 4. A second 180° rotation gives a second circle coincident with the first, and closer pairs of rays give the smaller circles 2 and 1. This blurring of the image due to failure of the skew rays to match the behavior of the meridional rays is called *coma*, the name coming from the comet-like shape of the image in Fig. 4. Such a shape is seldom observed, because we have assumed that circles are imaged perfectly. For a lens which is not well-corrected, the double circles in the image plane will be asymmetrically arranged, as shown in Fig. 5, and the resulting pattern will be a cardiod [Fig. 5(b)].

Coma can be associated only with off-axis object points, since all rays from an axial point are automatically meridional. Let us assume that a lens system has been corrected both for spherical aberration and for coma. Since these are due to essentially different causes, we have no guarantee that the image point of the meridional and of the skew rays is identical and this failure to agree is then the third point aberration, *astigmatism*. Figure 6 shows a meridional or *tangential* fan of rays leaving an off-axis object point P and forming a sharp image at P_{T}'. Another set, the *sagittal* fan, is at right angles, and all of these rays (except for one in the vertical plane) have to be skew. The sharp image is at P_{S}', and the tangential fan at this point images as a line. In between the two lines shown, we have the ellipses and circle of

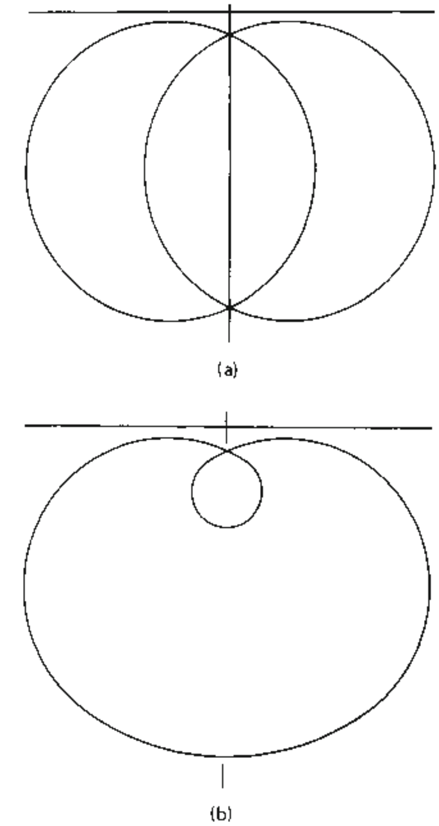

FIG. 5.

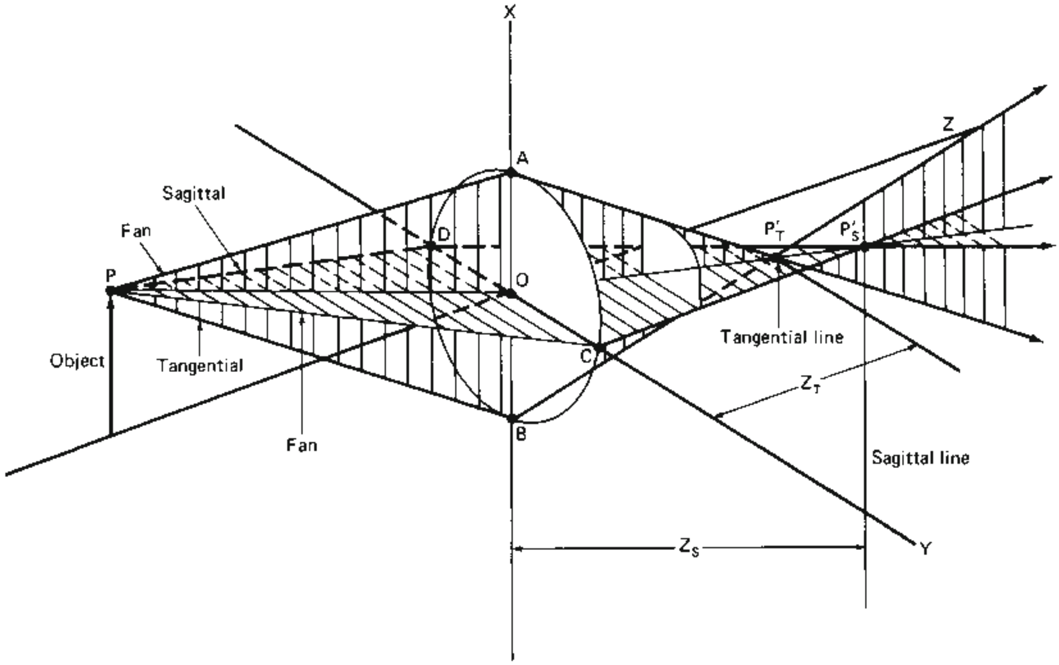

FIG. 6.

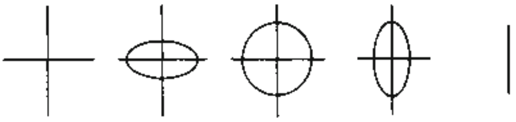

FIG. 7.

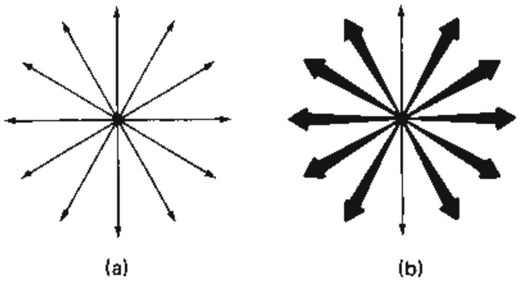

FIG. 8. Astigmatism: (a) object; (b) image.

Fig. 7, so that again we have blurring. Note that a bundle of arrows [Fig. 8(a)] would have images going from sharp to blurry, as shown in Fig. 8(b); this also explains the use of the term *sagittal*, from the Latin *sagitta*, arrow. This 90° transition explains why cylindrical corrections are used for astigmatism of the eye; after the original prescription is determined, this defect requires further correction in one plane only.

The last two aberrations are associated with objects of finite extent. If we correct for astigmatism by having the tangential and sagittal focal surfaces merge to form a common *Petzval surface* (Fig. 9), this image surface will in general be curved, since the amount of astigmatism can depend on the distance of the object point from the axis. The resulting aberration, associated with the *OZ* axis, is called *Petzval curvature* or *curvature of field*. A similar effect can occur for distances measured in the *XOY* plane, producing the *barrel* or *pincushion* distortion of Fig. 10. In addition to, and independent of these five geometric aberrations, the fact that the index *n* is a function of wavelength leads to *chromatic aberrations*, which are discussed in the article OPTICS, GEOMETRICAL.

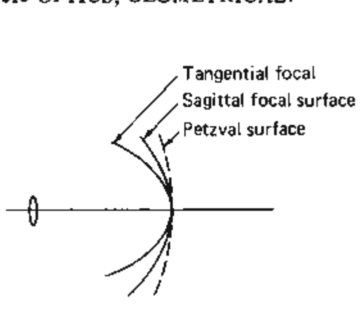

FIG. 9.

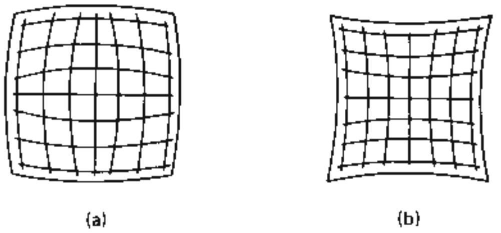

FIG. 10. Barrel (a) and pincushion (b) aberrations.

Finally, we point out that the matrix equations as outlined above are applicable only to spherical lenses (or mirrors), with plane surfaces as a special case. This treatment, however, can be readily extended to aspheric surfaces (hyperboloids, paraboloids, and ellipsoids, with spheres as a special case) by a straightforward generalization of the auxiliary relations [Nussbaum (1979)]. A brief computer program will handle the numerical aspect of ray tracing in such systems.

OPTICS, PHYSICAL

Physical optics deals with those phenomena that are described using the *wave nature of light*. These are *interference, diffraction and polarization*. Of these, interference is the most important; interference phenomena require the wave concept for their explanation. Diffraction and polarization can, at least in principle, be discussed using the particle nature of light.

The unique property of a wave is that it is in two or more places at the same time (a particle, on the other hand, is well localized). A light wave has a phase and can either have a positive or negative value. A wave can be divided into two or more parts.

The *principle of superposition* states that several individual waves at any location can be

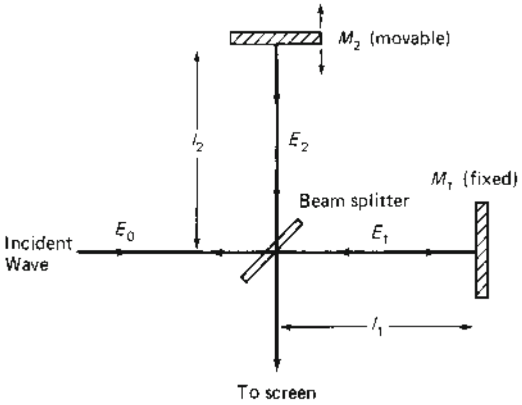

FIG. 1. Michelson interferometer.*

superimposed to determine the resultant. Because the phase of the wave is important, leading to negative as well as positive amplitudes, the summation of several waves can be zero.

Interference There are two broad categories of interference: *division of amplitude* and *division of wavefront.* The Michelson interferometer, Fig. 1, illustrates division of amplitude and two-beam interference. The incident wave with amplitude E_0 strikes a glass plate at 45°. The back side of the plate is lightly coated with silver so that it serves as a beam splitter; part of the wave is transmitted to mirror M_1 and part is reflected to mirror M_2. The coating on the beam splitter is made with a density that will give the two parts of the beam equal amplitudes.

After reflection by mirrors M_1 and M_2, the components are recombined at the beam splitter where, on average, half the energy is reflected onto a screen and the other half is transmitted back toward the source. The path difference Δ for the two waves, which may be varied by changing the position of M_2, is given by $\Delta = 2(l_1 - l_2)$, where l_1 and l_2 are the lengths of each arm of the interferometer. The phase difference δ is $2\pi\Delta/\lambda$, where λ is the wavelength. For a monochromatic wave the total field at the output is:

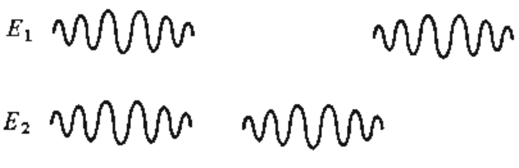
$$\begin{aligned} E_T &= E_1 + E_2 \\ &= 0.5E_0[1 + \cos\delta] \\ &= 0.5E_0[1 + \cos 2\pi\Delta/\lambda]. \end{aligned}$$

Here we see an important property of interference; when $\delta = n\pi$ (where $n = 1, 3, 5, \ldots$) the two axial components will combine in such a manner that there is zero amplitude on the screen. Yet if we place a card in either arm of the interferometer, blocking one beam, we will see one half of the initial amplitude. With no card (i.e., using both beams), we get zero because one beam is 180° out of phase with the other. This is the essence of interference. To explain the phenomenon, we have to invoke the wave nature of light.

In the preceding analysis we assumed that the source was perfectly monochromatic. When Michelson used his interferometer to examine real sources, he found a very interesting phenomenon. As the path difference between the two arms of the interferometer was increased, the visibility of the fringes decreased and finally disappeared. A simple interpretation of this result is that light from an ordinary spectral lamp consists of wave trains of finite length. When the path difference is less than the length of the wave train, part of the train coming from the other arm, interference occurs [Fig. 2(a)]. When the path difference is greater than the length of the wave train [Fig. 2(b)], the light from one arm is added to the light from the other arm which consists of a different wave train. Since the phase relation between two trains is a random variable (the trains come from independent atoms) and since many such superpositions take place in an observation time, no interference will be observed, and the intensity will be a constant. The length of the wave train is related to the temporal coherence length of the light. Ordinary spectral-line sources have coherence lengths on the order of millimeters, whereas lasers have coherence lengths on the order of kilometers.

An alternative but equally correct explanation of the disappearance of fringes can be made if we consider the spectral distribution of the source. If more than one wavelength is emitted, each will form its own interference pattern. At zero path difference, all wavelengths will form a maximum and the fringes will be very sharp, but at large path differences the fringe maxima for the different wavelengths will not coincide and the fringes will vanish. Since one may Fourier analyze a wave train and obtain its spectral distribution, it turns out that these two explanations are equivalent.

After observing the loss in visibility of fringes with increasing path difference, Michelson went on to explain this quantitatively, and he ob-



(a) (b)

FIG. 2.

*Figures 1–5 and 7–10 adapted from *Contemporary Optics for Scientists and Engineers,* by A. Nursbaum and R. Phillips, © Prentice-Hall, 1976. Reprinted with permission of the publisher.

tained an extremely important result which we shall consider next. Let the incoming wave contain a number of frequencies, rather than being monochromatic.

Most optical detectors including the eye, photocells, and photoconductors detect energy, which is porportional to the square of the amplitude, i.e., E^2. In optics, this is also designated intensity, I. The total intensity for a polychromatic wave or group of waves, then, is given by a summation over frequency. When we compute intensity by squaring an amplitude, which itself involves a summation, the cross-product terms are converted into functions such as $\cos[(\omega_1 - \omega_2)t]$ and these average to zero over one or several cycles. This will be the case here for all the products of the form $E_1(\omega_1)E_2(\omega_2)$, since any physically realistic observation time will extend over many cycles. The total intensity I_T will then be

$$I_T = \sum_m I(\omega_m).$$

We assume that the distribution of frequencies is continuous rather than discrete, therefore this sum should be replaced by an integral. References 1 or 2 show that when this expression is evaluated the result is

$$I_T = \int_{-\infty}^{\infty} I(\sigma)\,[1 + \cos\{2\pi\Delta(\sigma_0 + \sigma\}]\,d\sigma$$

where

$$\frac{1}{\lambda} = \sigma_0 + \sigma.$$

This extremely important formula states that, in a Michelson interferometer, the average intensity $I_T(\Delta)$, a function of spacing, is the Fourier transform of the intensity $I(\sigma)$, a function of wavelength (spectrum). We may thus regard this instrument as a form of computer which performs a Fourier analysis of the spectrum of the source. (We shall see that a lens behaves in a similar way. In fact, it can instantly produce a two-dimensional Fourier transform of the spatial distribution of a source, and this is something which is extremely complicated when done numerically or by an electrical network.)

An interferometer can be used as a spectrometer, by measuring $I_T(\Delta)$ and taking its Fourier transform to yield $I(\sigma)$. One may then ask about the advantages of the interferometer as compared to a conventional grating spectrometer. In the latter, light from the source is dispersed over a wide area, and a narrow spectral band is detected. It is difficult to detect a signal from weak sources and simultaneously attain high resolution because most of the light available at a given moment is not used. On the other hand, in Fourier transform spectroscopy, only one-half of the light, on average, is discarded. This gives a better signal-to-noise ratio for a given detector. This technique is widely used for high-resolution analysis of weak sources, particularly in the infrared region.

FIG. 3. Interference in thin films.

Thin films illustrate multiple beam interference. (See Fig. 3.) Consider reflection from two parallel surfaces separated by a distance t. The index of refraction of the film is n, and that of the surroundings is n_0 and n_2. The amplitude of the incident wave is taken as E_0. At the first interface, the coefficients of amplitude transmission and reflectance are σ_1 and ρ_1, respectively, and at the second interface, they are σ_2 and ρ_2, respectively, where

$$-\rho_1 = \frac{n_0 - n_1}{n_0 + n_1}, \qquad \rho_2 = \frac{n_1 - n_2}{n_1 + n_2}.$$

The negative sign in $-\rho_1$ means that it is measured *inside* the layer of index n_1. (As explained below, we want to calculate the *transmitted* wave.) The phase difference introduced by two consecutive reflections inside the middle layer for a wave incident perpendicular to the surface is

$$\delta_1 = \left(\frac{2\pi n_1}{\lambda}\right) 2t.$$

We will calculate the expression for the transmission coefficient and then apply conservation of energy to obtain the expression for the reflection coefficient. The amplitudes of the transmitted components are:

$$\begin{aligned} E_1 &= \sigma_1 \sigma_2 E_0 \\ E_2 &= \sigma_1 \sigma_2 \rho_1 \rho_2 E_0 \\ E_3 &= \sigma_1 \sigma_2 \rho_1{}^2 \rho_2{}^2 E_0, \\ &\vdots \end{aligned}$$

and the total transmitted amplitude E_t is

$$E_t = E_1 + E_2 + E_3 + \cdots + E_n.$$

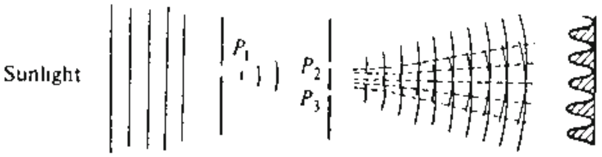

FIG. 4. Young's divided wavefront experiment.

Combining the amplitude and phase expressions and using $I_0 = \frac{1}{2}E_0^2$ yields

$$I_T = \frac{I_0\sigma_1^2\sigma_2^2}{1+\rho_1^2\rho_2^2 - 2\rho_1\rho_2\cos\delta}.$$

In the absence of absorption, the reflection coefficient R and the transmission coefficient T add to unity, or

$$R = 1 - T$$

where

$$T = I_T/I_0.$$

Combining the above three equations with $1 = \sigma^2 + \rho^2$ gives

$$R = \frac{\rho_1^2 + \rho_2^2 - 2\rho_1\rho_2\cos\delta}{1+\rho_1^2\rho_2^2 - 2\rho_1\rho_2\cos\delta}.$$

It can be seen by inspection of this equation that, with proper selection of values for n_1, n_2, t, and λ, R can be zero, i.e., reflection can be eliminated from the surfaces.

Today multiple-layer thin films are used to achieve many interesting and useful results. For example, multiple layer interference filters can achieve very low reflection over a broad band, or increased reflection, or high reflection at one waveband accompanied by low reflection at another waveband.

The two-slit experiment illustrates the other type of interference—*division of wavefront*. It was first performed in 1802 by Thomas Young, who used pinholes. In repeating the experiment, slits are usually used because they transmit more light and the resulting pattern is easier to observe. In the arrangement used by Young (Fig. 4) sunlight pass through a pinhole P_1, which acts as a point source. This assures that the wave on the right-hand side of the pinhole is spatially coherent. A screen with two adjacent pinholes, P_2 and P_3, divides the wave front into two portions, and the openings act as mutually coherent point sources of spherical waves. At a spot on the screen where the path difference for the two waves is zero, they are in phase, and a maximum in the intensity exists. If the path difference is $\lambda/2$, the two waves are 180° out of phase, and a minimum exists. The alternating maxima and minima constitute a fringe system, each of the maxima corresponding to a different order of interference.

We shall calculate the interference pattern produced by a single point source emitting monochromatic waves and later generalize this to polychromatic and extended sources. In Fig. 5 a monochromatic point source S is located on the line perpendicular to the midpoint between the two slits, S_1 and S_2. The separation of the slits is a. The intensity distributions of the pattern which would be observed on a screen at a distance d from the slits is given by

$$I_T = 4I_0\cos^2\frac{\delta}{2}$$

where δ is the phase difference:

$$\delta = \frac{2\pi}{\lambda}\frac{ay}{d}.$$

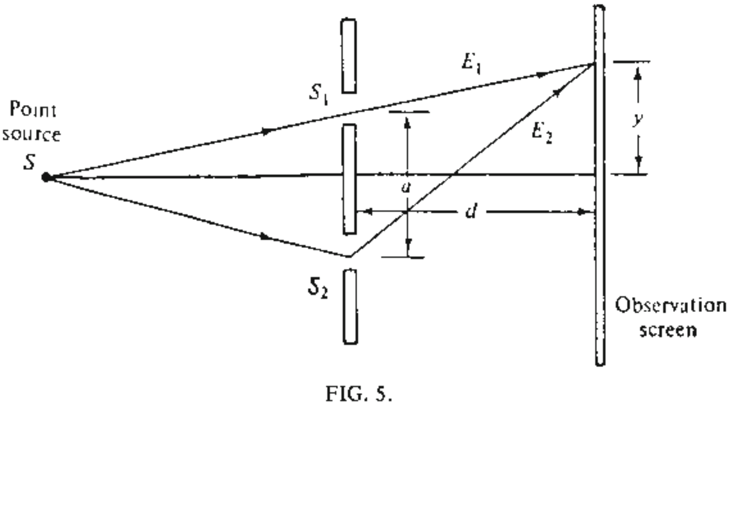

FIG. 5.

For an extended source in place of the pinhole source, the contribution of each point on the source must be summed. A point j is located a distance u from the center of the source which is at a distance D from the slits. The phase difference between the two beams from passing through the slits is:

$$\delta = \frac{2\pi}{\lambda}\left(\frac{ay}{d} + \frac{au}{d}\right).$$

Then the contribution to the intensity on the screen from the jth point is given by

$$dI_j(y) = 2I(u)\,(1 + \cos\delta)\,du.$$

For incoherent sources, the total intensity at point y is the sum of the intensities from each point j on the sources; therefore

$$I_T(y) = 2\int_{-\infty}^{\infty} I(u)\,(1 + \cos\delta)\,du.$$

Again we see a Fourier transform relationship between the intensity distribution of the pattern and the intensity distribution of the source. As the source becomes larger the pattern becomes less distinct. The visibility of the fringes is related to the spatial coherence of the source just as the visibility of fringes in the Michelson interferometer is related to the temporal coherence of the source.

Division of wavefront has been used to measure the angular diameter of stars with an accuracy exceeding that attainable from telescopes.

Diffraction Diffraction is the bending of light as it passes an object. Under certain conditions examination of a shadow of an object on a screen behind it reveals that some light did not travel in a straight line from source but was bent. A close examination of the edge of certain shadows reveals that they are composed of alternating light and dark bands. The patterns can be explained and predicted using wave theory.

Division of wave front leads naturally into diffraction, for the two phenomena are closely related. When parts of a wave front come from different openings and combine, we have interference; but when parts of a wave front come from a single opening and combine, we have diffraction.

There are two categories of diffraction: Fraunhofer and Fresnel. Fraunhofer diffraction occurs when both the source of light and the observation screen are located at distances from the aperture which are very large compared to the size of the opening. It is the simpler of the two to evaluate and is the condition normally encountered. Fresnel diffraction occurs when the source, observation screen, or both are at distances such that the ratio of aperture size to distance cannot be neglected.

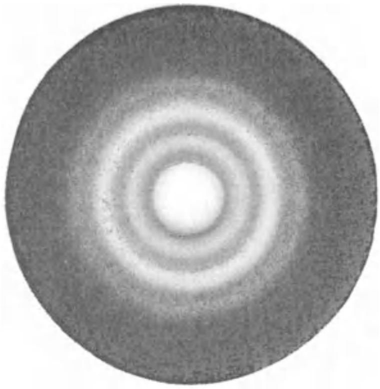

FIG. 6. Fraunhofer diffraction.

A classical example of Fraunhofer diffraction is produced by a circular aperture of radius R. The pattern (Fig. 6) was first calculated by G. B. Airy in 1835 and is often referred to as the *Airy disk*. The derivation can be found in many references.[2] The intensity is given by

$$I = I_0\left[\frac{2J_1(x)}{x}\right]^2$$

where J_1 is the first order Bessel function and $x = (2\pi/\lambda)R\sin\theta$. The angle θ is the measurement between the normal at center of the aperture and the point of observation. (See Fig. 7.)

Diffraction is very important in optical imaging. The limit on the performance of many optical systems is set by their diffraction properties.

Polarization Polarization of light was discovered in 1808 by E. Malus, a French engineer, while looking at sunlight reflected from the windows of the Palace of Luxembourg through

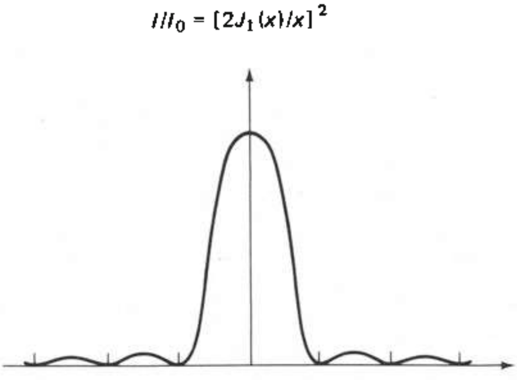

FIG. 7. Plot of Airy disk function.

a calcite crystal. He saw two images which varied in intensity as he rotated the crystal.

This and other polarization phenomena establish that light waves are transverse rather than longitudinal. Only a transverse wave i.e., one in which the amplitude is perpendicular to its direction of travel, can be two sided.

Waves of perpendicular polarization do not interfere. If, for example, polarizers are placed in each arm of a Michelson interferometer and oriented at right angles to each other, the interference pattern disappears.

Light waves are electromagnetic and usually interact most strongly with materials via the electric field. The magnetic interaction is proportional to v/c, where v is the velocity of the electrons in the material and c is the velocity of light. Hence, it is small.

An early demonstration of the polarization of electromagnetic waves was performed by Hertz. His demonstration can be repeated using a set of parallel wires. When the wires are oriented along the direction of the electric field of a radio wave, as determined by the orientation of the transmitting antenna, currents are set up along their length. By conservation of energy, the wave must be absorbed in the process. When the wires are rotated 90° so that they are perpendicular to the direction of the electric field, the wave is not absorbed.

This experiment was repeated in 1963 by Bird and Parrish using light waves. They deposited gold strips onto a plastic diffraction grating have 50,000 lines/inch. The gold film was evaporated onto the grating from the side. Viewed from the top, the gold looked like wires, each less than a wavelength wide. When incident light was polarized parallel to the gold "wires," it was absorbed, and when polarized in the perpendicular direction, it was transmitted.

It should be pointed out that the usual analogy of polarized light with waves on a string and a picket fence is off by 90° because of the orientation of the electric vector E. When the amplitude of string waves is polarized parallel to the openings of a picket fence, the waves are transmitted through the fence. But electromagnetic waves polarized parallel to wires are absorbed.

The amplitude of a light wave is a vector—it has both magnitude and direction—and the simplest type of polarization is linear polarization. In this case, the amplitude vector points in a fixed direction normal to the direction of propagation k (also a vector). This is also known as *plane-polarized light*, because the amplitude and the wave vector define a plane.

Light can also be *circularly polarized*. In this case, the direction of the amplitude rotates in time. The most general state is *elliptical polarization*, where the amplitude pattern at any one location is an ellipse. Both linear and circular polarization are special cases of elliptical polarization. There are always two orthogonal states of polarization, as shown in Fig. 8.

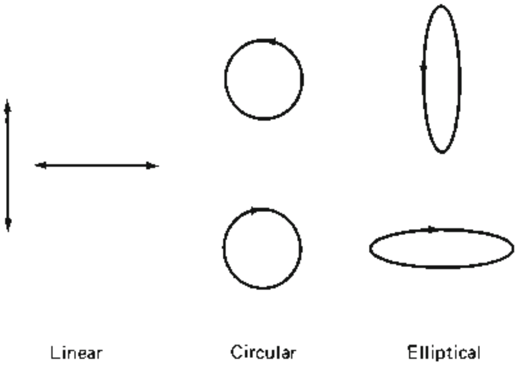

FIG. 8. Polarization.

Polarization manifests itself through the interaction of light with matter. To exhibit the polarized nature of light effects, the matter must be anisotropic. Crystals such as quartz, calcite, and cordierite can be used to display polarizing effects.

Double Refraction This phenomenon is exhibited by certain materials. A beam of light can be refracted or deviated into two portions, each of which travels in a different direction. Double refraction was discovered in 1669 by Bartholinus, who observed two images when he looked at an object through a crystal of Iceland spar (calcite, $CaCO_3$) (see Fig. 9). The effect can be explained by assuming that the crystal had two different indices for this double refraction. Therefore, light is refracted in two different directions as it enters the crystal (hence the name, double refraction).

The indices for this double refraction are referred to as *ordinary* (n_0) and *extraordinary* (n_e) (Fig. 10). We then apply Snell's law twice, namely

$$\frac{\sin\theta}{\sin\phi_0} = n_0$$

and

$$\frac{\sin\theta}{\sin\phi_e} = n_e(\phi_e).$$

There are many interesting phenomena which depend on the interaction of polarized light and anisotropic materials. A convenient way to

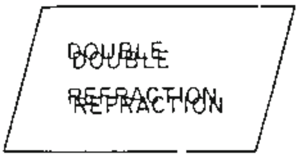

FIG. 9.

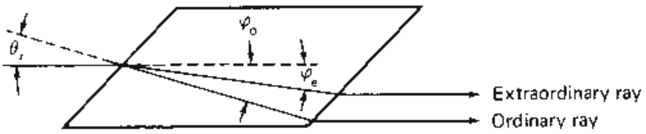

FIG. 10.

categorize them is by the general expansion of the material response P in a power series in the electric and magnetic fields and the spatial derivatives.

$$P_i^{\omega} = P_i^{0} + X_{ij}E_j^{\omega} + X_{ijl}\nabla_l E_j^{\omega} + X_{ijl}E_j^{\omega_1}E_l^{\omega_2} + X_{ijlm}E_j^{\omega_1}E_l^{\omega_2}E_m^{\omega_3} + X_{ijl}E_j^{\omega_1}B_l^{\omega_2} + X_{ijlm}E_j^{\omega_1}B_l^{\omega_2}B_m^{\omega_3},$$

where the superscripts denote the frequency of the field and the subscripts denote Cartesian components. Each term in this series describes one or more effects; for example, the first term describes pyroelectricity and ferroelectricity; the second double refraction; the third, optical activity; and the fourth, the linear electrooptic effect and second harmonic generation. This last is the generation of a light wave at twice the frequency of an incident wave; it is analogous to the generation of harmonics in electronic circuits due to the nonlinear response of circuit elements.

OSCILLOSCOPES

The oscilloscope is a measurement instrument that presents electrical phenomena (signals) in the form of an X-Y graph on a cathode ray tube (CRT) for analysis. This CRT, much similar in appearance to the one in a small television, typically presents signals in a *voltage* (Y-axis) versus *time* (X-axis) relationship. (See Fig. 2(B).) As *voltage* increases, the corresponding location on the CRT moves upward. *Time*, with relation to the displayed signal, starts at the left side of the CRT and increases as the display travels to the right. Signals measured by oscilloscopes are usually generated electrically. Other physical signals must be developed mechanically and converted to electrical energy for display on the oscilloscope through the use of transducers.

Today, most oscilloscopes require manual operation. Each has a CRT to display data, a vertical input to condition the signal, a trigger section to select the signal parameter to begin the display and a horizontal section to provide an accurate time comparison to the signal being displayed. A description of how these fundamental sections of the oscilloscope function together follows. (See Fig. 1.)

Display The oscilloscope develops a graphic representation of the signal by moving the CRT's electron beam across a phosphor coating on the inside of the viewing screen. This results in a bright, visible display that traces the path of the electron beam. (See Fig. 2.) The display brightness is controlled by the oscilloscope's *intensity* control [Fig. 1(A).] Proper *focus* provides a crisp display. The display is turned on at the time the trigger section has sensed the correct input characteristic that a user has selected as the starting point (usually a voltage level).

Vertical Section The primary functions of the vertical section are to supply the display section with a Y-axis and to condition the signal being captured. Conditioning includes display size, input coupling, display position, signal delay to allow viewing of leading edge transcient responses and trigger signals. (See Fig. 3.) The vertical section is further broken down into key blocks: an attenuator to set display size, input coupling to select fundamental signal characteristic, trigger pickoff to trigger display start, and a delay to allow user to see leading edge of signal.

The vertical sections's attenuator reduces large signals to a size necessary for display on the CRT. Attenuator sections also provide three input coupling sections: AC, DC, and GND. AC is selected for changing or AC (alternating current) signals. DC is selected for measuring DC levels like those in power supplies. And GND is selected to identify where ground or zero voltage is located on the display.

The vertical amplifier increases the display size for extremely small signals. In addition the amplifier generates a trigger pickoff signal to drive the trigger circuitry.

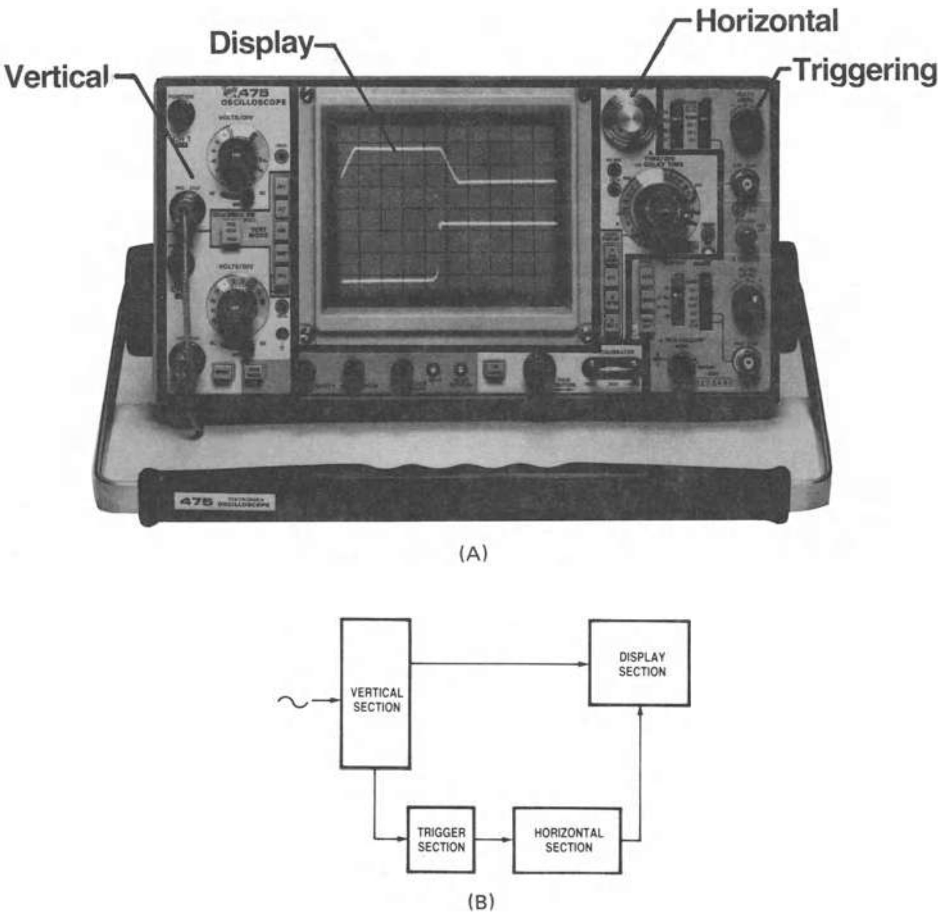

FIG. 1. (A) Front Panel Controls for functional blocks. (B) Functional relationship of blocks.

The delay compensates for normal propagation delays in any electronic circuit. With the delay line the CRT is able to display leading edges of the signal that are lost otherwise. Figure 4 illustrates how a delay line enables the CRT to display the leading edge of a positive step response.

Horizontal Section To develop a graphic representation of the signal being captured, an oscilloscope needs an accurate time relationship on the X-axis of the CRT. This is accomplished by using a very linear sweep generator which produces a *sawtooth* (ramp) waveform. Many different ramp (time/div sweep) rates are available for selection so the user can choose the one that will develop the required graph of the signal. (See Fig. 5.) The horizontal section incorporates an extremely linear and accurate timing ramp that turns the display on at the trigger point. As the ramp voltage increases the X-axis of the signal, it travels left to right on the display. At the end of the selected sweep (ramp) rate the horizontal section generates a retrace signal to move the electron beam back to the left side of the CRT. An internal holdoff time is then generated to reset the trigger circuit to accept another trigger signal, thus completing the horizontal signal loop. (See Fig. 6.) The horizontal section establishes an accurate timing reference at several different possible time selections, trigger holdoff, X-axis signals, and positioning.

Triggering Section Triggering determines when the oscilloscope draws the graph. The trigger circuit tells other oscilloscope circuits when to start drawing the graphic representation of the input signal (Fig. 7). Controls in the trigger section that set up the required trigger condition are coupling, slope, level, and source. The control circuit is much like the vertical input coupling with possible AC and DC selections. Positive and negative trigger slopes are available on almost any oscilloscope. [The trigger slope represented in Fig. 7 is positive (+).] The level control determines the trigger signal amplitude required to activate the trigger circuit. Most

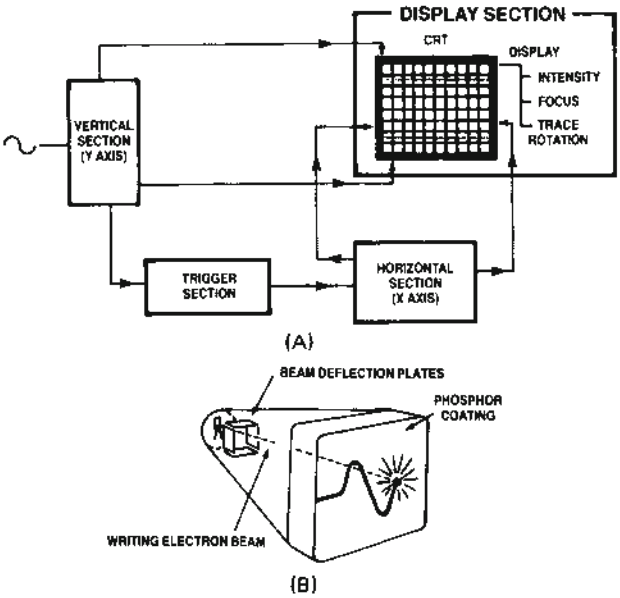

FIG. 2. (A) The basic sections of the oscilloscope work together to create a graph. (B) Changes in voltage on the CRT's deflection plates move the electron beam across the display, causing the phosphor coating to glow.

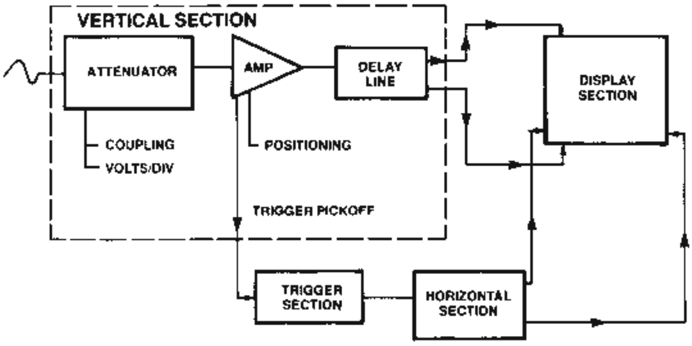

FIG. 3. Blocks of the vertical section.

oscilloscopes provide internal source (from vertical input signal) or external to trigger on a different signal than the one displayed.

Those who use an oscilloscope span many different industries and several job functions.

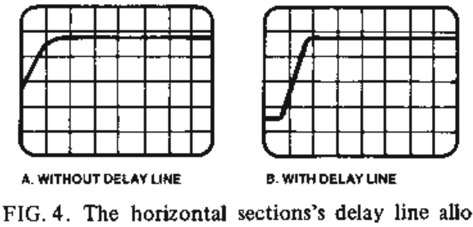

FIG. 4. The horizontal sections's delay line allows viewing of a signal's leading edge.

Applications for oscilloscopes are limited only by one's imagination. Researchers in the computer field are using oscilloscopes in developing smaller, high-speed data processing units. Also using oscilloscopes, the development of electric control systems necessary to continue the exploration of deep space is underway. Faster, more efficient digital communications systems are being designed with the help of scopes. Using scopes, designers in the automobile industry are developing safer cars. Advancement in LSI circuitry, new digital high-speed memories, and A-D converters are aided by the oscilloscope. Using scopes, medical researchers continue to develop methods of restoring eyesight. Work on robotics is advancing with the help of scopes, and eventually will

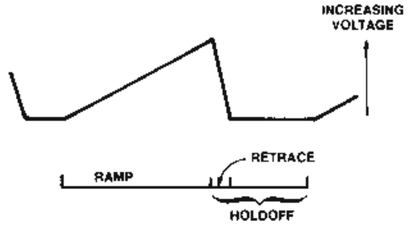

FIG. 5. Horizontal sections sweep ramp.

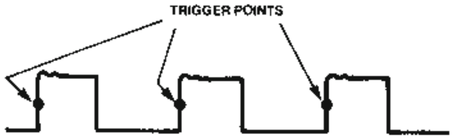

FIG. 7. Trigger points tell the oscilloscope when to begin drawing a graph. Also, for repetitive signals the trigger signal is sent at the same time to produce a stable "repetitive" display.

improve manufacturing productivity in all industries.

The Development of the Oscilloscope The use of CRT's began around the turn of the 20th Century. Their use in advanced oscilloscopes began about 40 years later, with the development of the first triggered oscilloscope. Since the late 1940's demands have increased for higher bandwidth, more accurate voltage and time measurements, better triggering, and the ability to capture and display signal shot or low repetitive rate signals.

Until the 1970s, oscilloscope designs required several dozen power-hungry vacuum tubes. As many as 20 different oscilloscope types were available. As bandwidth pressure continued, the vacuum tube became economically unfeasible. The 1970s saw increased usage of semiconductors in the oscilloscope, and eventually vacuum tubes were rendered obsolete. Semiconductor technology provided the in-

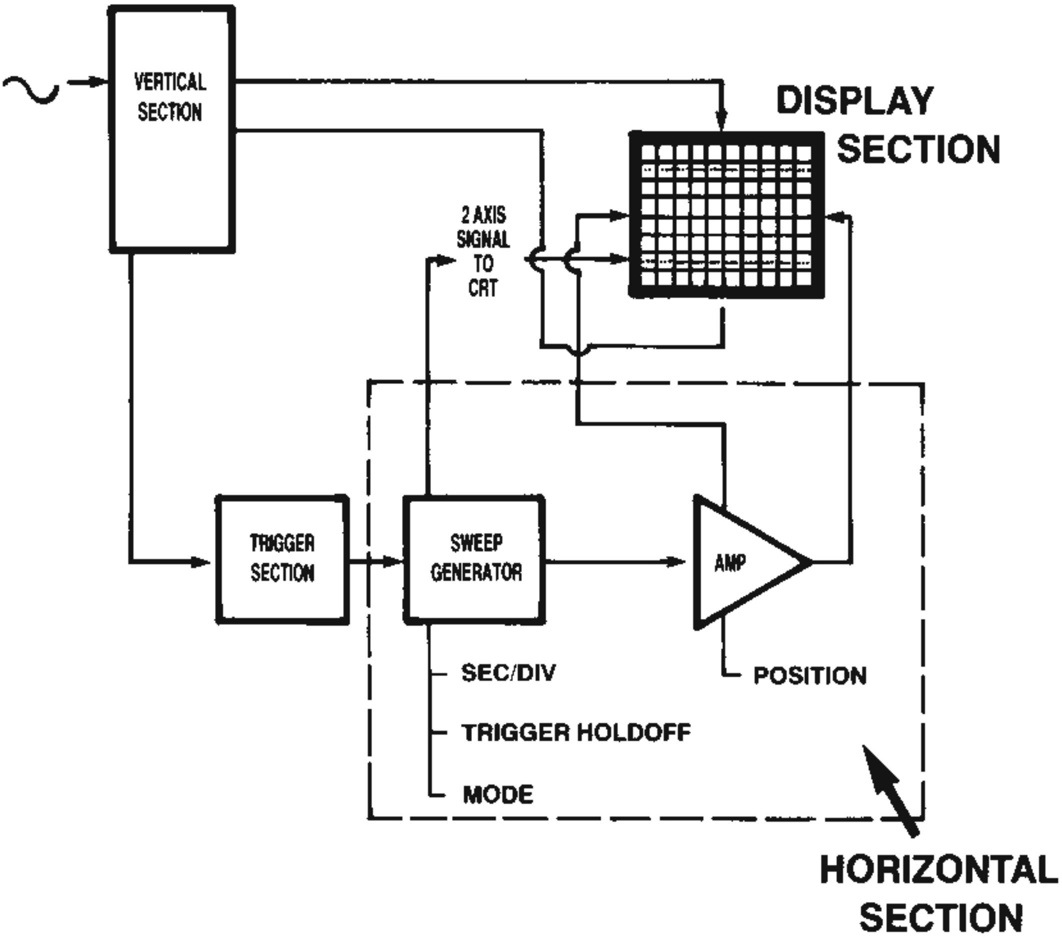

FIG. 6. Blocks of the horizontal section.

crease in accuracy and stability and the higher bandwidth demanded by users. The semiconductor also provided small size and power consumption, which made possible more than 100 different sophisticated types of scope.

Storage Scopes In addition to advancements in traditional oscilloscopes that have historically addressed repetitive signal measurements, new "storage" oscilloscopes were developed that could capture, store, and display single events. This storage technique was made possible by the use of special phosphors and processes that stored the signal for long periods of time on the inside of the CRT viewing screen in a bistable storage mode. (*Bistable* is the name given to a storage process that provides a long viewing time.) Soon, faster storage oscilloscopes became available as variable persistence and fast transfer storage CRT's were invented. People requiring storage products used the storage speed as a major criterion for selection, second only to vertical bandwidth.

With the development of storage CRT's, the oscilloscope market took two basic directions in the 1970s: (1) improved bandwidth and accuracy for making repetitive signal measurements, and (2) improved bandwidth and storage speeds for those requiring nonrepetitive signal measurements. Nonstorage oscilloscopes passed the 1 GHz mark. During the same decade, conventional CRT storage speeds became sufficient to capture and display 400 MHz signals.

Advancements in digital memory speeds, and faster and lower priced A-D converters, resulted in a new type of storage oscilloscope in the late 1970s that did not require special CRT storage. In addition, digital storage provides an effective method of securing signal data and transferring it to a computer for processing of long-term documentation.

Special Purpose Scopes Over the years, special purpose oscilloscopes have made possible totally new measurement methods. The first, the *spectrum analyzer*, was developed for specialized measurements made predominantly in the communications industry. Instead of presenting graphic data in the traditional voltage (Y-axis) versus time (X-axis) format, the spectrum analyzer displays dB (Y-axis) versus frequency spectrum (X-axis).

A second type, the *sampling oscilloscope*, maintains the traditional oscilloscope graphic display in voltage versus time, but higher bandwidths (to 14 GHz) are made available using a random sampling method. However, sampling oscilloscopes are only good for making repetitive signal measurements.

The latest development is the *logic analyzer*. Like the traditional oscilloscope, some logic analyzers show time on the X-axis. Instead of voltage on the Y-axis, however, logic analyzers display only digital wave shapes without reference to voltage. This new type of instrument has been used primarily to make high-resolution timing measurement of digital logic circuits. Other types of display (e.g., state tables, mapping, etc.) are also available in many logic analyzers.

The Future Prior to the 1980s oscilloscopes were developed primarily for manual operation. Future developments will, with continued advancements in LSI, A-D memory speeds, and programmable instrumentation, focus on the oscilloscope's interface with a computer. New oscilloscopes of the 1980s will provide improved productivity through the use of programmability, digital storage, and increased measurement specialization.

Oscilloscopes not tied to the external controllers/computers will offer the user more than just graphic CRT displays. Instead, answers (e.g., risetimes, falltimes, pulse width, frequency, period, etc.) will be available automatically with a higher degree of accuracy and repeatability. Vast improvements in the traditional oscilloscope parameters (e.g., bandwidth, stored writing speed, accuracy, and timing resolution) will occur. Oscilloscope numbers will expand beyond the 100 types available in 1980.

OSMOSIS

If, into the bottom of a jar containing water, a solution of cane sugar is introduced with care so as to avoid mixing, not only will the molecules of cane sugar diffuse into the water but the molecules of water will diffuse into the sugar solution. These processes will go on until the concentration of sugar, and of water, is the same throughout.

If the solution is placed in a container, whose walls are relatively impermeable to the sugar while being permeable to the water, and the container is placed in water, the water will pass from the outside into the container. The term osmosis is usually restricted to the passage of water. If the influx of the water results in an overflow of solution to somewhere other than the surrounding water this overflow will continue until all the sugar is removed from the container. If the container is closed, water will continue to enter until there is sufficient stress in the stretched walls to cause a pressure on the solution inside; this will eventually stop the influx. Of course, if the walls of the container are not completely impermeable to sugar, then the sugar will be escaping into the water outside the container and this will go on until the concentration of sugar is the same outside and inside. If the walls of the container were impermeable to water but permeable to solute, the latter would escape. The cause of this osmosis, this "pushing," of water into the solution is that the tendency of the water molecules to escape from the pure water is greater than that of the water molecules in the solution. Consider water in contact with a limited volume of air. Of those molecules of water striking the surface some will have sufficient energy to escape into the air and this escape will result in net loss to the air which will continue until the concentration of water vapor molecules there is such that the rate of escape from the air (into the water) equals the rate of escape from the water (into the air). If the volume of the air space is fixed, the pressure will rise. Just as the temperature of all bodies is the same when they are in thermal equilibrium, although their heat content per unit volume varies with their specific heat, so the escaping tendency of the water is the same in all systems when they are in aqueous equilibrium, whether the system is pure water, solution, gas phase, wettable solid, etc. The same concept can be applied to any substance, say mercury in pure mercury, in air containing mercury vapor, and in an amalgam with another metal such as zinc. The term osmosis is usually restricted to the passage of water from a solution where the escaping tendency is higher to a solution where it is lower. Moreover it is usually restricted to the passage through a solid or liquid barrier which prevents the solutions from rapidly mixing. It is not used for the passage of water in the form of vapor through the air from a dilute solution to a stronger solution in the same confined space, although the process is fundamentally the same. It is sometimes restricted to the case where the barrier is semipermeable, that is, lets through water but not solute.

The escaping tendency of water is lowered by the addition of a solute. If the molecules of the solute have no other effect than to reduce the number of molecules of water in unit volume, then the escaping tendency of the water will be reduced proportionately to the reduction in the mole fraction of water, N_1, the ratio of the moles of water to the sum of the moles of water and solute. Such is a "perfect" solution. If, however, there is some attraction between the solute and water molecules, a smaller fraction of the latter will have energy sufficient to escape—a "nonperfect" solution. The escaping tendency is increased by pressure. Hence a solution in which the water has lower escaping tendency than it has in pure water at the same pressure, P^0, can be brought to water equilibrium by a sufficient increase in the pressure on the solution to a value P. This sufficient increase, $P - P^0$, is the osmotic pressure of the solution. In general we cannot state $P - P^0$, the osmotic pressure, knowing only N_2, the ratio of moles of solute to the sum of the moles of water plus solute, the mole fraction of solute. ($N_2 = 1 - N_1$).

What we can say is, that if in a solution with a mole fraction N_2 of solute under a pressure P the water has the same escaping tendency as it has in pure water at the same temperature and at a pressure P^0, then $dP/dN_2 = A/B$ where dP/dN_2 is the increase of P relative to increase of N_2 to keep the escaping tendency unchanged; A is the decrease of escaping tendency relative to increase of N_2 when P is unchanged; and B is the increase in escaping tendency relative to increase in P when N_2 is unchanged. For dilute solutions A/B approximates to RT/V_1 and so $P - P^0$ approximates to N_2RT/V_1 where V_1 is the volume of one mole of water, R is constant 82.07 cm^3 atm/deg, and T is the absolute temperature. For very dilute solutions N_2/V_1 approaches n_2/V, the number of moles of solute in a volume V of solution and $P - P^0 = n_2RT/V$ (van't Hoff's equation). This gives an osmotic pressure of 1 atm for one mole of solute in 22.4 liters at 0°C. There is a departure from both these equations for stronger solutions. The fact that one mole of a perfect gas in 22.4 liters at O°C exerts a pressure of 1 atmos, coupled with the above, has led some to say that the osmotic pressure is the bombardment pressure of the solute molecules. It is correct to say that for very dilute solutions the osmotic pressure of a solution is equal in magnitude to the pressure the solute molecules would exert if they were alone in the same volume and behaved as a perfect gas, but that is another matter.

To measure the osmotic pressure, a semipermeable membrane must be prepared which itself can stand sufficient pressure, or it must be deposited in the walls of a porous pot so that the pressure can be sustained. With the solution being inside and water out, pressure is applied to the former until there is no net movement of water.

Observations by Berkeley and Hartley showed that for 3.393 gms of cane sugar per 100 gms H_2O, the osmotic pressure at 0°C is 2.23 atmos while the van't Hoff equation gives 2.17 atmos since $n_2/V = 9.27 \times 10^{-15}$. If N_2/V_1 is used instead of n_2/V, the value of 2.22 is obtained. With stronger solutions the measured osmotic pressure exceeds that calculated: with 33.945 gms of sugar, 24.55 atmos is the value measured, while van't Hoff's equation gives 18.41 and the other 21.8 atmos. The observed value is given if, in calculating N_2/N_1, it is assumed that each sugar molecule immobilizes five molecules of water.

The solutes in the vacuole of a plant cell are exposed to the inward pressure of the distended cell wall and that of the turgid surrounding cells. Water will pass into the cell vacuole from water outside as long as the total inward pressure on the vacuole falls short of the osmotic pressure of the solution in the vacuole. Passage of water into the vacuole dilutes the contents and lowers the osmotic pressure and increases the inward pressure by distension. The amount by which the inward pressure falls short of the osmotic pressure is called by some the suction pressure.

A substance such as cellulose or gelatin tends to take up water, the tendency decreasing with increase in water content until the stress in the substance causes a sufficient rise in the escaping tendency of the water in the substance. This process, which like osmosis is a movement from higher to lower escaping tendency, is called imbibition, and the pressure on the substance sufficient to stop the uptake is the imbibitional pressure. Hence, if a plant cell with a cellulose wall, after coming to equilibrium with a solution, is transferred to water, the wall takes up water by imbibition and the vacuole by osmosis. The latter considers only the over-all movement from outside to vacuole and does not consider the movement from cellulose to vacuole, a process which is the reverse of imbibition. A plant cell in equilibrium with a solution having an osmotic pressure of 25 atmos would also be in equilibrium with air about 98 per cent saturated with water vapor. If the cell were transferred to a saturated atmosphere, it would take up water. We lack precise terms for the passage of water from air into the cellulose and into the vacuole. Condensation, which might be used, ranges more widely.

The escaping tendency of water is affected by factors other than concentration of solute and pressure. Increase of temperature increases escaping tendency. This is a complex problem involving not only transfer of water but also of heat. To a minor extent, the passage of water from pure water to a solution involves a heat transfer.

For many naturally occurring membranes which are not completely semipermeable, i.e., they let solute molecules through slowly, electro-osmosis is important. If the membrane tends to lose negative charges to, or take negative charges from, water or solutions, then the water molecules, in the pores of the membrane, will tend to take on an opposite charge to the membrane. If there is a gradient of electric potential across the membrane, the charged water will move in the appropriate direction. If the potential difference is established by the use of electrodes, this is electro-osmosis.

If, for any reason such as the greater solubility of the solute relative to that of water in the membrane, the volume flow of the solute from the side of higher concentration is greater than that of water in the opposite direction, then there is negative osmosis. This occurs with some plant cells with lipid-soluble substances of small molecular weight.

The rate of osmosis depends, not only on the excess of the escaping tendency of the water in the phase from which it moves, over that in the phase to which it moves, but also upon the area of surface of interchange and the over-all resistance experienced by the water. The rate of shrinkage of the vacuole of a plant cell when it is placed in a strong solution at first seems surprisingly high. When allowance is made for the fact that the ratio of surface to volume increases as the linear dimension is reduced then it is realized that when the vacuole of a spherical cell of radius 30 μ shrinks to half its volume in say 5 minutes the passage of water is only 1 ml per 10 000 cm^2 per minute although the thickness of the layer between vacuole and external solution is of the order of 1 μ in thickness. Under other circumstances, this layer might be said to be relatively impermeable to water. It seems probable that much of the resistance resides not in the cellulose wall or cytoplasm but in the tonoplast which separates the latter from the vacuole.

G. E. BRIGGS

P

PARACRYSTALS*

There are three states of aggregation: solid, liquid and gaseous. This categoric division, however, does not explain why there are, within the solids category, such different substances as metals, minerals, and glasses, or why liquids, when solidifying, convert partly into a crystalline and partly into a glassy state. At the same time substances exist which do not belong in any one of these groups. The word "paracrystal" was used for the first time by Stanley (1) in connection with biological substances and by Rinne (2) in connection with liquid crystals. It is the task of this contribution to find an atomistic definition of the paracrystal (3) and to demonstrate the fundamental importance of this idea relative to concept and application. In doing this one cannot neglect discussing at the same time the x-ray interferences of all these substances, because without the discovery by von Laue (4) that one can gain direct information on shape and ordering of atoms and molecules, everything would remain pure philosophy. One can understand the paracrystalline state only if one simultaneously has knowledge of the other existing modes of solids.

Gases The gaseous state is characterized by a maximum of disorder. The molecules are distributed in space completely irregularly according to purely statistical laws. Their distribution of velocity and proximity obeys, in the ideal case, the Boltzmann statistics. The more compressed the gas, the narrower become these distribution functions.

Liquids The mobility of molecules in liquids is considerably less than that in gases; opinions on their spatial order, however, are at present still divided. The school of Bernal (6) advocates the extreme of highest disorder; whereas the other extreme of quasicrystalline order is supported by Kaplow, Strong and Averbach (7).

Liquid Crystals Whereas liquids generally exhibit equal properties in all three dimensions, i.e., they are isotropic; so-called "crystalline liquids"† are also known, which in the vicinity of the interface with their container exhibit anisotropic optical and electrical properties. The explanation for this phenomenon is derived from the shape and the dipole moment of the molecules of the (mostly organic) liquids. They are oblong or platelet-shaped as in soap solutions.

Crystals Today we have much more knowledge of the crystalline state. The regular and plane-facets-limited shape of a polyether, which exhibits many single crystals, has inspired Haüy (8) to speak of "elementary building blocks" of equal size in the crystal, in the shape of cubes or parallelepipeds, which accumulate densely like a three-dimensional chessboard. In present terminology these are the "lattice-cells," and Seeber (9) recognized very early that they represent the space in which the basic unit of atoms, ions, or molecules of the crystal is housed. Since the distance between centers of gravity (CG) of the basic units is absolutely constant, i.e., 4 Å in certain lattice directions,* we can safely say that in a range of 1 μ† in these directions, exactly 2500 building blocks are situated, or that the distance from one CG to the 2501st neighbor is 10004 μ. Thus, because the building blocks are lined up in a countable fashion, one uses the expression "ideal remote order."

Amorphous Solids Almost all glasses, ceramics, and plastics have properties, which can be explained by the presence of "amorphous" components, in which the atoms are particularly disordered. How one visualizes the order of the atoms is open to discussion. It is generally agreed upon, however, that no lattice regions and no remote order exist here.

The Idea of Paracrystals The status today is that we have lattice structures with remote order on one hand and amorphous materials, liquids, and melts as structures without lattice and without remote order on the other hand opposing each other. On the basis of some fundamental work by J. J. Hermans (10) it was shown (3) that the idea of a statistical close-order for all building blocks, as it is advocated by Zernike (11) and Debye (12), definitely allows three-dimensional lattices of

*The editor is indebted to Mr. Walter Trapp of the Air Force Materials Laboratory for his careful translation of this article.

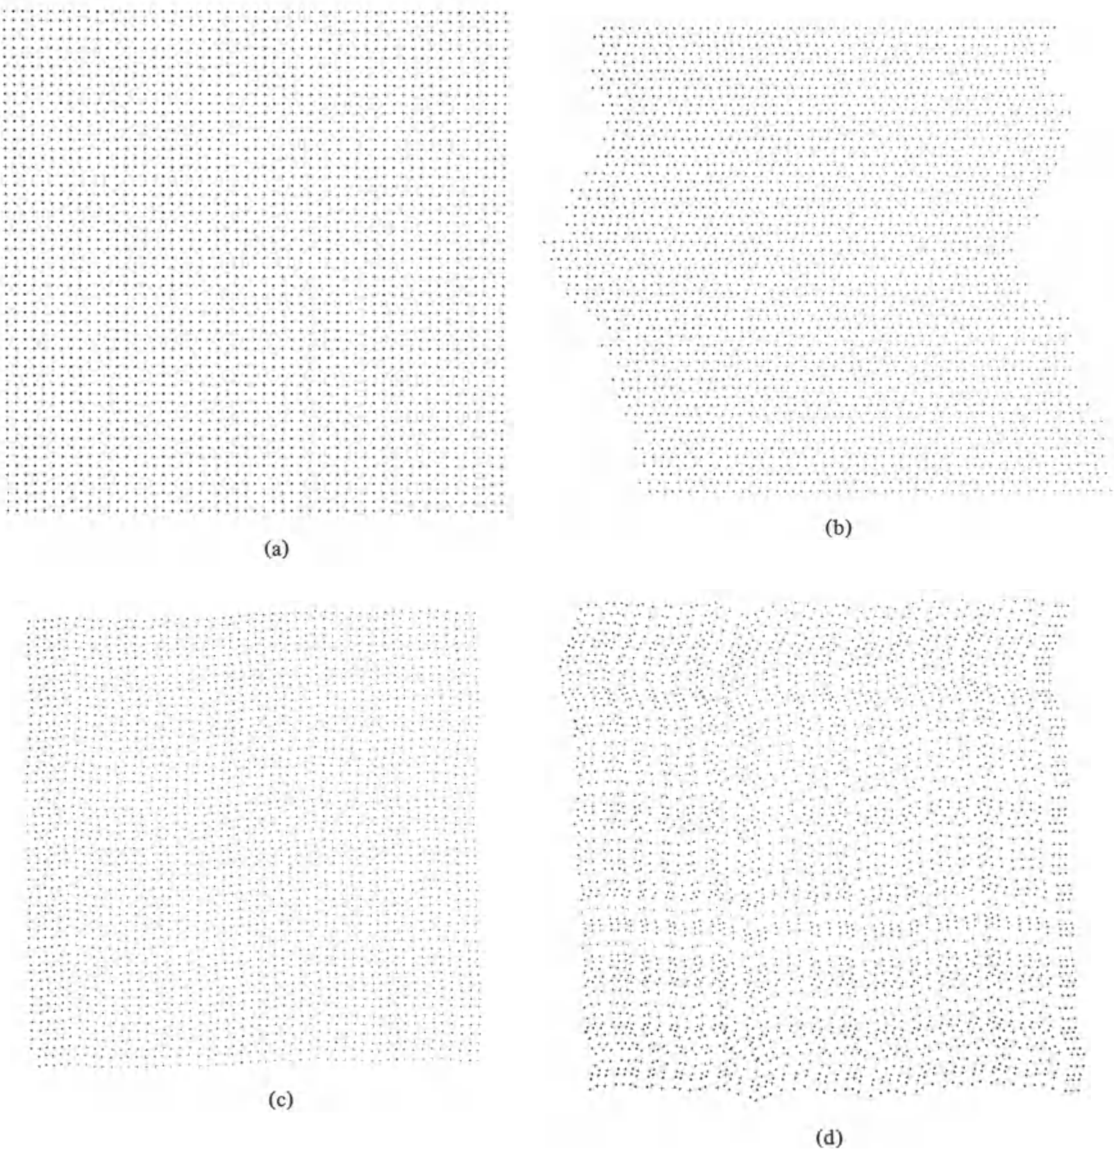
*1 A(named after the Swedish physicist Angström) is equal to one ten-thousandth of a micron.

†1 μ(micron) is equal to one ten-thousandth of a centimeter.

the CG of the building blocks. These lattices consist of rows of countable building blocks (running number p), spaces (running number q), and columns (running number r); however, these are not straight lattice lines, but somehow curved in such a way that, for instance, along the rows of building blocks the distances between adjacent CGs (p, q, r) and $(p + 1, q, r)$ are not constant but adopt different values $\mathbf{y}$ with the frequency $H(\mathbf{y})$. This means also that this frequency distribution guarantees the same close-order ratios for all building blocks (p, q, r). From the building block $(p + 1, q, r)$ to the adjacent CG $(p + 2, q, r)$, one finds a completely different distance vector $\mathbf{z}$, which once more obeys the same probability level $H(\mathbf{z})$. According to the rules of probability the combination of the quantities $\mathbf{y}$ and $\mathbf{z}$ occurs with the frequency $H(\mathbf{y}) \cdot H(\mathbf{z})$.

If one is interested in the statistics of the distance between nearest neighbors (p, q, r) and $(p + 2, q, r)$, one has to calculate the frequency $H_2(\mathbf{x})$ for the vector $\mathbf{y} + \mathbf{z} = \mathbf{x}$, taking into consideration at the same time all possible



(a)

(b)

(c)

(d)

FIG. 1. Two-dimensional point-lattices; computer-drawn, with disturbances increasing from left to right. (a) Crystal. (b) Fibrous material (fiber axis vertical) in which, especially, the horizontal lines are not distorted and proceed equidistantly. (c) Metal melt with relative distance variations of 10 percent and without any partial crystalline residue. (d) Compressed gas, idealized by building blocks sorted in lines and columns.

combinations of y with z as long as they lead to the same x. This means that one has to ensure that $z = x - y$ and only y varies. This leads to the following "convolution integral"*

$$H_2(x) = \int H(y)H(x - y)\,dy.$$

In order to derive the distance statistics between third neighbors one has to apply this folding process twice, etc. In this manner the statistics of the whole distorted lattice is derived from knowledge of the neighbor relationship. Since the scatter of distance increases with the distance of the building blocks from each other, the remote order is lost in the paracrystalline lattices. In Fig. 1 a few two-dimensional examples are given, which demonstrate that the paracrystal contains the gaseous as well as the crytalline state as degenerated exceptions.

Macroscopic Examples Nature, as it is directly visible to us, offers many more examples of paracrystalline structures than one would normally believe. Figure 2, for instance, shows a paracrystalline laminar lattice created by water running off of a sand beach. Repeatedly new waves are introduced, which correspond to step dislocations in solid-state physics. The statistical deviations in the direction and in the spacing of the waves obey the laws of paracrystals. The same holds for the two-dimensional lattices, which are exhibited by the grains of the corncobs in Fig. 3. Since they are statistically of various sizes, only a paracrystalline lattice can originate. This is clearly evidenced in Fig. 4. by the experiment with steel balls of two different sizes located in the

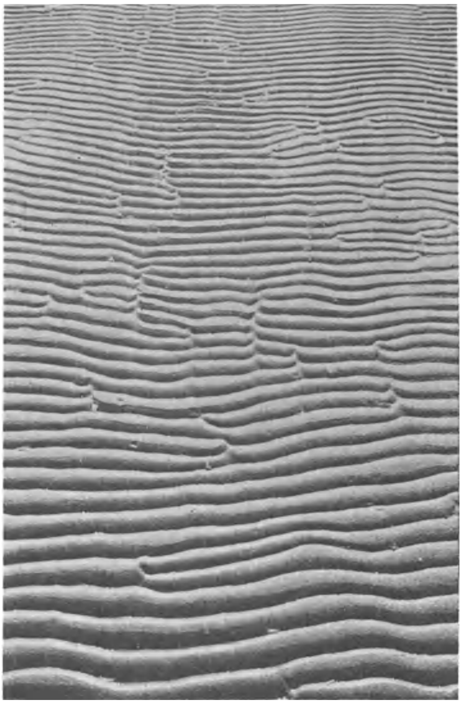


FIG. 2. Beach at the Tagliamento as an example of a paracrystalline laminate lattice, as it appears also in biological and synthetic fiber structures transverse to the fiber axis.

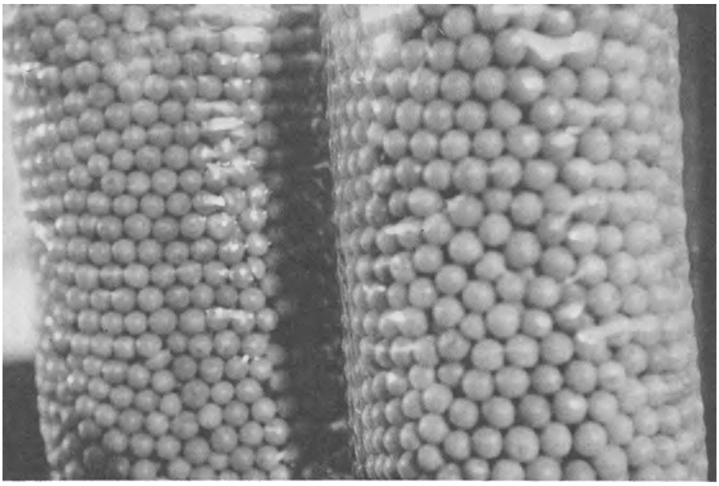

FIG. 3. Two corn cobs, wrapped in cellophane, the grains of which build a multitude of two-dimensional paracrystals with disturbances.

*In pure mathematics "convolution integrals" have been well known for a long time, particularly in the theory of the Laplace transformation. (compare, i.e., (15)). Their importance for mathematical physics has become obvious only in the last few years, specifically since more and more numerical problems have become solvable through the use of modern computers.

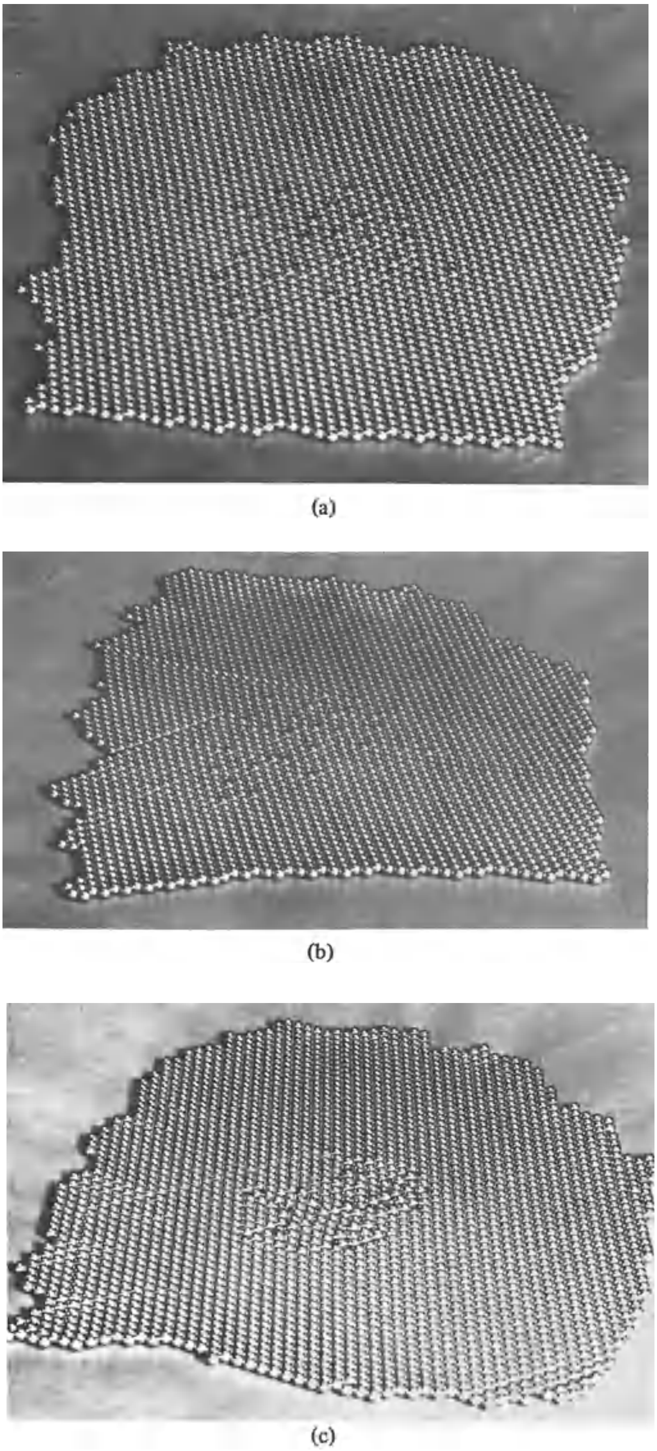

FIG. 4. Identical steel balls on a slightly sagging support. (a) In the middle section, a few balls are carefully replaced with a pair of tweezers by slightly larger ones, without disturbing the surrounding area. (b) The same after shaking lightly. The large balls make space for themselves, which is done by way of step dislocations in the surrounding host-lattice. (Two can be seen in upper left corner.) (c) The large balls have reached the support and thus created a paracrystalline lattice in the center.

center of the structure. Outside all balls have the same diameter and they form the crytalline lattice in whose center the paracrystal is embedded.

Electron-microscopic Examples Synthetic high polymers in colloidal dimensions (below 1 μ to 1/100 μ ~100Å) supply us with excellent examples of paracrystalline laminar structures analogous to Fig. 2. As soon as one transforms them into fibers, for instance in a spin process, one recognizes in the electron microscope that they consist of subfibers ("ultrafibers") of 100

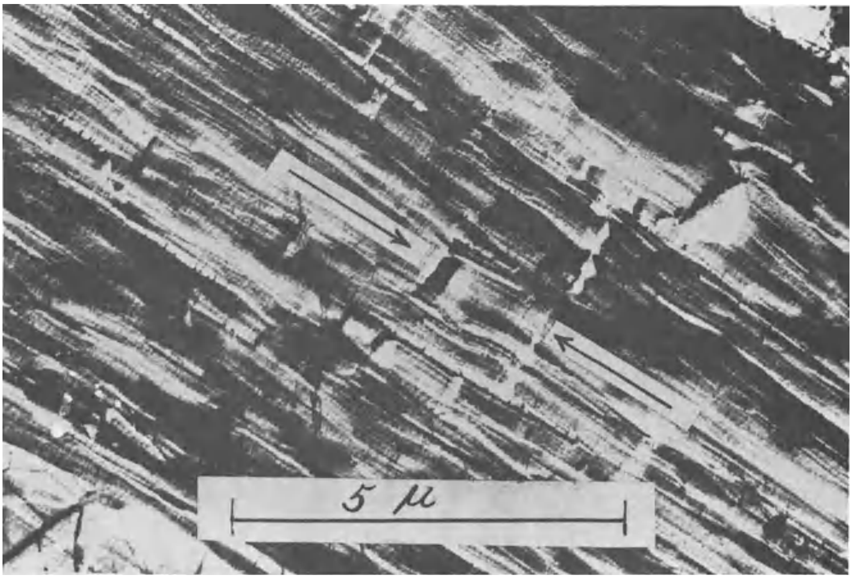

FIG. 5. Electron micrograph of a paracrystalline laminar structure, transverse to fiber, in Teflon (14). Chain molecules are located in direction of arrow. Fibrils are cross-striped. Interval of laminates is approximately 500 A.

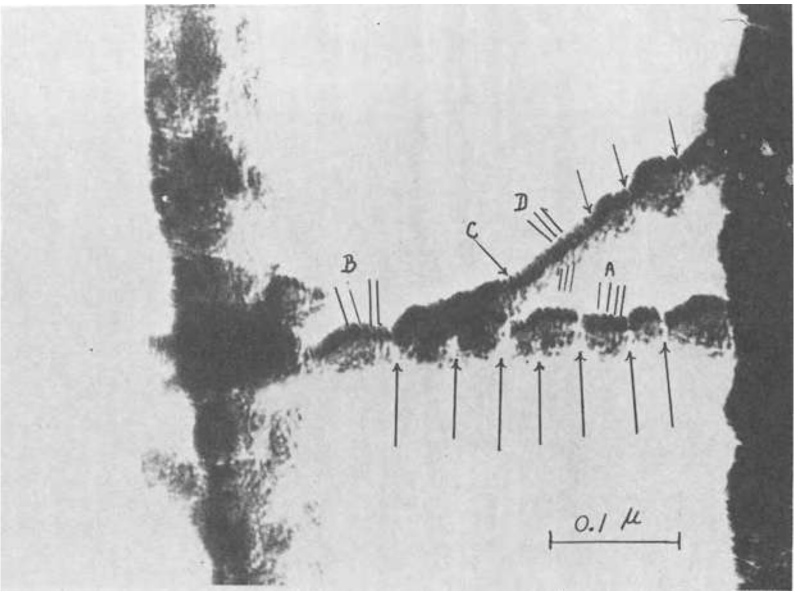

FIG. 6. Electron micrograph (light-field) of a small section of a scraped Teflon surface, where a few ultrafibrils have splintered off (14). The arrows, in an interval of approximately 500 A, designate the boundaries of the individual blocks. These blocks each consist of about 8 disks that either are oriented vertically to the fiber (A) or are partly inclined due to paracrystalline disturbances (B) or bent (C) or buckled.

to 500Å. In these, crystalline and amorphous regions, with a paracrystalline period between 50 and 1000Å (depending on treatment), follow each other as in a string of pearls. By the assembling of ultrafibers into a microfiber the laminar structure originates (Fig. 5). But even in isotropic material (cast in the form of plates) one finds these ultrafibers (14) as is shown in Fig. 6. Here, the crystalline ranges, being approximately 500 Å thick and about equally high, consist of eight lamellae. These cross striations can be found in almost all biological fibers. However, here one reaches the limit of resolution of the electron microscope.

Interferences The only route to take from here is to investigate the interferences generated by the structures. As an example, Fig. 7 shows the Fraunhofer diffraction patterns of the greatly reduced, transparent negatives of the models in Fig. 1, which have been produced with monochromatic visible light. Through their study the static parameters of the paracrystalline lattices can be calculated.

X-ray Interferences In order to generate interference patterns of atomic structures, the wavelength used must be smaller than the length of the edges of the lattice cells. This, for instance, is the case for x-rays which emanate from a copper anode when it is irradiated with electrons. The larger the lattice cells the closer the interference points move together and they finally yield, as for instance

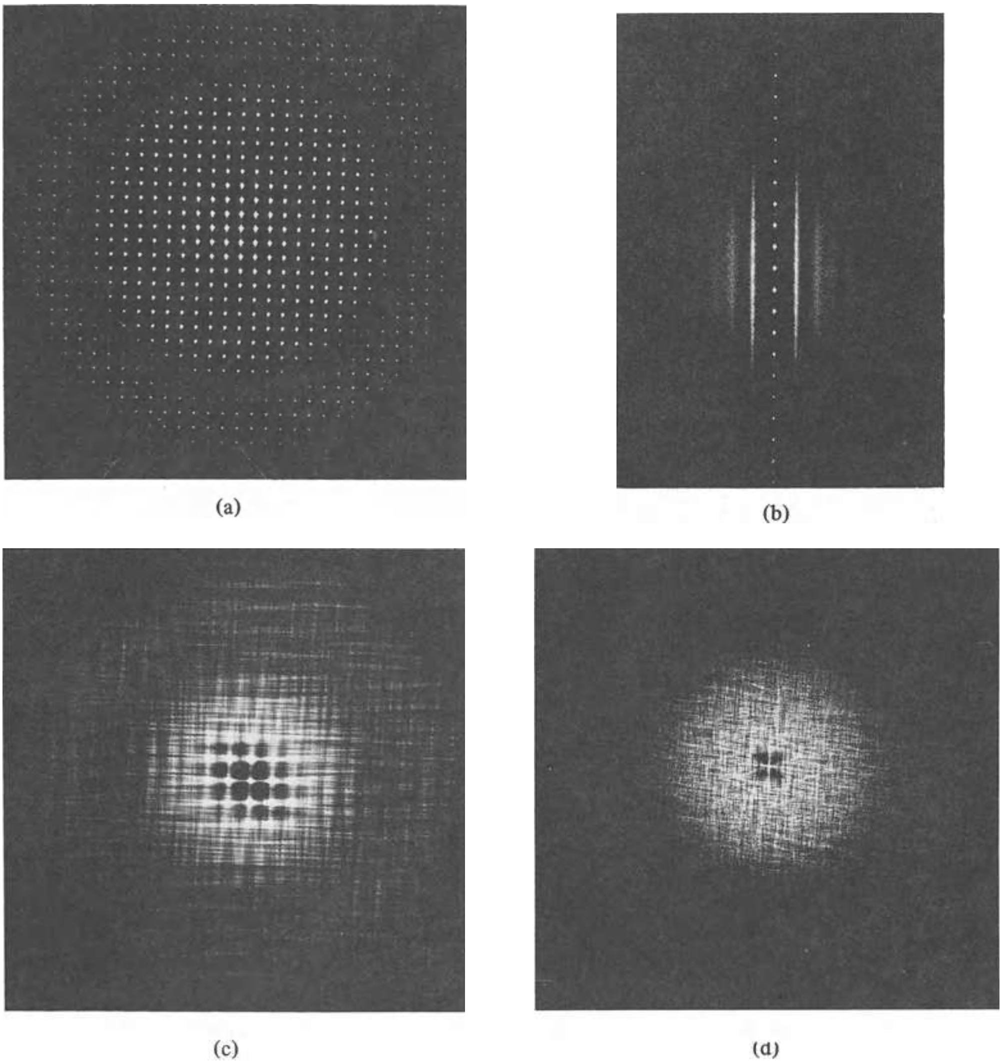

FIG. 7. Fraunhofer diffraction pattern made from the reduced transparent negatives of Fig. 1 with a He, Ne laser (13).

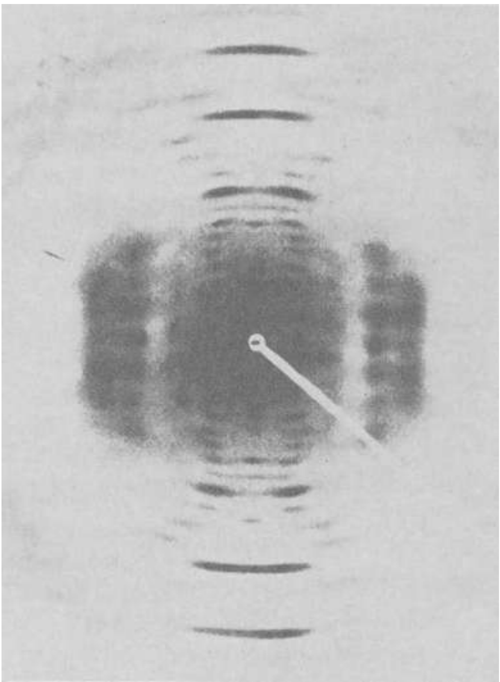

FIG. 8. X-ray small angle diagram of β-keratin of the quill of a seagull (23). Observe the similarity with Fig. 7(b). From the angle position of the interferences one can calculate that the bent lines parallel to the fiber have a distance from each other of about 12 Å, whereas the points along these lines, i.e., the centers of gravity of the basic building blocks of the protofibrils, have a distance of 183Å. This means that the basic building block is very long and thin.

MODEL OF LINEAR POLYETHYLENE

FIG. 9. Principal figure of the structure of a synthetic material consisting of long molecules. The paracrystals consist of 100 to 500 Å thick bundles of parallel-oriented chain molecules. On the front planes, part of the molecules is folded back in larger or smaller loops; some of these run, stretched out, into the next paracrystallite and some are more or less bent. On cold drawing, chains of paracrystallites split into ultrafibrils, separating from each other (left); whereas, with heat-treatment they join again close to each other, whereby the paracrystallites form a paracrystalline, laminate-super-lattice (center). When grown from solution, the portion of the chains which does not fold back decreases with the degree of dilution (right).

in Fig. 8, a so called x-ray angle diagram. The one shown here was the first with which it could be proven that in biological materials paracrystals exist in submicroscopic dimension (17). Their building blocks, being long, thin structures, have the characteristics of fibers, since they can deviate along the fiber only in direction and not in distance from each other.

Superstructures in Polyethylene Similarly, large lattice cells are exhibited also by the so-called "superstructures" which frequently occur in synthetic polymers. As an example, a few results from polyethylenes are given which are representative of many plastic products with long molecules and which have been obtained from the analysis of large and small angle x-ray interferences (18). The fundamental Fig. 9 shows that a lattice cell of the superstructure consists (in the fiber direction) of many basic chemical building blocks C_2H_4 (their CG marked by a dot) and is limited in the fiber direction by amorphous regions in which the chain-backfolding takes place. The lateral extension in the extreme left is particularly evident during cold drawing, where the fibrils separate spatialy. In these lateral grain boundaries, as in the grain boundaries of a crystal, an increased disorder exists. This increased disorder is thought to be caused mainly by a high concentration of "kinks" as displayed in Fig. 10 [according to Pechhold (19)].

Influence of Mechanical Properties In the lateral grain boundaries an increased mobility of the chains relative to each other exists, because kinks can move along the chain by means of the simple flipping-over of some of the CH_2 groups, and the chain therefore creeps on like a caterpillar according to Renecker (20). If one clamps, for instance, both ends of a synthetic fiber and moves them parallel to each other as shown in Fig. 11, one can see in the small inserted diagram that the fibrils glide relative to each other. This explains why metal fibers are much less flexible, and glass fibers can only be bent elastically. In Fig. 12 the influence of heat treatment on the superstructure of stretched polyethylene is shown, by which the mechanical properties are changed. With increasing temperature the crystalline re-

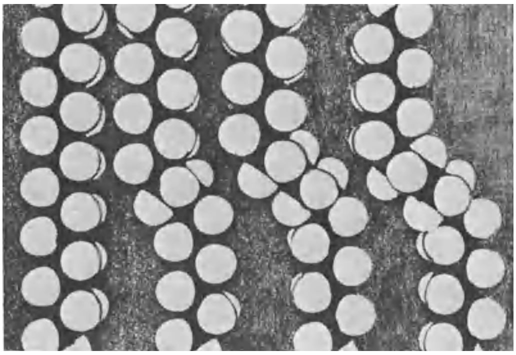

FIG. 10. Model for various kinds of "kinks" in linear polyethylene after Pechhold (19). The white half-spheres represent the hydrogen atoms. They mask the black-symbolized Carbon atoms to a great extent. In the crystalline state (extreme left) the CH_2-groups are arranged in zig-zag fashion.

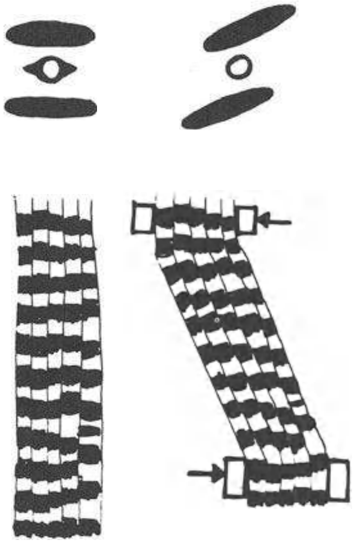

FIG. 11. Bending of a hot-worked piece of polyethylene (schematic). From the x-ray small-angle diagram (at the top) one calculates the superstructures. On the left, before, and on the right, after, bending of both ends of the piece. The crystalline ranges are marked black.

regions grow and the fiber finally loses its desirable properties.

Paracrystalline Atomic Lattices As Fig. 7(c) shows, the widths of the reflexes increase with growing scatter angle the larger the paracrystalline disturbances are.* These disturbances can qualitatively be determined by accurate measurements of line profiles of x-ray angle interferences. According to Fig. 4 they grow with the mixing ratio and the differences in size of the building blocks. Thus, one gets information on their shape when one knows their concentration. In this manner, the ammonia catalyst (enriched with 3 weight per cent aluminum) was investigated. It distinguished itself by the fact that its inner surfaces do not decline even with long service times, thus keeping the connected regions equally small. The result is shown in Fig. 13: A considerable part of the aluminum is built into the cubic-centered α-iron lattice in form of $FeAl_2O_4$ "motives" or units. One unit displaces seven iron atoms. It has the

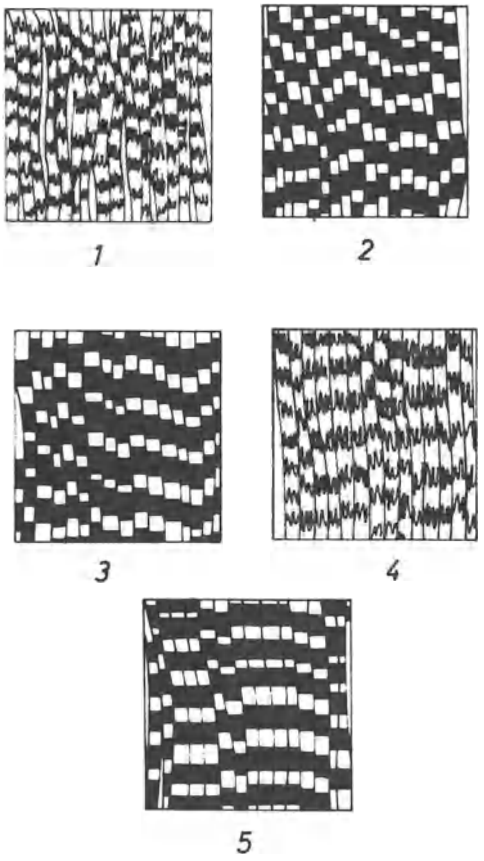

FIG. 12. Influence of heat treatment on the superstructures of polyethylene (18). 1, Cold-stretched. Splintering into ultrafibrils. 2, 500 hours tempered at 110°C. The empty spaces or vacancies have disappeared; the front planes are more distinctly defined. No other changes have occurred. 3, 5 minutes at 120°C produces additionally an elongation in cross-section of the paracrystals. 4, 10 minutes at 120°C causes growth of the average value of the lengths at constant density, but gives a more diffuse front plane. 5,500 hours at 120°C recrystallizes the adjacent ultrafibrils at the same time generating thicker paracrystallites with smaller disturbances. The density and the average laminate interval grow, and the front planes are again well defined.

*Unlike the widening of reflexes through internal stresses, these vary not in a linear fashion, but with the square of the sine of the Bragg angle.

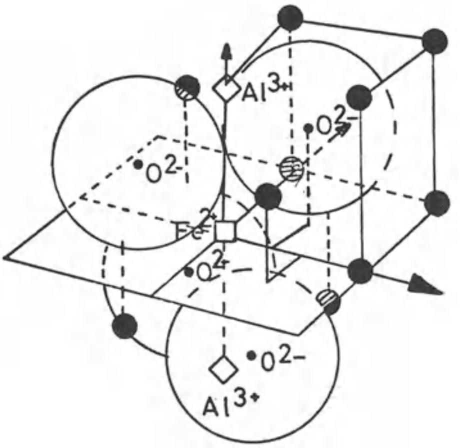

FIG. 13. Atom model of the ammonia catalyst, promoted with 3 weight per cent aluminum. $FeAl_2O_4$ units are built into the metallic iron atom lattice (●) under the substitution of seven atoms each, which fit into the lattice only in respect to their volume but not their shape. The unit consists therefore of one iron ion (▫), two aluminum ions (◇), and four oxygen ions (○).

same volume, but not the same shape as these, a fact which explains the measured paracrystalline disturbances quantitatively (21). Similar measurements on polyethylenes demonstrated that the disturbances in the transverse direction of the paracrystalline microfibrils become smaller with their extension. In all the cases mentioned here, the distance variations are at the largest, 3 per cent, which is hardly recognizable in models. Figure 1(c), in comparison, with 10 per cent relative paracrystalline disturbance variations, corresponds to those values which are found for the very small lattice ranges in metallic melts (22).

Outlook The sketched examples may demonstrate that the theory of paracrystals can be applied to a multitude of groups of substances, and that it furnishes quantitative criteria for the definition of these substances through a series of novel statistical structure parameters. One result, already of interest in colloid-chemistry, is that the lattice ranges are, and remain, smaller the larger their paracrystalline disturbances are. The large and stable inner surface of the ammonia catalyst and the remarkable similarity between many biological and synthetic super-structures, as well as the similarity of a metal structure above and below the melting point, indicate that new fundamentals have been found upon which one could build.

PARAMAGNETISM

Classically, paramagnetism is defined as the acquisition of a magnetization **M** that lies along the direction of an applied magnetic field **H**. This definition implies that when no field is applied, the magnetization is zero, which in essence eliminates ferromagnetism and ferrimagnetism. In the light of today's knowledge, at least one caveat must be added; specifically, antiferromagnetism must be excluded. However, ferro-, ferri-, and antiferromagnets above their ordering temperature behave as paramagnets. Temperature-dependent and temperature-

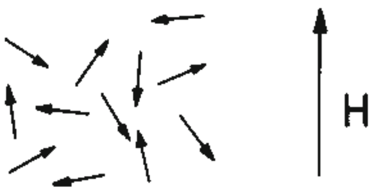

FIG. 1.

independent paramagnetism have different origins, and require separate discussion.

Temperature-dependent paramagnetism can be conveniently discussed by considering a collection (ensemble) of magnetic dipoles, as indicated in Fig. 1. In general the dipoles may have different magnetic moments, but for simplicity they will be assumed to have the same moment $\boldsymbol{\mu}$. Then the vector sum over a unit volume V yields the magnetization, that is, $\Sigma_V \boldsymbol{\mu} = \mathbf{M}$. The dipoles may be located at random positions in configurational space, as in a gas or vapor, or at sites with some short-range order, as in a liquid or an amorphous solid, or at sites with translational symmetry, as in a crystalline solid. Thermal energy, kT, where k is Boltzmann's constant and T is the absolute temperature, will then ensure that the moments are distributed over the possible orientations. Then if $\mathbf{H} = \mathbf{0}$, it follows that $\mathbf{M} = \mathbf{0}$. However, if a magnetic field is applied, the dipoles will tend to align along the field direction, in order to minimize the interaction (Zeeman) energy, $-\boldsymbol{\mu} \cdot \mathbf{H}$. Thermal agitation will normally ensure that complete alignment of the dipoles will not occur.

Classically all dipole orientations are allowed, whereas quantum mechanics requires spatial quantization. If no interactions occur between the dipoles, then either a classical or quantum mechanical calculation shows that M is linearly related to H provided $\boldsymbol{\mu} \cdot \mathbf{H} \ll kT$. The susceptibility, defined as $\chi = M/H$, is found to be given by $\chi = C/T$, where C is a constant. This result is known as *Curie's law*, and indeed several systems are found to follow this relationship. If there are interactions between the dipoles, an elementary and oversimplified approach yields the *Curie-Weiss law*, $\chi = C/(T - \theta)$, where θ is another constant which is a measure of the interaction strength; some materials have susceptibilities that can be fitted to this equation. If H is very large, or T is very low, then the dipoles will tend toward complete alignment. The magnetization at the temperature $T, M(T)$, compared to its value at absolute zero, $M(0)$, is then given by the *Brillouin function*, $B_J(x)$, viz.,

$$\begin{aligned} M(T)/M(0) &= B_J(x) \\ &= \frac{2J+1}{2J} \coth \frac{2J+1}{2J} x \\ &\quad - \frac{1}{2J} \coth \frac{x}{2J} \end{aligned}$$

where J is the total angular quantum number, and $x = \boldsymbol{\mu} \cdot \mathbf{H}/kT$. In the classical limit ($J \to \infty$), $B_J = L(x) = \coth x - 1/x$, where $L(x)$ is called the *Langevin function*. For $J = S = \frac{1}{2}$, where S is the spin quantum number, $B_{1/2}(x) = \tanh x$. Plots of $B_{1/2}(x)$, $B_{5/2}(x)$, and $L(x)$ are shown in Fig. 2. For small x the curves approach straight lines; this is the Curie Law region.

The dipoles of the ensemble can be realized in a variety of ways. Atoms, ions, or molecules with unpaired electrons, that is, with nonzero angular momentum $\mathbf{G}$, (orbital and/or spin),

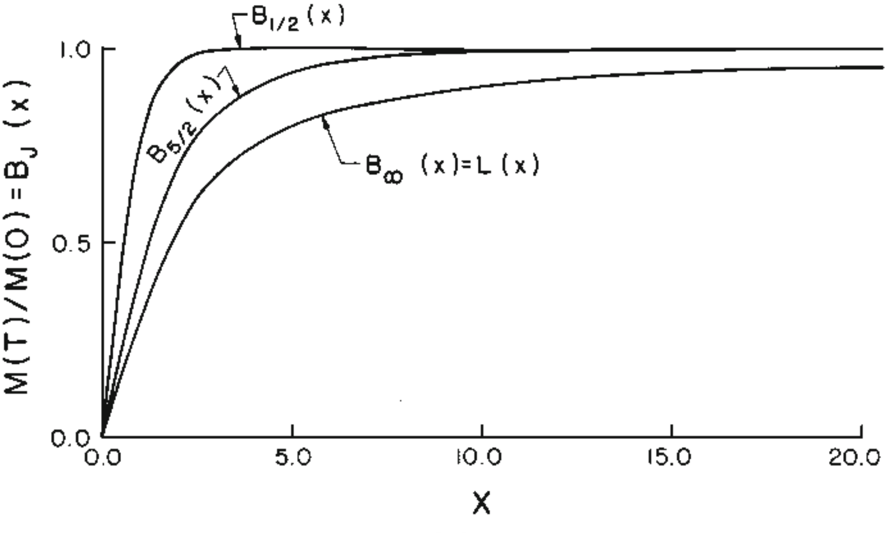

FIG. 2.

have magnetic dipole moments $\boldsymbol{\mu}$. These moving electrons are essentially equivalent to an electric current, and give rise to a permanent magnetic moment given by

$$\boldsymbol{\mu} = \frac{e}{2mc}\,\mathbf{G},$$

where e and m are the charge and mass of the electron, respectively, and c is the velocity of light. Since $\mathbf{G}$ is quantized in integral or half-integral units of Planck's constant, $\hbar$, it is convenient to introduce a unit of magnetic moment, called the Bohr magneton, μ_B, and given by $\mu_B = e\hbar/2mc$, with a value of 9.2741×10^{-21} erg G^{-1} (9.2741×10^{-24} J T^{-1} in SI). For a free atom or ion the dipole moment is given by $\boldsymbol{\mu} = g\mu_B \mathbf{J}$, where g, called the *g-factor* or *spectroscopic splitting factor*, is the Landé formula of atomic spectroscopy. For ions in a solid, the same form of equation may be used, except that g is essentially a phenomenological constant that reflects the splitting of the orbital and spin states by the internal interactions. Atomic and molecular electronic dipole moments are usually of the order of one Bohr magneton.

Examples of paramagnetic gases are sodium vapor and nitric oxide. Even though molecular oxygen, O_2, has an even number of electrons, its ground state has $S = 1$, and consequently it is a paramagnet. Other molecular paramagnets are organic free radicals and biradicals.

By far the largest number of substances with permanent dipole moments are liquids or solids containing ions of transition group elements, that is, those with partially filled $3d$, $4d$, $5d$, $4f$, or $5f$ electron shells. The lanthanides, comprising the elements from La to Lu in the periodic table, usually in the trivalent state, have 0–14 $4f$ electrons. The $4f$ electrons, which are surrounded by outer $5s$ and $5p$ electrons, are situated well to the interior of the ions. Hence, the dipoles almost behave as if the ions were free, and often obey Curie's Law fairly well, at least provided the temperature is not too low. However, the electric crystalline fields of the diamagnetic ions (ligands) in a solid do interact with the $4f$ electrons, and lead to susceptibility changes that are important at low temperatures. In recent years, interest in the actinides or $5f$ group has increased. The trivalent ions, Th^{3+}, Pa^{3+}, U^{3+}, Np^{3+}, Pu^{3+}, Am^{3+}, and Cm^{3+} have 1–7 $5f$ electrons, respectively. Complex ion groups, such as $(UO_2)^{2+}$, $(NpO_2)^{2+}$, and $(PuO_2)^{2+}$ are also formed with 0, 1, and 2 unpaired $5f$ electrons, respectively. Both spin-orbit coupling and crystal-field interactions tend to be more important in the actinides than the lanthanides.

The $3d$ group are usually divalent, but may be in trivalent or other states; this group includes Cr^{2+}, Cr^{3+}, Mn^{2+}, Fe^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, and Cu^{2+}. The relatively exposed $3d$ electrons interact with the ligand fields much more strongly than the $4f$ electrons of the rare earths. As a result, the orbital energy levels are split. Then the dipole moments are largely determined by the spin only, and often a Curie or Curie-Weiss Law is observed, again if the temperature is not too low. Indeed, the susceptibility is a measure of the paramagnetic ion's energy levels and the number of ions in each level, as determined by the principles of statistical mechanics. In principle, a susceptibility measurement provides information on the energy levels of the paramagnetic ion. In practice, details of these energy levels can be deduced from χ only for a few special cases. Instead, the procedure today is to determine these energy levels by other methods, usually electron paramagnetic (spin) resonance, and then to calculate the susceptibility. Other techniques used to deduce the magnetic energy levels include specific heats, magnetooptics, and Mössbauer spectroscopy.

In some compounds, the paramagnetic ions may be covalently bound, that is, electrons are shared with the diamagnetic ions. The dipole moments are then somewhat spread out spatially, and the localized permanent dipole moments of Fig. 1 become somewhat fuzzy. Covalent interactions are usually important for ions of the palladium ($5d$) and platinum ($6d$) groups.

Other examples of electronic permanent dipole systems include electrons trapped at vacant lattice sites (F-centers), radiation damaged bonds, and localized donors and acceptors in semiconductors. Next, the nucleus may also have a nonzero angular momentum, and hence a permanent magnetic moment. It is much smaller ($\sim 10^{-3}$) than the electronic magnetic moment, and consequently the nuclear contribution to the susceptibility is usually negligible. However, the nuclear susceptibility of solid (atomic) hydrogen, water, and $C_6(CH_3)_6$ has been detected. Nuclear magnetic energy levels are usually investigated by nuclear magnetic resonance (NMR).

Small particles, about 10 nm in diameter and containing transition atoms, may be ferro- or ferrimagnetic; examples are iron or iron oxide (Fe_3O_4 or γ-Fe_2O_3). Thus, in the context of Fig. 1, the permanent magnetic moment of each particle is about $\mu = 10^6\ \mu_B$. Thermal agitation may still be sufficient to overcome any anisotropy in each particle, and hence cause oscillations of the magnetic moment between various energy minima. Since the time average of the moment of a particle is zero, the particle is said to be a *superparamagnet*. Application of a field to the system of particles will then produce a magnetization given by the Langevin function.

Electrons in an unfilled energy band, as in a metal or alloy, give rise to a weak paramagnetism that is essentially temperature independent. These electrons have a magnetic moment

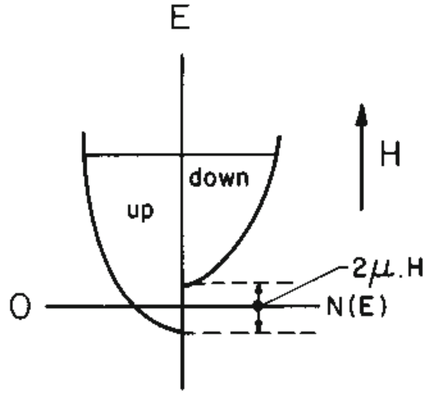

FIG. 3.

$\mu \simeq \mu_B$ since $S = \frac{1}{2}$ and $g \simeq 2$. Suppose the electron gas is considered as two subsystems, with half the moments lying along a given direction, say up, and half in the opposite direction, down. The net moment is of course zero until a magnetic field is applied. Then the energy of the electrons with magnetic moments parallel to $\mathbf{H}$ is decreased by $\mu_B H$ and the energy of those antiparallel is increased by $\mu_B H$. Thermodynamic equilibrium then requires that electrons with antiparallel moments enter the parallel-moment subsystem until the two subsystems are filled to the same energy levels, that is, the Fermi levels of the two systems become equal, as shown in Fig. 3. The susceptibility, first calculated by Pauli, is

$$\chi = \frac{3N\mu_B{}^2}{2E_F(0)}$$

at absolute zero, where N is the number of conduction electrons per unit volume and $E_F(0)$ is the Fermi energy at $T = 0$ K. Since the Fermi energy changes slightly with temperature, then so also does the susceptibility.

Second-order quantum mechanical perturbation theory applied to atomic electron wave functions also yields a small temperature-independent susceptibility. This second-order Zeeman effect was first derived by Van Vleck. The order of magnitude of the Van Vleck susceptibility is given by

$$\chi \propto \frac{N\mu_B{}^2}{E_n - E_0}$$

where E_n is the energy of the nth excited state and E_0 is the ground state.

In addition to the paramagnetic susceptibility, there is always a diamagnetic one, and it is the sum of these two that is measured in an experiment. For permanent moments of about one Bohr magneton, the diamagnetic contribution is small, and may often be neglected. The diamagnetic susceptibility must be considered when the temperature is high, when the relative numbers of atoms or ions with permanent moments are small, or when Pauli or Van Vleck paramagnetism dominates. If $\mu = \mu_B$, then the paramagnetic susceptibility for a mole of dipoles is about 10^{-4} at room temperature, and 10^{-2} at 1 K (cgs units). Pauli susceptibilities are of the order of 10^{-6} to 10^{-5} emu cm^{-3}.

PARITY

The theoretical description of any physical process in the relativistic domain must remain invariant under a Lorentz transformation. In a classical theory, where the interactions depend on the relative spatial separation of the position coordinates and the relative temporal separation of two instants of time implying a finite velocity of propagation of the interaction, the description of the interaction must be independent of the coordinate frame in which the process is described. A proper Lorentz transformation from one frame S to another S' is given by

$$x_\mu{}' = a_{\mu\nu} x_\nu$$

where

$$x_\mu \equiv (x_1, x_2, x_3, x_4) = (x, y, z, ict),$$

and a summation is to be made over repeated indices. (This summation convention applies throughout the present article.) Similarly,

$$p_\mu{}' = a_{\mu\nu} p_\nu$$

where

$$p_\mu \equiv (p_1, p_2, p_3, p_4) = (p_x, p_y, p_z, iE/c).$$

The four coordinates x_μ are collectively called the *space-time coordinates* and the four quantities p_μ are collectively called the *four momenta*, the first three being the spatial components of the momentum and the fourth being proportional to the energy within a factor i/c. The $a_{\mu\nu}$ are constants independent of the space-time coordinates such that the relativistic interval is to remain invariant:

$$x_\mu x_\mu = x_\mu' x_\mu' = a_{\mu\nu} x_\nu a_{\mu\tau} x_\tau$$

$$p_\mu p_\mu = p_\mu' p_\mu' = a_{\mu\nu} p_\nu a_{\mu\tau} p_\tau = -m^2 c^2 .$$

This invariance requires that

$$a_{\mu\nu} a_{\mu\tau} = \delta_{\nu\tau}$$

and, in order to preserve the reality conditions of the space-time coordinates, $a_{\mu\nu}$ with $\mu, \nu = 1$ 2, 3, and a_{44} are real, while $a_{\mu 4}$ and $a_{4\mu}$ are imaginary.

These transformations are continuous, being obtained from a series of infinitesimal transformations from unity, and are characterized by $\det(a_{\mu\nu}) = 1$. They do not change the direction of the time axis.

Such a formalism can be used to describe proper rotations of the physical system and boosts to a different velocity of the physical system with respect to the space-time coordinate system. The requirement of equivalence between different Lorentz frames leads directly to the laws of conservation of four-momentum and angular momentum.

In addition, there are the improper Lorentz transformations of space inversion and time inversion, which are discontinuous, unlike the proper Lorentz transformations. These improper transformations each have the property that $\det(a_{\mu\nu}) = -1$. The transformed system under space inversion is

$$x_i' = -x_i, \quad \text{where} \quad i = 1, 2, 3,$$

and that under time inversion is

$$x_4' = -x_4 .$$

Clearly, $x_\mu' x_\mu' = x_\mu x_\mu$ for either case or for both taken together. It should be noted that the reversal of the space coordinates changes a right-handed coordinate system to a left-handed system, or vice versa. This implies that if there is a physical system in nature that has a definite handedness it is also possible to have a system of the opposite handedness obeying the same physical laws. Classically, this invariance under reflections leads to no conservation law in the way that invariance under rotations leads to the conservation of angular momentum. This is not so in quantum mechanics.

In a relativistic theory time inversion is not equivalent to an operation where every velocity is replaced by the opposite velocity so that the position of the particle at $+t$ becomes the same as it was, without time inversion, at $-t$. This latter operation may properly be called velocity reversal or motion reversal, but in quantum mechanics or quantum field theory it is usually, perhaps illogically, called *time reversal* or *Wigner time reversal*. The laws of classical physics, apart from statistical effects such as frictional forces and electrical resistance, are invariant under time reversal where one has the normal motion in reverse.

Time inversion is actually the product of time reversal and charge conjugation, an operation where all particles are changed into their antiparticles. Charge conjugation is a relativistic quantum-mechanical concept only, and like space and time inversion, is a discontinuous operation. In the limit where a nonrelativistic approximation is valid the operation of charge conjugation is not meaningful, so only space inversion and time reversal have physical meaning there.

In quantum mechanics, the interacting objects such as elementary particles, atoms, and nuclei are described by a wave function $\psi(\mathbf{r}, t)$ which is itself a function of the space-time coordinates. Here a symmetry property called *parity* is introduced to express the equivalence between left and right. If we denote by $\psi(-\mathbf{r}, t)$ the wave function in the space-reflected system, then

$$\psi^P(\mathbf{r}, t) = \eta_P \psi(-\mathbf{r}, t).$$

The space inversion quantum number η_P is called *parity* and has two eigenvalues, ±1. When $\eta_P = 1$ the wave function is said to have even parity and when $\eta_P = -1$ the wave function is said to have odd parity.

The supposition that any nondegenerate stationary quantum-mechanical state of an object, such as an atom or nucleus, will have a definite parity has led to very powerful conservation laws in the description of physical processes involving interactions of atoms or nuclei. The principle that the total parity of the system was conserved was regarded until recently as a fundamental principle of physics.

Stated formally, if P is a unitary operator that inverts the space coordinates through the origin such that

$$P\psi(\mathbf{r}, t) = \psi'(\mathbf{r}', t) = \eta_P \psi(-\mathbf{r}, t)$$

then the wave equation

$$H\psi(\mathbf{r}, t) = E\psi(\mathbf{r}, t)$$

can be transformed into

$$PHP^{-1} \psi'(r', t) = E\psi'(r', t).$$

The wave equation in the transformed coordinate system is unchanged provided that $PHP^{-1} = H$ or $PH - HP = 0$. The Heisenberg relation for a time rate of change of an operator P is

$$\frac{dP}{dt} = \frac{\hbar}{i} (HP - PH).$$

Therefore P is a constant of motion provided it commutes with the Hamiltonian operator.

Operating twice with P on any wave function gives the same wave function, i.e., $P^2 = 1$, so the only possible eigenvalues of P are +1 and −1.

It is now well established that the strong interactions between elementary particles and the electromagnetic interactions are invariant under space inversion, so any nondegenerate energy eigenstate of an atom or nucleus will be also an eigenstate of the parity operator P. Similar statements can be made for the time reversal operator T and the charge conjugation operator C.

A quantum-mechanical system such as an atom or nucleus is usually described by wave functions in the angular momentum representation. The one-particle wave functions of the individual constituents are a product of an intrinsic part that may be also an eigenfunction of the spin angular momentum operator and an orbital part that is an eigenfunction of the orbital angular momentum operator ℓ_z. The latter eigenfunction is a spherical harmonic $Y_\ell{}^m(\theta, \phi)$ having an eigenvalue $(-1)^\ell$ of the space inversion operator P. The total parity of the system is then the product of the parities of the constituents. The intrinsic parity of any elementary particle cannot be determined theoretically, nor can the eigenvalues of the time-reversal operator T and the charge-conjugation operator C, often called *time parity* and *charge parity*.

For a meaningful and satisfactory formulation of charge conjugation and time reversal it is essential to consider the field operators in a quantized theory, taking into account the ordering of operators and their commutation relations appropriate to Bose statistics for integer spins and Fermi statistics for half-integer spins. The wave function for a particle is the one-particle expectation value of the field operator. In Table 1 the transformation properties of various kinds of field operators are listed for the linear transformations P and C and the antilinear transformation T. These transformation properties are obtained by considering the invariance of the free-field equations of motion.

TABLE 2. TRANSFORMATION OF OBSERVABLES UNDER SPACE INVERSION, TIME REVERSAL, CHARGE CONJUGATION, AND TIME INVERSION

Observable		P	T	C	P_4
Position	$\mathbf{x}$	$-\mathbf{x}$	$\mathbf{x}$	$\mathbf{x}$	$\mathbf{x}$
Time	t	t	$-t$	t	$-t$
Velocity	$\mathbf{v}$	$-\mathbf{v}$	$-\mathbf{v}$	$\mathbf{v}$	$-\mathbf{v}$
Momentum	$\mathbf{p}$	$-\mathbf{p}$	$-\mathbf{p}$	$\mathbf{p}$	$-\mathbf{p}$
Energy	E	E	E	E	E
Mass	m	m	m	m	m
Orbital angular momentum	ℓ	ℓ	$-\ell$	ℓ	$-\ell$
Spin angular momentum	$\mathbf{s}$	$\mathbf{s}$	$-\mathbf{s}$	$\mathbf{s}$	$-\mathbf{s}$
Charge	e	e	e	$-e$	$-e$
Force	$\mathbf{f}$	$-\mathbf{f}$	$\mathbf{f}$	$\mathbf{f}$	$\mathbf{f}$
Acceleration	$\mathbf{a}$	$-\mathbf{a}$	$\mathbf{a}$	$\mathbf{a}$	$\mathbf{a}$

In Table 2 the transformation properties of various physical observables are listed. The transformed observables are independent of the values of η_P, η_T, and η_C, of the fields.

The phases η_P, η_T, η_C, etc. for those particles that can be created or destroyed can be found experimentally from the properties of their mutual interactions, assuming conservation of P, T, or C in these interactions. For example, the π^0 neutral meson decays into two photons; an analysis shows that its intrinsic parity $\eta_{P'} = -1$ independently of the $\eta_{P''}$ for the electromagnetic field. The π^0, having odd parity and zero spin, is therefore a *pseudoscalar particle*, as opposed to a scalar particle having even parity and zero spin. The charged mesons $\pi^\pm$ also have $\eta_P = -1$, but charge conservation prevents their decay into two photons so that an interaction where the $\pi^\pm$ are created or absorbed through interactions with nucleons must be considered. The number of nucleons is conserved, so only the product $|\eta_P|^2 = 1$ is determined for the nucleons. Similarly, the

TABLE I. TRANSFORMATION OF INTRINSIC FIELDS UNDER SPACE INVERSION, TIME REVERSAL, AND CHARGE CONJUGATION

Intrinsic Field		P	T	C
Scalar	$\varphi(\mathbf{r}, t)$	$\eta_{P'}\varphi(-\mathbf{r}, t)$	$\eta_{T'}\varphi(\mathbf{r}, t)$	$\eta_{C'}\varphi^+(\mathbf{r}, t)$
Dirac spinor	$\psi(\mathbf{r}, t)$	$\eta_P\gamma_4\psi(-\mathbf{r}, t)$	$\eta_T\gamma_3\gamma_1\psi^*(\mathbf{r}, -t)$	$\eta_C\gamma_2\psi^*(\mathbf{r}, t)$
Four vector	$A_\mu(\mathbf{r}, t)$	$\eta_{P''}(-1)^{\delta\mu4}A_\mu(-\mathbf{r}, t)$	$\eta_{T''}(-1)^{\delta\mu4}A^*(\mathbf{r}, -t)$	$\eta_{C''}A_\mu{}^*(\mathbf{r}, t)$
Pseudoscalar	$\pi(\mathbf{r}, t)$	$\eta_{P'''}\pi(-\mathbf{r}, t)$	$\eta_{T'''}\pi^*(\mathbf{r}, -t)$	$\eta_{C'''}\pi^*(\mathbf{r}, t)$
Electric field	$\mathcal{E}(\mathbf{r}, t)$	$\eta_P\mathcal{E}(-\mathbf{r}, t)$	$-\eta_{T''}\mathcal{E}(\mathbf{r}, -t)$	$\eta_{C''}\mathcal{E}(\mathbf{r}, t)$
Magnetic field	$\mathcal{B}(\mathbf{r}, t)$	$-\eta_{P''}\mathcal{B}(-\mathbf{r}, t)$	$\eta_{T''}\mathcal{B}(\mathbf{r}, -t)$	$\eta_{C''}\mathcal{B}(\mathbf{r}, t)$
Two-component neutrino	$\psi_{(\nu)}(\mathbf{r}, t)$	does not exist	$\eta_T\gamma_3\gamma_1\psi_{(\nu)}(\mathbf{r}, -t)$	does not exist

electromagnetic field interacting with an electron current determines $\eta_P'' = -1$ for the electromagnetic field and $|\eta_P|^2 = 1$ for the electrons. In analogous ways all the phases for those particles with integer spin (bosons) can be found by experiment, while those with half-integer spin (fermions) cannot and, indeed, are indeterminate. Although the intrinsic parity is indeterminate for fermions, the intrinsic parity for an antiparticle is opposite to that for a particle, in contrast to the boson case; e.g., the intrinsic parity is odd for e^+e^- in an S state and even for $\pi^+\pi^-$ in an S state. Considering the conservation of C, P, and angular momentum J, the only allowed modes of annihilation of an electron-positron system are a singlet-S system decaying into two photons and a triplet-S system decaying into three photons.

Conventional usage assigns $\eta_P = +1$, i.e., positive parity, for fermions. Any fermion state of total angular momentum j can be specified by $\psi_{j\ell s}$ where $j = \ell + s$ and has total parity $(-1)^\ell$ by convention. Similar arguments define a "time parity" and a "charge parity" for each quantum-mechanical state. Likewise, the electromagnetic field can be expanded into multipoles in an angular momentum representation; however, here the intrinsic parity is specified. A photon of angular momentum J can have two possible parities, characterized by electric multipole radiation EJ, with parity $(-1)^J$, and magnetic multipole radiation MJ, with parity $(-1)^{J\pm1}$. These different types result from possible vector products of the intrinsic spin and the orbital angular momentum to give the same J.

Several examples of the use of parity conservation follow. Consider the interaction of the electromagnetic field with a quantum-mechanical system, a transition from an initial state of definite angular momentum, I_i, and parity, π_i, to a final state of definite I_f and π_f, with the emission or absorption of electromagnetic radiation of angular momentum J and parity π. The conservation of angular momentum and parity requires that

$$|I_i - I_f| \leqslant J \leqslant I_i + I_f$$

$$\pi_i \pi_f \pi = 1.$$

The possible transitions are shown in Table 3.

In atoms, the predominant electromagnetic transitions are of electric dipole type. The characteristic lifetimes of the other multipoles are long compared with the typical atomic collision times, an alternative method of deexcitation. The first concept of the use of parity in atomic physics resulted from the experiments of Laporte showing that the initial and final states were always of opposite parity. This result is predicted in Table 3.

TABLE 3. ELECTROMAGNETIC MULTIPOLE SELECTION RULES

ΔI / $\Pi_i\Pi_f$	0 $I \neq 0$	1	2	3	4	5
+	M1	M1	E2	M3	E4	M5
−	E1	E1	M2	E3	M4	E5

In nuclei, collision plays little role, so all electromagnetic multipoles can contribute, but usually the lowest-order multipole comparable with the conservation of angular momentum and parity predominates. These restrictions are known as angular momentum and parity selection rules.

The parity of the probability density $\psi^\dagger\psi$ is always even. The expectation value of an operator θ is $\psi^\dagger\theta\psi$ and vanishes if θ is an odd function under the parity operation. From the properties of the multipole operators, all odd electric multipole moments and all even magnetic multipole moments vanish. The restriction to nondegeneracy is essential and is satisfied for all atomic and nuclear systems. In molecular systems there are many observed static electric dipole moments. These usually result from the accidental degeneracy of coulomb wave functions with different orbital angular momenta.

One of the best evidences for the conservation of parity and invariance under time reversal in electromagnetic interactions is the lack of an electric dipole moment in the neutron.

A plane wave of definite linear momentum can be decomposed into a sum of degenerate, even and odd, angular momentum states and is not an eigenstate of parity. Localized wave packets can be obtained by superimposing many plane waves. Any macroscopic classical body, so described, will be degenerate in states of opposite parities and thus can have such properties as electric dipole moments.

In 1956 T. D. Lee and C. N. Yang, after a careful examination of experimental evidence, concluded that there is abundant evidence for parity conservation in strong and electromagnetic interactions, but could not find any evidence for conservation in weak interactions, including nuclear beta decay. They suggested several experiments to test parity conservation in weak interactions.

An experiment performed by C. S. Wu, E. Ambler, R. W. Hayward, D. D. Hoppes, and R. P. Hudson in 1956 at the National Bureau of Standards and published in 1957 demonstrated that parity conservation was violated in nuclear beta decay. The experiment measured the angular distribution of beta and gamma radiation from radioactive ^{60}Co nuclei that had been cryogenically oriented. The angular distribution for the beta radiation obeyed a relation

$$W(\vartheta) = 1 + a\,\frac{\langle \mathbf{j} \rangle}{|\mathbf{j}|} \cdot \frac{\mathbf{p}}{|\mathbf{p}|}$$

where **j** is the nuclear spin and **p** the momentum of the beta particle. The angular distribution of the gamma radiation is a known function that depends only on even powers of **j** · **k**, where **k** is the momentum of the photon, and on numerical factors depending on the spin of the nuclear states involved in the gamma transition.

A measurement of the gamma ray anisotropy, in turn, determines the amount of nuclear polarization $\langle \mathbf{j} \rangle / |\mathbf{j}|$. Inspection of Table 2 indicates that momenta change sign under the parity operation while the spins do not. Neither the momenta nor spins change sign under the charge conjugation operation. The beta ray angular distribution will change under the operations *P* or *CP* but not *C*, while the gamma ray angular distribution is unaltered under *C*, *P*, or *CP*. The measured beta ray angular distribution from ^{60}Co gave a value for the coefficient $a = -v/c$, apart from some small coulomb corrections. A subsequent experiment measuring the angular distribution of positrons from polarized ^{58}Co gave similar results but with the opposite sign for the coefficient *a*. The nonzero value for the coefficient *a* indicates that space inversion invariance is violated. The opposite signs for the coefficient *a*, depending on whether electrons or positrons are emitted, indicate that charge conjugation invariance is violated. An analysis shows that both the *P* and *C* violations are maximal but that the product *CP* is conserved.

In the beta-decay process within the nucleus we have a neutron making a transition to a proton with the emission of an electron and an antineutrino. The inverse process has a proton making a transition to a neutron, emitting a positron and a neutrino. One of the most satisfactory explanations of the violation of *C* and *P* in the beta-decay process can be ascribed to the properties of the neutrino. Rather than being a particle which can be described by the Dirac equation with a four-component wave function, its zero mass permits a modification of the Dirac equation to one that has a two-component wave function. This two-component description, although invariant under proper Lorentz transformations, is not invariant under *C* or *P*.

Experiment shows that the antineutrino emitted in beta decay is right-handed, i.e., its intrinsic spin is parallel to its momentum. Noninvariance under *P* implies that there is no left-handed antineutrino, while noninvariance under *C* implies that there is no right-handed neutrino. Invariance under *CP* implies the existence of a left-handed neutrino as well as the right-handed antineutrino. The symmetry of right- and left-handedness in matter is broken and replaced by a symmetry where matter has a characteristic handedness and antimatter the opposite handedness.

A left-handed, massless neutrino appears as a left-handed neutrino in all Lorentz frames which can be continuously transformed into one another. The postulate of space inversion symmetry allows us to infer the existence of a right-handed massless neutrino; however, there is no reflection symmetry, so the existence of both right- and left-handed neutrinos in nature would be coincidental. Only if the neutrino had mass could the existence of both helicity states follow from the existence of a single state and from the properties of proper Lorentz transformations.

At present, three charged leptons are known with nonzero mass: the electron, the μ lepton, and the τ lepton, each having associated with it a left-handed neutrino, ν_e, ν_μ, and ν_τ, respectively. The ν_τ has not been observed directly but may be conjectured from the dynamical properties of the weak interaction.

In all the weak-interaction phenomena, which includes all decays of the elementary particles, except the electromagnetic decays $\pi^0 \rightarrow 2\gamma$ and $\Sigma^0 \rightarrow \Lambda + \gamma$ that were experimentally investigated prior to 1964, the violation of *P* and *C* invariance and conservation of *CP* and *T* invariance was fully established. In 1964, experiments at the Brookhaven National Laboratory showed that the K^0 meson, which should decay only into three π-mesons according to *CP* invariance, decayed a small fraction of the time into two π-mesons, a process violating *CP* invariance. Vigorous experimental research since that time has fully confirmed this *CP* violation result, but no other process has been observed where *CP* is violated. There have been many theoretical attempts to account for this small *CP* violation, but no fully satisfactory explanation has emerged. However the small amount of *CP* violating interaction in the decay of the *K* mesons may account for the present preponderance of particles over antiparticles, assuming that both were created in equal amounts initially after the big bang occurring at the origin of the universe.

Whether or not there is invariance under the operations *C*, *P*, *T*, or *CP* individually, any local field theory must be invariant under the product *CPT*. This invariance is known as the *CPT theorem*. The combined operation is equivalent to the product of space inversion and time inversion and is often referred to as *strong reflection*. This transformation in which $x_\mu{}' = -x_\mu$, although discontinuous, is characterized by $\det(a_{\mu\nu}) = 1$, and an equivalent transformation can be achieved by a proper Lorentz transformation, i.e., continuous rotations in space-time. At present only the *CPT* invariance remains unbroken experimentally.

PERIODIC LAW AND PERIODIC TABLE

When the chemical elements are compared in order of increasing atomic number, many of their physical and chemical properties are observed to vary periodically rather than randomly or steadily. This relationship, recognized empirically a century ago by de Chancourtois in France, Newlands in England, Lothar Meyer in Germany, and Mendeleev in Russia, is now known to be the logical and inevitable consequence of the fundamental periodicity of atomic structure. The familiar statment of the periodic law is this: "The properties of the chemical elements vary periodically with their atomic number." A more informative statement of this same law is: *The atomic structures of the chemical elements vary periodically with their atomic number; all physical and chemical properties that depend on atomic structure therefore tend also to vary periodically with atomic number.*

The periodicity of atomic structure (see ATOMIC PHYSICS) is described by quantum theory as developed through modern wave mechanics. Each successive electron, beginning with the first, that comes within the field of an atomic nucleus, occupies the most stable position available to it. The number of possible positions is limited by quantum restrictions which describe each position in terms of four quantum numbers, and by the Pauli exclusion principle that no two electrons within the same atom may have the same four quantum numbers. These electron positions, or energy levels, are grouped with respect to their average distance from the nucleus as "principal quantum levels or shells," designated by the "principal quantum number" $n = 1, 2, 3, 4, \cdots$, successive integral values increasing in order of increasing average distance from the nucleus. The total capacity of each shell can be expressed as $2n^2$, being 2 for $n = 1$, 8 for $n = 2$, 18 for $n = 3$, and 32 for $n = 4$; no higher level actually contains more than 32 electrons.

These total capacities can easily be accounted for by the several quantum number restrictions and the Pauli principle. Within each principal energy level are differently shaped regions called "orbitals," that can be occupied by electrons. The shape of each orbital is designated by the "orbital quantum number" l, which may only have integral values from 0 up to $n - 1$. The number of orbitals of each shape that can exist within a principal quantum level depends on the fact that an electron in an orbital is a charge in motion and therefore has magnetic properties which influence the orientation of the orbital in an external magnetic field. The possible orientations are designated by the "orbital magnetic quantum number" m_l, which may have values from 0 to plus or minus the orbital quantum number l. Thus when $n = 1$, l can only have the value 0, which means that only one orbital is possible, having orbital magnetic quantum number 0. When $n = 2$, l can have the values 0 and 1. For the value 0, one orbital is possible, but when $l = 1$, m_l can have values 0, +1, and −1, corresponding to three orbitals. Four orbitals are therefore possible in the principal quantum level $n = 2$. When $n = 3$, the same kinds of four orbitals are possible, and in addition, l can equal 2. This gives five possible values, for m_l: 0, +1, +2, −1, and −2, corresponding to five more orbitals for a total of 9. When $n = 4$, the same kinds of 9 orbitals are possible, and in addition l can equal 3. This gives seven possible values for m_l: 0, +1, +2, +3, −1, −2, and −3, corresponding to 7 more orbitals for a total of 16. No principal quantum level uses more than 16 orbitals even though more are theoretically possible when $n = 5$ or more.

One additional property of an electron in an atom needs to be considered. This is its property as a magnet, irrespective of its orbital motion. This is designated by the "spin magnetic quantum number," which can have only the values $+\frac{1}{2}$ and $-\frac{1}{2}$. Since each orbital is uniquely specified by the first three quantum numbers, n, l, and m_l, the capacity of each orbital is thus limited to 2 electrons, and these only if, according to the Pauli principle, they are of opposed spins (differ in the fourth quantum number). The total capacity of each principal quantum level is therefore twice the number of orbitals within it, because this represents the total number of permissible combinations of four quantum numbers within that level. For example, the capacity of the $n = 4$ level is limited to 32 electrons by the fact that only 32 different combinations of the four quantum numbers are possible within that level; these electrons will occupy 16 orbitals.

The differently shaped orbitals having orbital quantum numbers $l = 0$, 1, 2, and 3 are commonly called *s*, *p*, *d*, and *f* orbitals. From the above discussion, it should be clear that within any principal quantum shell, there can be only one *s* orbital, three *p* orbitals, five *d* orbitals, and seven *f* orbitals. The *p* orbitals do not appear until $n = 2$, the *d* until $n = 3$, and the *f* until $n = 4$. Within any given principal quantum shell, the order of decreasing stability, and therefore the order of filling with electrons, is always *s-p-d-f*.

The periodicity of atomic structure arises from the recurrent filling of new outermost principal quantum levels, but it is complicated by the fact that, although the principal quantum levels represent very roughly the general order of magnitude of energy, there is considerable overlapping. This overlapping is such that the outermost shell of an isolated atom can never contain more than 8 electrons. In the building up of successively higher atomic numbers, electrons always find more stable positions, once a set of *p* orbitals in a given principal quantum level is filled, in the *s* orbital of the *next higher* principal quantum level rather than the *d* orbitals of the same principal quantum level. When this *s* orbital is filled, electrons then go into the underlying *d* orbitals until these are filled, before continuing to fill the outermost shell by entering its *p* orbitals. The building-up of the atoms of successive atomic numbers may be represented by the following sequence: 1*s*, 2*s*, 2*p*, 3*s*, 3*p*, 4*s*, 3*d*, 4*p*, 5*s*, 4*d*, 5*p*, 6*s*, 5*d*, 4*f*, 6*p*, 7*s*, 6*d*, 5*f*. *The periodicity of atomic structure thus consists of the recurrent filling of the outermost shell with from one to 8 electrons that corresponds to the steady increase in nuclear charge.*

A *period* is considered to begin with the first electron in a new principal quantum shell and to end with the completion of the octet in this outermost shell, except, of course, for the very first period, in which the outermost shell is filled to capacity with only two electrons. From the order of orbital filling given above, it should be apparent that periods so defined cannot be alike in length. The first period, consisting of hydrogen and helium, has only two elements. The second period, beginning with lithium (3) and ending with neon (10), contains 8 elements, as does the third period, which begins with sodium (11) and ends with argon (18). The fourth period begins with potassium (19), but following calcium (20), the filling of the outermost (fourth) shell octet is interrupted by the filling of the *d* orbitals in the *third* shell. Thus 10 more elements enter this period before filling of the outermost shell is resumed, making the total number of elements in this period 18. In the fifth period, the first two outermost electrons are added in rubidium (37) and strontium (38), but then this outer shell filling is interrupted by the filling of penultimate shell *d* orbitals, which again adds 10 elements before filling of the outermost shell is resumed; this period also contains 18 elements. The sixth period begins as before with two electrons in the outermost shell, but then there is an interruption at lanthanum (57) to begin filling the 5*d* orbitals. Here, however, occurs an additional interruption, in which 14 elements are formed through filling of the 4*f* orbitals, before the remaining 5*d* orbitals can be filled, and in turn before the outermost shell receives any more electrons. Consequently here it takes 32 elements to bring the outermost shell to 8 electrons and thus end the period. The seventh period is similar but incomplete. In principle it would end with element 118, but artificial element 105 is the highest in atomic number known at the time of writing.

These elements which represent interruptions in the filling of the outermost *s* and *p* orbital octet are called "transitional elements" (where *d* orbitals are being filled), and "inner transitional elements" (where *f* orbitals are being filled). This is to distinguish them from the other, "major group," elements in which underlying *d* or *f* orbitals are either completely empty or completely filled.

Physical properties of the elements that depend only on the electronic structure of the individual atom, such as the ionization potential and atomic, radius, vary periodically with atomic number simply because of the recurrent filling of the outermost shell. Increasing the atomic number by increasing the nuclear charge while adding to the outermost shell of electrons maintains the electroneutrality of the atom but has a highly significant effect on that part of the nuclear charge which can be sensed by outermost electrons. Underlying electrons are quite effective at shielding the nucleus, but in the outermost shell, each additional electron is evidently too involved in avoiding the others for them to be very effective in shielding one another from the additional nuclear charge. In fact each additional electron is successful in blocking off only about one-third of the positive charge that is simultaneously added. Therefore, with each unit increase in atomic number, when electrons are being added to the outermost shell to form the major group elements, the *effective nuclear charge*—that part of the total nuclear charge that is sensed by an electron in the outermost shell—increases by about two-thirds. This causes the electronic cloud to be drawn closer to the nucleus, diminishing the atomic radius and holding the electrons more tightly, as generally indicated by increasing ionization energy. The combined effect of increased effective nuclear charge and shorter radius increases the attraction between nucleus and outermost electron, defined as the *electronegativity*. Thus from left to right across the major groups, within each period, the radius decreases and the electronegativity increases.

Similar but smaller effects are observable for the addition of *d* or *f* electrons to underlying shells, in the transitional and inner transitional series.

The bonding properties of elements also depend on the electronic structure of the individual atom and therefore likewise vary periodically. For example, each period (except the first) begins with an alkali metal, lithium (3), sodium (11), potassium (19), rubidium (37), cesium (55), and francium (87), all of which show similar metallic bonding, crystallizing in a body-centered cubic lattice. Each has but one outermost electron per atom and can therefore form but one covalent bond. Each is very low in electronegativity and thus tends to become highly positive when bonded to another element. Crossing each period the elements become less metallic, higher in electronegativity, and able to form a greater number of bonds until limited by the number of outer shell vacancies rather than the number of electrons. The halogens, fluorine (9), chlorine (17), bromine (35), iodine (53), and astatine (85), each of which is next to the end of its period, are all nonmetals, highest of their respective periods

in electronegativity and thus tending to become highly negative when bonded to other elements. Having seven outermost electrons, each has but one vacancy, permitting but one covalent bond.

Physical properties of the elements that are of greatest interest are usually properties that depend indirectly on the atomic structure but directly on the nature of the aggregate of atoms which results from the atomic structure. Such properties are melting point, density, and volatility. They may tend to vary periodically, but the periodicity is not necessarily consistent or even evident, because of abrupt differences in the type of poly-atomic aggregate. For example, the identical atoms of carbon may form graphite or diamond, depending on the kind of bonding, with entirely different properties resulting. Nitrogen follows carbon in atomic number, but because it forms N_2 molecules instead of giant three-dimensional structures like diamond or graphite, it is a gas with physical properties strikingly different from those of either form of carbon.

Among the most useful applications of the periodic law is to an understanding of the differences among compounds, whose properties also vary in a periodic manner. For example, oxides of elements at the beginnings of periods tend to be very stable, high-melting, nonvolatile solids of strongly basic character and practically no oxidizing power. Oxide properties change progressively across each period until toward the end the oxides tend to be unstable, low-melting, volatile compounds, acidic in nature and of high oxidizing power. Such periodicity is recognizable throughout a very large part of chemistry.

In order to erect a framework upon which the myriad facts that accord with the Periodic Law can be organized, the chemical elements can be arranged in an orderly manner called a "periodic table." Any such arrangement[1] can be satisfactory if it organizes the elements in some order of increasing atomic number, showing the separate periods and at the same time grouping elements of greatest similarity together.

In Fig. 1 is shown a modern version of the periodic table[2], together with the "long form." Figure 2 shows the "long form" as currently most widely used. From left to right across the table are the "periods," representing the elements in order of successively increasing atomic number and therefore progressive change in atomic strucutre. Across the period, the properties of the elements and their compounds tend to change from one extreme to the opposite. From top to bottom the periods are placed so that the most similar elements are grouped together. A distinction (shown by a physical separation) is made between "major groups" and

"transitional groups" because of the bonding dissimilarities originating in the availability in the transitional elements of underlying *d* orbitals that are not available in the major group elements. In older tables, major groups are usually, although inconsistently, designated as "A" and transitional groups as "B." At this time of writing (early 1982) a number of the world's chemical societies, in long overdue recognition of these inconsistencies, are seeking a generally acceptable alternative. In Fig. 1, the designations are consistently "M" (major) and "T" (transitional). But whether in the major group or the transitional group, the elements are arranged vertically on the basis of similarity in electronic configuration, which is then reflected in similarities in the physical and chemical properties of the elements and their compounds.

No amount of organization or correlation will ever alter the fact that each chemical element is an individual and unique, nor will the properties of any element be changed one iota by placing that element in any special position in a periodic table. Nevertheless, there is enough consistency to the structure and behavior of atoms to make any reasonable form of the periodic table an extremely useful framework upon which to organize and correlate an enormous quantity of chemical information[3]. The periodic law is truly one of the great generalizations of science.

PHASE RULE

The phase rule is a general equation $F = n - r - 2$, stating the conditions of thermodynamic equilibrium in a system of chemical reactants. The number of degrees of freedom or variance (F) allowed in a given heterogeneous system may be examined by analysis or observation and plotted on a graph by proper choice of the components (n), the phases (r), and the independently variable factors of temperature and pressure.

Josiah Willard Gibbs propounded the rule about 1877, and H. W. B. Roozeboom about 1890 began pioneering in specific cases. This rule has been an important instrument in the study of stability and metastability in geology, physics, metallurgy, ceramics, mineralogy, and engineering (e.g., in the exploitation of the salt deposits at Stassfurt, Germany, and Searles Lake, California, in the development of alloys, solid-state devices, and large crystals). Its use in the sophistication of techniques continues to expand; as an example, the calculation of reactions from basic structural data by computer techniques.

A phase is a homogeneous, physically distinct and mechanically separable portion of a system. H_2O has the three phases: water, vapor and ice. Each crystal form present is a phase. The relative amounts of each phase do not affect the EQUILIBRIUM.

The one-component system, water-vapor-solid, is unary. The components of a system are the smallest number of independently variable constituents by means of which the composition of each phase taking part in the equilibrium can be expressed in the form of a chemical equation.

With the components fixed in a system, variance—the degrees of freedom (F)—depends on the number of phases present. If water vapor alone is present, the system is bivariant since both temperature and pressure can vary within limits without affecting the number of phases; but if a second phase, liquid water, is present, the system is univariant and if either the temperature or pressure of the system in equilibrium is set, the other is automatically fixed as long as a second phase is present. A third phase, ice, makes the system invariant (the triple point), and any change in temperature or pressure, if maintained, results in the disappearance of one phase. Addition of another component forms a binary system, one degree of freedom is added, and the system is univariant until a fourth phase appears and the system becomes invariant (the quadruple point).

Schematic phase equilibrium diagrams outline experimental observations of physical and chemical changes in the system as the conditions of temperature, pressure and composition are varied. For unary systems, the diagram has two dimensions, for binary systems, three, and for ternary systems, four, etc. Binary systems are easily plotted with pressure or temperature constant, while ternary systems may be treated similarly as condensed systems with both constant if the vapor pressure is less than atmospheric. This added restriction reduces the variance by one, and at constant temperature, composition relationships may be plotted on a triangular diagram. Quarternary or quinary systems and ternary systems above atmospheric pressure may be treated by projections of surfaces of thermodynamic stability, but more complex systems require a mathematical approach.

The simple one-component system, water, plotted with rectangular coordinates, i.e., pressure and temperature, shows a variety of concepts which may be extended to more complex systems (see Fig. 1 in STATES OF MATTER). Each area in the diagram is a bivariant, one-phase state. Each curve separating the areas is a univariant, two-phase state showing the conditions under which a transition of the phase occurs. These are also called "indifferent phase reactions," where the amount of the phases may vary and are contrasted with "invariant equilibrium," where the degree of freedom is zero. The fusion curve for the equilibria between the solid phase and the liquid phase, the sublimation curve for solid and vapor, and the vaporization curve for liquid and vapor meet at the triple point. The three distinct phases differ in all properties except chemical potential. The end of the vaporization curve is a singular point, the critical point where liquid and vapor become identical, a restriction which reduces the variance by one so that F becomes zero.

In a binary (or higher) system, a liquidus is a curve representing the composition of the equilibrium liquid phase and a solidus represents the composition of the solid phase. The conjugate vapor phase is represented by a vaporous with tie-lines or conodes to the liquidus or solidus points in equilibrium. A minimum point for the existence of a liquid is the eutectic, sometimes (in an aqueous system) called the cryohydric point. In a ternary system the eutectics of three binary systems initiate curves leading to a ternary eutectic. If two liquids form a miscibility gap in the system, multiple quadruple points are possible. At a peritectic, a phase transition occurs at other than a minimum, i.e., one solid melts to another solid and a liquid. The solid may be a compound or a solid solution (mixed crystals) in which the composition of the solid varies with relative proportion of components and is shown by the solidus. A congruent melting point is a maximum in its curve, i.e., the solid melts to a liquid of the same composition. Where two phases become identical in composition, an indifferent or critical point exists. Where two conjugate phases become identical, the point may also be called a consolute point.

PHONONS

Phonons are quanta of vibrational energy, and are in many ways analogous to photons, which are the quanta of light energy. The vibrations of a solid can be considered as the sum of oscillations of many traveling waves of different frequencies. Quantum theory restricts the energy of a wave of frequency ω to the possible values

$$E_n = n\hbar\omega \qquad (1)$$

where $\hbar$ is Planck's constant (6.65×10^{-27} erg · sec) divided by 2π, and n is a positive integer or zero. The total energy E_n of the wave may be considered to be the sum of the energies of n phonons, each of energy $\hbar\omega$.

A solid contains phonons having a wide distribution of frequencies. For each phonon the frequency depends on the wavevector **q**. In a crystalline solid with spacing a between the molecules, the shortest wavelength that phonons may have is $2a$, and hence the maximum wavenumber is π/a ($\sim 10^8$ cm^{-1}). In a typical case the relation between frequency and wavenumber (phonon dispersion relation) is as shown in Fig. 1. For each value of **q** there are $3r$ phonons, where r is the number of atoms per unit cell. These different phonons may be labelled by a *polarization index* j which runs from 1 to $3r$, and it is usual to indicate this by writing the phonon frequency as $\omega_{\mathbf{q}j}$. Figure 1 therefore represents the case $r = 2$.

For three of the polarizations (i.e. for three values of j) the frequency varies approximately linearly with wavenumber for small enough q. These are called *acoustic phonons* (A) because the motion of the atoms which occurs when these phonons are present is the same as is caused by an acoustic wave. Thus, neighboring atoms oscillate approximately in phase with each other. The remaining phonons are called *optical phonons* (O). For these phonons the atoms within each unit cell vibrate in different

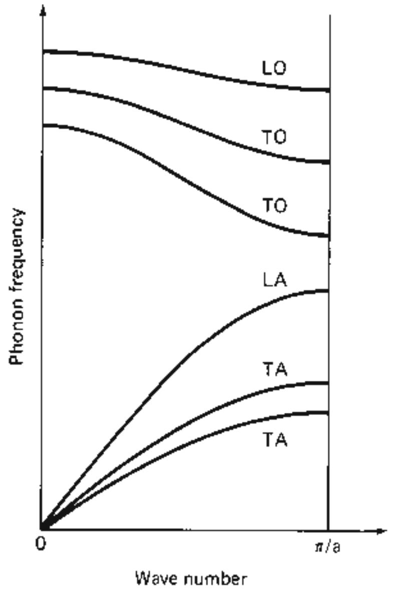

FIG. 1.

directions, and the center of mass of each cell remains approximately stationary. In ionically bonded crystals each atom has an electrical charge (positive or negative). The optical phonons in these crystals cause the atoms to move relative to each other, thereby producing strong oscillating electric fields inside the crystals. For this reason there is a large coupling of these phonons to light waves, and this is the origin of the name *optical phonon*. Note that in a crystal with only one atom per unit cell there are only acoustic phonons.

The different types of phonons may be further classified into longitudinal (L) and transverse (T). For longitudinal phonons the atoms vibrate in the same direction that the phonon is travelling, whereas for the transverse phonons the vibration is perpendicular to the direction of propagation.

For any crystal there is maximum frequency ω_m that the phonons may have, and this is usually between 10^{13} and 10^{14} sec^{-1}. Information about phonon frequencies has been obtained by many different experimental techniques. The most detailed measurements have been made using the technique of inelastic neutron scattering. A neutron of known energy E_0 and momentum $\mathbf{p}_0$ enters the crystal. This neutron may create a phonon in the crystal and emerge from the crystal with a different energy E_1 and momentum $\mathbf{p}_1$. From conservation of energy it is known that

$$E_0 = \hbar\omega_{\mathbf{q}j} + E_1 \tag{2}$$

where $\omega_{\mathbf{q}j}$ is the frequency of the phonon produced. Thus, if E_1 and E_0 are both known the phonon frequency can be determined. The wavevector of the phonon can be found from the equation

$$\mathbf{p}_0 = h\mathbf{q} + \mathbf{p}_1 \tag{3}$$

which represents the condition of conservation of momentum, $h\mathbf{q}$ being the momentum of the phonon. By this means the phonon spectra of most of the common crystals have been determined.

Other techniques can be used to study the phonon dispersion relation, but these usually give less complete information. Measurements of the velocity of sound give results for acoustic phonons of small q. The frequency of optical phonons with $q = 0$, and some phonon frequencies at the zone boundary ($q = \pi/a$) can be found by light scattering or absorption experiments. Measurement of the temperature dependence of the specific heat can be used to estimate the maximum phonon frequency.

Phonons and Interatomic Forces If the forces which act between the atoms in a crystal are known, it is possible to calculate theoretically the phonon spectrum. It is therefore also possible to use measurements of the phonon spectrum to study the strength and "character" of the interatomic forces. The strength of the forces is related, roughly speaking, to the average phonon frequency. By "character" one means the range of distance over which the interatomic forces act, whether or not they are simple central forces dependent only on the atomic separation, etc. To study these features requires a more detailed analysis of the experimental results for the phonon spectra. This analysis has been carried out for many crystals, and much interesting and useful information has been obtained.

Specific Heat At a temperature T the average number $\langle n_{\mathbf{q}j}\rangle$ of phonons of a particular type with wave vector $\mathbf{q}$ and polarization index j is given by the Bose-Einstein law

$$\langle n_{\mathbf{q}j}\rangle = [\exp(\hbar\omega_{\mathbf{q}j}/kT) - 1]^{-1} \tag{4}$$

where k is Boltzmann's constant (1.38×10^{-16} erg K^{-1}). Thus, the number of phonons increases with increasing temperature. Note also that because of the exponential factor in (4) most of the phonons which exist at temperature T have frequency less than or comparable to kT/h. The total energy of the phonons is

$$E_{\text{ph}} = \sum_{\mathbf{q}j} \langle n_{\mathbf{q}j}\rangle \hbar\omega_{\mathbf{q}j} \tag{5}$$

where the sum is over all possible values of $\mathbf{q}$ and j. The phonon contribution to the specific heat is thus

$$C_{\text{ph}} = \frac{dE_{\text{ph}}}{dT}. \tag{6}$$

An approximate calculation of C_{ph} was made by Debye with result

$$C_{\text{ph}} = 9Nk(T/\theta_{\text{D}})^3 \int_0^{\theta_{\text{D}}/T} \frac{x^4 e^x \, dx}{(e^x - 1)^2} \quad (7)$$

where N is the number of atoms per unit volume, and θ_{D} is a certain characteristic temperature called the *Debye temperature*. This temperature varies from crystal to crystal, and the value of θ_{D} is very roughly equal to $\hbar\omega_{\max}/k$, where $\omega_{\max}$ is the maximum phonon frequency. For $T \ll \theta_{\text{D}}$, C_{ph} is proportional to T^3, and for $T > \theta_{\text{D}}$, C_{ph} has a constant value.

Thermal Conduction When one part of a solid is hotter than another it contains more phonons. These excess phonons gradually spread out from the hot region and eventually the distribution of phonons throughout the solid become uniform. Macroscopically, this is described by saying that there is a flow of heat from the hot region to the cold. One can show that the thermal conductivity arising from the flow of the phonons is given approximately by

$$k = \tfrac{1}{3} C_{\text{ph}} v_{\text{ph}} l_{\text{ph}}, \quad (8)$$

where v_{ph} is the average velocity of a phonon, which is of the same order of magnitude as the sound velocity; and l_{ph} is the distance a phonon travels in a straight line before it is scattered. Phonons may be scattered by other phonons, by electrons, by defects of impurity atoms, and by the walls of the solid. The measurement of the thermal conductivity provides rough information about the strength of these scattering processes and how they depend on temperature.

Phonon Interactions The scattering processes that phonons undergo have been studied in great detail in the last few years. It is now possible to produce artificially phonons of a definite frequency and to study their interactions with other phonons, with electrons, defects, etc. One method for the generation of phonons which has proven particularly important uses superconducting tunnel junctions. These devices can also be employed as tunable detectors of phonons. However, the development of other devices for the generation and detection of phonons remains a very active field of research.

PHOTOCHEMISTRY

Photochemistry is that branch of chemistry which deals with the permanent, chemical effects of the interaction of electromagnetic radiation and matter, as distinct from the usually temporary physical effects. Upon absorption of a quantum of radiant energy a molecule is raised to an excited state, stable or unstable, in which, depending upon the particular wavelength absorbed, the energy may be retained in rotational, vibrational, and electronic degrees of freedom. Photoionization following the absorption of x- or γ-rays is usually referred to as *radiation chemistry*. Excitation by longer wavelengths, the infrared, at the intensities available from standard sources leads only to an increase in the population of the higher vibration-rotation levels of the ground electronic state; since no chemical effects are produced, such excitation is of little interest to the photochemist. Thus until recently there has existed, near 700 nm, a theoretical upper limit to the wavelength region of interest. The lower limit of this region, which theoretically extends to the wavelengths of soft x-rays, is defined in practice by the availability of materials transparent to the far ultraviolet—~160 nm for synthetic fused silica and ~120 nm for lithium fluoride.

A molecule in an upper electronic state may undergo one of several processes. (1) Almost immediately, or after losing or gaining a number of vibrational quanta by collision, it may return to the ground electronic state with emission of light (fluorescence). (2) A major portion of the energy may be transferred to rotational, vibrational and translational degrees of freedom (rarely to electronic levels in molecular energy transfer) of the neighboring molecules or to the walls in collisions of the second kind (thermal degradation or collisional deactivation). (3) It may, within a period of one-half a vibration ($\sim 10^{-13}$ sec) dissociate into mono- or polyatomic fragments, each of which may retain part of the excitation energy in any of its degrees of freedom (dissociation). (4) After a period of several vibrations in a vibrational level below the dissociation limit of the upper electronic state, but before a single rotational period ($\sim 10^{-11}$ to 10^{-12} sec.), it may, with no change in total energy, undergo a radiationless transition to a vibrational level in a second upper electronic stage; if the second vibrational level is above the dissociation limit of the second state, dissociation will occur after one-half a vibration. The transition probability may be sometimes enhanced by collisions (predissociation and induced predissociation). If the transfer occurs to bound vibrational levels of the second excited electronic state, the molecule in this excited state may undergo all the processes cited for the excited state formed directly by absorption. Often this second electronically excited state is of a different multiplicity than either the ground state or the initially formed state, and the process is termed *intersystem crossing*. The emission from this second state (if it occurs) is termed *phosphorescence* and usually exhibits a much longer lifetime than the fluorescence described in (1). (5) It may be transferred to an upper state of an isomeric molecule, which is then usually stablized by (2). This is called *rearrangement*. (6) It may react directly with other normal or excited molecules utilizing the excitation energy to overcome all or part of the activation energy barrier.

One or more of these processes must occur in any assembly of molecules absorbing light energy in the gaseous or liquid state, but not all need occur concurrently. The interpretation of the absorption spectrum of diatomic molecules and, to an increasingly greater extent, of polyatomic molecules may, in some cases, give definite information regarding (3) and (4). Advances in spectroscopy have been reflected in photochemistry; indeed, until the advent of quantum theory no satisfactory explanation of photochemical phenomena existed.

The advent of lasers, most commonly pulsed, which provide highly monochromatic beams of great intesity in many regions of the spectrum, has stimulated interest in photochemical isotope enrichment. It often is possible to stimulate reaction almost exclusively of those molecules which contain a rare isotope, thus leading to products highly enriched in that isotope, or conversely to cause almost exclusive reaction of those molecules containing an abundant isotope so that the rare isotope is enriched in the unreacted starting material. The very high radiation field provided by lasers, especially the CO_2 laser in the infrared, may cause a single molecule to absorb many photons (10–30 is not uncommon) in a single pulse. Such excitation leads to the phenomenon of *multiphoton decomposition* from the ground electronic state and whole new areas of non-steady-state kinetics have become available for study.

One of the major interests in photochemistry has been the production of free radicals by processes (3) and (4) and the study of their reactions. Studies of the photolyses of various aldehydes, ketones, alkyl halides, azocompounds, and organometallic compounds have been most fruitful in this respect. Intermittent illumination may be used to determine the lifetimes of the radicals in reactions in which the radical concentration is proportional to the absorbed intensity raised to a power n $(0.5 \leqslant n < 1.0)$; this leads to the evaluation of rate constants for radical association reactions. A special case of (2) has also led to useful results. Metal vapors (Hg, Cd, or Zn) are raised to the excited $^3P_1$ and $^1P_1$ states upon absorption of resonance radiation from lamps containing these metals. Resonance fluorescence is efficiently quenched by the vapors of a large variety of compounds usually resulting in the production of atoms, radicals and metal atoms in the ground state. Such photosensitized methods are not confined solely to atomic vapors, but photosensitization by polyatomic molecules through collisions of the second kind has not been well developed.

The initial act of absorption and the various reactions of the excited state are usually referred to together as the primary process. The *primary quantum yield* ϕ, i.e., the number of molecules changed per quantum absorbed, is given by the rate of processes (3) to (6) divided by the rate of absorption of light; in the absence of fluorescence and deactivation, $\phi = 1$. This is merely a statement of the *Stark-Einstein law of photochemical equivalence*, known as the first law of photochemistry. The concept of the quantum yield may be extended to include secondary processes [e.g., the reverse of (3)]. Overall quantum yields are measurable directly; ϕ must be inferred from kinetic studies of the secondary processes. Thus, any photochemical investigation is immediately separable into a chemical and an optical problem.

That fraction of the incident light which is absorbed by the reactant is readily measured by standard photometric procedures. The measurement of the absolute intensity is usually more difficult; all such determinations are based ultimately upon thermopile measurements of radiant energy, although a photocell may be calibrated as a more convenient secondary standard. To obviate the use of a thermopile or photocell, chemical actinometers have been used; these are photochemical reactions whose quantum yields have been established accurately as a function of wavelength, etc. Hence the measurement of absolute intensity reduces to the determination of the amount of chemical change. Since the response of all actinometric reactions and photocells is sensitive to wavelength, monochromatic radiation is desirable for this reason as well as for the theoretical interest of the effect of various wavelengths on the photochemical reaction. This is obtained by removing the unwanted lines from sources of discontinuous spectra by means of monochromators or gaseous, liquid, and glass filters; unfortunately, the intensity of the wavelength of interest is usually reduced by this procedure.

The last factor has a profound influence on the problem of determining the amount of chemical change. Under the most advantageous conditions with unfiltered light, the rate of production of product is rarely as large as 10^{-4}

mole/hr if the quantum yield is approximately unity; with filtered light and small fractional absorption, a few micromoles must be estimated. Inorganic compounds in solution can usually be handled in such quantities, and techniques of gas phase chromatography, infrared spectroscopy, and gas chromatography coupled with mass spectrometric detection now permit the qualitative and quantitative analysis of all but the most intractable of product mixtures. In certain instances (photopolymerizations, the photolysis of HCl, etc.) long reaction chains are set up with the quantum yield reaching 10^6 in the second example quoted. Measurements of physical properties (pressure of gases, density of solutions, etc.) then become practical and convenient methods of following the reaction.

PHOTOCONDUCTIVITY

Introduction Photoconductivity is the increase in electrical conductivity of nonmetallic solids produced by the motion of additional free electronic carriers created by absorbed electromagnetic radiation. Solids are characterized by the existence of bands of energy levels which electronic carriers may occupy and in which conduction takes place. The highest occupied band is called the *valence band* and the next empty (at absolute zero of temperature) band is called the *conduction band*. These conduction and valence bands are separated by an energy E_g in which, in the absence of any atomic defects or impurities, no available states exist for occupancy by photoexcited carriers from the filled valence band. As a result the spectral dependence of photoconductivity is characterized by the existence of an energy threshold E_g. Only for photon energies $h\nu > E_g$ is photoconductivity, associated with the simultaneous excitation of an electron into the conduction band and the creation of a hole in the valence band detectable. This intrinsic photoconductivity characterized by a sharp spectral threshold is one of the most direct experimental confirmations of the band theory of solids. In actual solids, of course, both defects and impurities exist and these create localized states or traps which lie within the energy gap. In particular in amorphous or noncrystalline solids the localized states exist in very high densities and are related to the disordered nature of these materials. In both crystalline and noncrystalline solids these *gap states* play a critical and usually dominant role in determining the recombination processes and rates and can also result in photoconductivity for photon energies $< E_g$, called *extrinsic photoconductivity*. Under constant illumination a new thermal equilbrium is reached such that a steady state photocurrent can be achieved. Under these conditions the rate of photogeneration is balanced by the various recombination processes by which the carriers tend to relax to their normal dark equilibrium distribution. Upon termination of the illumination the excess photoconductivity decays until the thermal equilibrium dark conductivity is recovered. The phenomenon of photoconductivity therefore involves absorption, photogeneration, recombination and electronic transport processes. For this reason photoconductivity has played and continues to play an important role in the development and understanding of the science of the solid state. Usually two general types of photocurrents can be observed depending on the role that the contact electrodes play and these will be discussed in turn.

Primary Photocurrents Figure 1 shows a schematic representation of a primary photocurrent produced by uniform volume photoexcitation. The dashed areas represent the electrodes by which electrical contact to the solid under study is made. The contacts are blocking, i.e., carriers may exit the sample but not enter. The primary photocurrent Δi is given by

$$\Delta i = \frac{\eta Fe(X_n + X_p)}{L} \tag{1}$$

where η is the photogeneration efficiency, F is the number of absorbed photons per second, and X_n, X_p are the distances that electrons and holes, respectively, move before becoming immobilized by being captured in a localized state or trap. These distances increase as the applied field increases, but since the maximum value of $X_n + X_p = L$ the photocurrent will eventually saturate. The photoconductive gain G is $\Delta i/Fe$, which is the photogeneration efficiency and which has a maximum value of unity. In practice this simplified view is complicated by the establishment of polarization fields due to the trapped charge. This polarization field opposes the externally applied field and characteristically the photocurrents decrease with

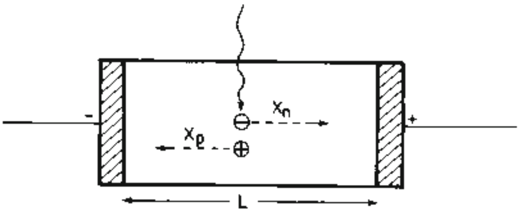

FIG. 1. Schematic representation of primary photocurrent. The electrodes are blocking so no carriers can enter the photoconductor.

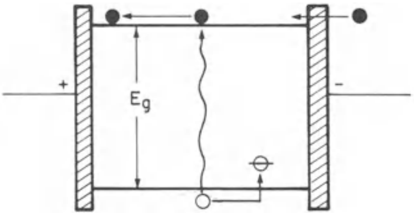

FIG. 2. Schematic representation of secondary photocurrents. Only the electrons are mobile and replenished at the electrode.

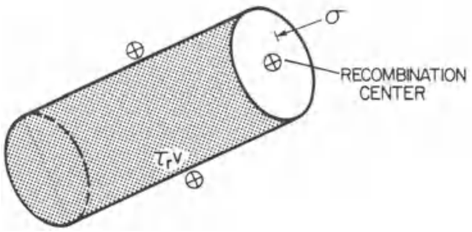

FIG. 3. Representation of recombination in a high-mobility photoconductor.

time. Thus, primary photocurrents are characterized by a photoconductive gain which has a maximum value of unity. Although this may seem hypothetical, under certain conditions the requirement of actually achieving the necessary blocking electrodes can be realized. A notable example is electrophotography, where corona charge is used to achieve a very good blocking electrode. In fact, because the electrophotographic process is such a good case of primary photocurrent, it is, where applicable, a direct and unambiguous way to study photogeneration efficiencies, since in the absence of trapping, Δi is directly controlled by η.

Secondary Photocurrents Figure 2 shows schematically an idealized photoconductor which nevertheless is a good approximation for many materials. One of the carriers, the electron, is mobile and is replenished at the electrodes. The hole created by light is considered to be immediately captured into a localized state and is effectively immobile. The photocurrent thus observed is exclusively due to the flow of electrons (the converse could of course be true). For this n-type photoconductivity the gain is given by

$$G = \frac{\tau_r \mu_n E}{L} \tag{2}$$

μ_n is the electron mobility and τ_r is the recombination lifetime of the electrons with the previously trapped holes. Since $L/\mu_n E$ is the time it takes an electron to transit the sample thickness L, the gain is clearly the number of transits, accompanied by replenishment at the contact, that can occur within the recombination lifetime. In some materials it has proved possible to increase τ_n by doping so as to produce gains $\sim 10^6$ and hence highly sensitive photodetectors.

Recombination A detailed discussion of recombination processes is impossible within a short space and in any event rapidly becomes very model specific. It is however possible to delineate the general concepts which are common to the most complex case. Figure 3 represents a simple physical picture which describes the general process of recombination. For conceptual ease it is assumed that a recombination center is already occupied by a hole and has a capture cross section σ for the capture of an electron. The electron is moving with an average thermal velocity $v \sim 10^7$ cm/sec (typically much greater than any drift velocity $\mu_n E$). In a time τ_r the electron will have moved a distance $\tau_r v$ will sweep out a volume $\tau_r v \sigma$. If a recombination center lies within this volume (this is clearly a function of the density of recombination centers N_r) then recombination is certain to occur. Therefore the condition for recombination is

$$1/N_r = \tau_r v \sigma \tag{3}$$

so that

$$\tau_r = 1/N_r v \sigma. \tag{4}$$

The dependence of photoconductivity on light intensity and temperature that can be observed is virtually unlimited. Thus, sublinear, and supralinear light intensities have been reported. With the right combination of intensity and temperature it is possible to go through these regimes with the same sample. Again a detailed attempt to explain these observations is very model dependent and a particular model may not be unique. Some general features can be understood however with reference to Eq. (1)–(4). Generally speaking, the photogeneration efficiency and carrier mobility are not intensity dependent so that any observed intensity dependence of the photoconductive gain is attributable to τ_r. In a material containing traps, if the light intensities are sufficiently low such that the occupancy of traps during illumination is substantially unchanged from that in the dark, τ_r will be independent of light intensity and the photocurrent Δi will be linear in intensity. If the intensity is increased such that the occupancy of traps changes substantially then previous trapping centers can be converted into new recombination centers. Therefore, in reference to equation (4) N_r effectively becomes intensity dependent. If the capture cross-sections of the new states are radically different, then highly non-linear photocurrents can be accounted for. Ultimately at a sufficiently high light intensity that the density of photoexcited free carriers exceeds the density of trapped carriers then bimolecular recombination will predominate and the photocurrent will vary as $F^{0.5}$.

From the preceding discussion it is clear that the phenomenon of photoconductivity is a particularly powerful tool for studying electronic transport properties and the nature and distribution of localized states in solids. This power stems from the ability to transiently produce a nonequilibrium excess of photogenerated carriers and observe their evolution and disappearance with time as they move, trap and then recombine. Indeed, in highly insulating materials such as amorphous materials, transient photoconductivity has emerged as the canonical technique, since more conventional methods such as electrical dark conductivity or Hall effect studies are either ambiguous in interpretation or impossible.

Field-Controlled Photogeneration It has so far been assumed that each photon absorbed for which $h\nu > E_g$ creates an electron-hole pair which instantaneously dissociates into a free electron and hole. For crystalline photoconductors this is a valid assumption. It has recently become clear that this is not a good assumption in low-mobility photoconductors, whether they be crystals such as anthracene or amorphous materials. Low mobility implies small mean free paths due to scattering of mobile carriers by potential fluctuations comparable to carrier energies. Thus excited electron-hole pairs may thermalize within a distance that is comparable to or less than the radius of their mutual coulomb well. In this case the carriers experience an attractive potential which results in the recombination of some of the pairs before they ever become free carriers. This *geminate recombination* (from Latin *gemini*, meaning twins), therefore, limits the photogeneration efficiency to less than unity. By application of an external electric field the amount of geminate recombination can be decreased since the field can aid the carriers in overcoming their mutual coulomb attraction. This leads to a field-dependent photogeneration process which is not seen in inorganic crystalline semiconductors such as silicon, cadmium sulfide, etc. Geminate field-controlled photogeneration is seen in amorphous selenium and in molecular crystalline solids such as anthracene. In the latter case, even with the periodicity of the aromatic molecular building blocks the very weak van der Waals binding forces lead to very narrow energy bands (a few kT) and therefore low electronic carrier mobilities.

In addition to straightforward photoconductivity a wide range of related photo-effects are potentially observable. In the absence of an applied field and for widely different diffusion constants for electrons and holes a voltage (Dember potential) can be developed [see Fig. 4(a)]. The sign of the voltage indicates which sign of carrier has the larger diffusion constant.

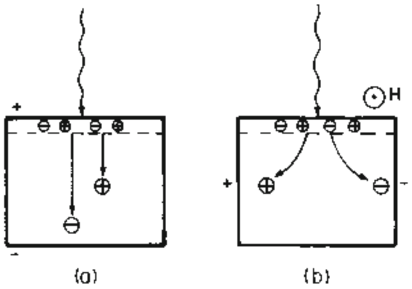

FIG. 4. Schematic representation of photovoltages developed due to diffusion of nonuniformly photogenerated carriers: (a) Dember effect, (b) in the presence of an applied magnetic field, the photomagnetoelectric (PME) effect.

Photomagnetoelectric effects are also potentially observable, Fig. 4(b). In materials with built-in internal fields due to Schottky barriers of *p-n* junctions, the photovoltaic effect may be produced. This is currently under intense investigation for the direct conversion of solar energy into electricity.

Photoconductivity has been observed to some degree or another in the majority of solids ranging from crystals to polymers and amorphous materials and from silicon crystals to polystyrene. Practical applications are both widespread and of enormous commercial value. These range from photodetectors and exposure meters to electrophotography and in total constitute a multibillion dollar industry.

PHOTOELASTICITY

When a transparent material is subject to a mechanical stress, optical properties are in general functions of the stress. In particular, the strain caused by the application of a stress may change the refractive index of the material. This property of transparent materials is called *photoelasticity*, and was first found by Brewster in 1816. Photoelasticity is now widely used as a useful, practical method to determine distributions of stresses or strains in materials.

The photoelastic effect can be explained in the following manner. When a stress T is applied to an elastic medium, the produced strain S is linearly related to T by Hooke's law: $S = sT$, where s is a proportionality constant called the *elastic compliance*. The change in the refractive index induced by the strain S is then expressed to good approximation by

$$n = n_0 - \tfrac{1}{2} p n_0{}^3 S, \qquad (1)$$

where n is the refractive index under the influence of the strain S; n_0 is the refractive index in the absence of the strain, i.e., when $S = 0$; and p is a material constant called the *photoelastic constant*, which describes the strength of the photoelasticity of a given material. If a transparent material is optically isotropic in the absence of stress, the material in general becomes optically anisotropic by the application of a uniaxial stress. This phenomenon is called *photoelastically induced birefringence* (or double refraction). The transmission of light in such anisotropic media has some unique features not present in isotropic materials.

Consider a transparent sheet of optically isotropic material of thickness t. Suppose that a uniaxial stress is uniformly applied so that the direction of the stress lies in the plane of the sheet. A plane-polarized light ray entering the sheet perpendicular to the sheet face is in general broken up into two components, called the *ordinary wave* and the *extraordinary wave*. These waves have polarization vectors at right angles to each other, corresponding to the principal stresses created by the uniaxial stress, and in general they have different velocities which are determined by Eq. (1). The ordinary wave has the polarization vector perpendicular to the direction of the uniaxial stress. The polarization vector of the extraordinary wave is parallel to the direction of the stress.

Since the two components propagate in the medium with different velocities, the phase difference δ will be produced between the two components upon emerging from the sheet. In principle, δ is proportional to the magnitude of the shear stress, which is defined as one-half the difference between the two principal stresses. The magnitude of δ can be effectively observed by passing the emergent light through a second polarizing unit, called the *analyzer*. The principal plane of the analyzer is usually put at right angles to the polarizer, which is the first polarizing unit used to create the incident plane-polarized light. The two wave components, upon emerging from the analyzer, are reduced into one plane and give rise to interference. When $\delta = (2m + 1)\pi$, where m is an arbitrary integer, constructive interference takes place and one may see the brightest field of view. When $\delta = 2m\pi$, the interference becomes destructive and the field becomes dark. In general, δ may take any value depending on the actual shear stress in the medium. If there is a distribution of stresses (or strains) in a medium, bright and dark fringes will be seen, and these fringes are contours of equal shear stress. The magnitude of the shear stress can be calculated from the interference order of the fringes. When the polarization vector of the incident lgith happens to be parallel to one of the principal stresses, the interference fringes disappear and the field of view becomes dark. Thus, the orientation of the principal stresses can be found by rotating the crossed polarizer and analyzer. In this way, one can determine the distribution of the shearing stress in a transparent material by making use of photoelasticity.

To detect stress patterns in opaque solid objects such as metallic machine parts, models are constructed from appropriate transparent materials and subjected to stresses in the same fashion as in the original object. It has been proved that the stress patterns observed in such models replicate those in the original objects, provided that the models and original objects are both elastic. The model materials most widely used today are glass, celluloids, and epoxy resins.

Since the advent of lasers for coherent light sources in the 1960s, the photoelastic effect has found another important application in electrooptic engineering. When an ultrasonic wave propagates in a transparent medium, it produces a sinusoidally periodic distribution of mechanical strain as given by $S(t, x) = S_0 \sin (2\pi ft - kx)$, where S_0 is the amplitude of the strain, f is the frequency of the ultrasonic wave, t is the propagation time, k is the wavenumber, and x is the distance in the propagation direction. This strain wave in turn produces a periodic modulation of the refractive index via the photoelastic effect described by Eq. (1). This provides a moving phase grating (or diffraction grating) which may diffract portions of an incident light into one or more directions. This phenomenon, known today as the *acoustooptic effect*, was originally predicted by Brillouin as early as in 1922, and since his discovery, extensive studies were done by a number of researchers toward the understanding and application of the phenomenon. Today, applications of the acoustooptic phenomenon to light modulation and deflection for optical communication and signal processing have become particularly important.

Figure 1 is a conceptual illustration of an acoustooptic light deflector. A piezoelectric transducer bonded on one of the ends of a transparent medium launches an ultrasonic

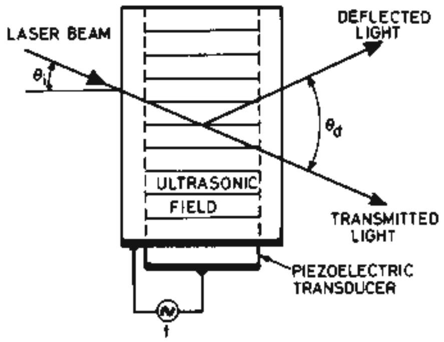

FIG. 1. Light deflector.

wave into the medium, and creates a phase grating with a spatial period equal to the wavelength of the ultrasonic wave. When the incident angle of the laser beam is adjusted so as to coincide with $\theta_i = \lambda f/2v$, where v is the sound velocity, an appreciable portion of the emergent light is deflected into the new direction. The frequencies usually used range from 10 to 1,000 MHz. The deflection angle, given by $\theta_d = \lambda f/v$, can be varied by changing the frequency f. The intensity of the deflected light can be controlled by the electrical power applied to the transducer, and thus the same device can also be used as a light modulator. The photoelastic materials most often used for this application are fused quartz, paratellurite (TeO_2), lithium niobate ($LiNbO_3$), and lead molybdate ($PbMoO_4$).

PHOTOELECTRICITY

In its broadest sense, the photoelectric effect is defined as the emission of electric charges (electrons, ions) resulting from the absorption of electromagnetic radiation (infrared, visible, ultraviolet, x-ray or gamma radiation) in a material (solid, liquid, or gas). Usually photoelectricity, or photoemission, is associated with the ejection of electrons from a solid surface.

Historically, the photoelectric effect played an important role in developing quantum mechanics in the beginning of the 20th Century and explaining the duality of electromagnetic radiation, namely, that light can be described as wavelike and still have the properties of discrete particles. The discovery of the photoelectric effect is ascribed to the German physicist H. R. Hertz, who in 1887 observed that ultraviolet radiation lowers the voltage at which sparking takes place between two electrodes. About a decade later, it was firmly established that cathode rays, produced by electric discharges, were nothing but the newly discovered electrons (particles with the elementary negative charge). In 1900 E. A. Lenard devised an experiment which directly showed that electrons were emitted from a metal surface under illumination of ultraviolet light. The name of the phenomenon, photoelectricity or photoelectric effect, was coined at this time. The most important findings during the first couple of years after Lenard's discovery can be summarized as follows: the number of ejected photoelectrons at a given excitation frequency is proportional to the intensity of the incident radiation; the photoelectrons have a kinetic energy distribution from zero up to cutoff energy, which is proportional to the excitation frequency but independent of the intensity; within the detection limits the photoelectrons seemed to be emitted instantaneously.

The characteristics described above could not be described by the classical theory of electromagnetic radiation by J. C. Maxwell and led A. Einstein to propose a fundamentally new theory of light in 1905. Einstein postulated that light (electromagnetic radiation) had properties like those of particles when it interacted with electrons. The discrete light particles are called photons, each with an energy $h\nu$, where h is Planck's constant and ν is the frequency of the photon. The electron absorbs the entire energy of the photon upon interaction, i.e., the radiation is quantized. The minimum energy required to eject an electron, Φ, is called the *photoelectric threshold energy* or *work function*. Einstein's theory of the photoelectric effect now postulates that the maximum energy of the photoemitted electrons E_k is given by

$$E_k = h\nu - \Phi.$$

Einstein's photoelectric law can account for the observations described above. A direct experimental proof for Einstein's law was given in 1916 by Robert A. Millikan, who was able to determine h with high accuracy and showed that it agreed with the constant M. Planck used in his theory of blackbody radiation.

The description of the photoelectric effect in this article will be limited to fairly low photon energies. It should be pointed out that at higher photon energies (say above 10,000 eV) it is necessary to consider conservation of both energy and momentum in the electron-photon interaction. A photon interacting with an electron will thus result in a wavelength shift between the incident and scattered photon. This phenomenon (established in 1923) is called the *Compton effect* after its discoverer, A. H. Compton. The wavelength shift, $\Delta\lambda$, can be written

$$\Delta\lambda = \frac{h}{m_0 c}(1 - \cos\theta)$$

where m_0 is the rest mass of the electron, c is the velocity of light, and θ is the scattering angle of the photon. At still higher photon energies ($h\nu > 10$ MeV), with the wavelength comparable to the nuclear dimensions, so-called *photonuclear effects* occur, which in the simplest case can be described as photoemission of a neutron or proton from the nucleus. Finally, a short remark should be made on the concept of compound photoelectric effect or *Auger effect* (named after its discoverer in 1925, P. V. Auger). The Auger effect arises from the photoelectric excitation of an electron from inner core levels in atoms. The produced vacancy level can be filled by the deexcitation of a less tightly bound electron, and the released excess energy may in its turn result in the emission of electrons from other states. The latter electrons are called *Auger electrons*. Since the original vacancy can be filled in a number of different ways the Auger spectra can be quite complex and rich in structure.

As pointed out earlier, Einstein's law for the photoelectric effect, $E_k = h\nu - \Phi$, predicts that the electron emission is directly proportional to the photon flux, i.e., the number of photons absorbed in the material. The photoemission process can in a simplified fashion be described as a three-step event:

Step 1 (Excitation). The absorption of a photon by an atom and the emission of an electron; this process may occur anywhere within the penetration depth of the incident photons.

Step 2 (Transport). The photoexcited electron is moving through the material and may undergo various scattering processes (electron-electron scattering, electron-phonon scattering, etc.); thus only some of the photoexcited electrons will reach the surface.

Step 3 (Escape). If the electron reaching the surface has sufficient energy to overcome the surface barrier, or the work function Φ, it will escape from the surface. This is the photoemitted electron.

The penetration depth of the photons into the material is determined by the absorption coefficient, which depends on the wavelength and the absorbing media. In the visible and ultraviolet regions it is typically a few hundred angstroms, Å (1 Å = 10^{-10} m). However, the distance into the surface from which the photoemitted electrons are coming is almost exclusively determined by the scattering length of the electrons during the transport process (step 2). The scattering length is a strong function of the kinetic energy of the electron. It starts out being several hundred angstroms close to threshold, decreases to about 30-50 Å at about 5 eV kinetic energy, and continues through a minimum of about 5 Å at 20-200 eV and then increases to about 30 Å at 100 eV. The scattering length is thus U-shaped as a function of electron kinetic energy. It is further noteworthy that the scattering length is extremely small, only 1-2 atomic layers at its minimum, making the photoelectric effect in this spectral region very surface sensitive. The surface barrier the electron has to overcome (step 3) is typically a few electron volts, 2-5 eV, though certain materials can have a work function as low as 1-1.5 eV. Photoemission is a very fast process. The time between the absorption of the photon (step 1) and the emission of the electron (step 3) is less than 10^{-10} seconds.

It is now appropriate to comment on the temperature dependence of the photoemission process. As is apparent from the discussion above, Einstein's law for the photoelectric effect does not include the temperature as a parameter. However, it was recognized early that the energy of the emitted electrons is influenced by the temperature. The situation was resolved in 1931 by R. H. Fowler, who derived a fairly complex relationship between the photoelectric current and the temperature. According to this relationship the photoelectric current I is proportional to the square of the temperature, T^2, multiplied by a photon-energy-dependent function. Using standard notation this equation can be written

$$I = \alpha A T^2 f\left(\frac{h\nu - \Phi}{kT}\right)$$

where α and A are constants and k is Boltzmann's constant. Note that $h\nu - \Phi$ is the kinetic energy of the emitted electron. The numerical values of $f[(h\nu - \Phi)/kT]$ have been tabulated for a large number of materials. The relationship derived by Fowler can be used in a convenient way to determine the threshold frequency (work function, Φ). This is quite simply done by plotting the experimental results of photocurrent, temperature, and incident photon frequency [written as $(h\nu - \Phi)/kT$]. This is known as the *Fowler plot.* For metals, it has been found that the photoelectric current is to a good approximation proportional to $(h\nu - \Phi)^2$ for photon energies $h\nu$ within 1 eV of the threshold. As was mentioned earlier, the threshold energies range from about 2 to 5 eV (Cs: 2 eV; Pt: 5 eV). The threshold energy varies for different crystal surfaces of the same material and is also very sensitive to adsorbed gases or other contaminants on the metal surface. A typical value of the photoelectric yield is 10^{-3} electrons per incident photon at 1 eV above threshold, i.e., when $h\nu - \Phi = 1$ eV.

In the discussions up to this point, it has been assumed that the photoemission occurs from a metal surface, in which case the work function and the threshold energy are two identical concepts. It has also been pointed out that the work function depends on many factors. The purity and surface conditions of the metal are important. But, even for a perfectly pure surface, the work function depends on the crystallographic orientation. The surfaces with the orientation of the most closely packed atomic planes have the highest work functions. A polycrystalline surface thus has a work function which is an average of the most common crystallographic orientations.

The photoelectric behavior of a semiconductor (and an insulator) has additional complications. In a semiconductor, there is a so-called *forbidden energy gap* between the occupied valence band and the empty conduction band. As a result, the photoelectric threshold energy is larger than the work function. For a metal and a semiconductor with the same work function, the semiconductor thus has a larger photoelectric threshold.

The photoelectric effect has found a number of very important technological applications. Many photoemissive devices are based on the fundamental properties of the photoelectric effect, namely, that the response (i.e., emitted electrons) is directly proportional to the light intensity and that the response time (i.e., the time lag between the absorption of a photon and emission of the electron) is very short. One such photoemissive device (photodiode) can be used to detect single photons. Another class of very common devices, the so-called photomultipliers, are equipped with secondary emitters.

Much effort has gone into the development of photoemissive materials for various applications. Still, most photoemissive materials are limited to a narrow spectral region, and even at peak performance the quantum efficiency is typically only about 10%.

A common goal for all photoemissive materials is to combine low work functions with high photoelectric yields. The development of low-work-function surfaces has been centered around compound materials. Some of the most successful photoemissive materials are: silver-oxygen-cesium, cesium-antimony, bismuth-silver-oxygen-cesium, and multialkali antimonides, illustrating the complexity of these systems. A few more details about one particular system, cesium antimonide (Cs_3Sb) can emphasize this further. Cs_3Sb is a semiconductor with a band gap of about 1.5 eV. The photoelectric threshold is a little higher than this (see above). Electrons can be excited from the occupied valence band to the empty conduction only as long as the photon energy is larger than the band gap, i.e., 1.5 eV, which is slightly lower than the photoelectric threshold. Thus, even the least energetic electrons have energies only slightly less than what is required for escape. This results in a higher probability for photoemission than is the case for metals or for semiconductors with a photoelectric threshold more than twice the band gap. Cs_3Sb can give photoyields of more than 0.2 electrons per incident photon and has good response over most of the visible region. Other compounds can be tailored to have the optimal response in the red or ultraviolet regions of the spectral distribution.

The photoelectric effect has also found very widespread application in a technique for surface analysis and diagnostics, called *electron spectroscopy.* In a broad sense, electron spectroscopy has during the last decade provided important insights into the electronic structure of surfaces, interfaces, and bulk materials. The energy distributions of the photoemitted electrons contain information about the electron population of occupied states, the so-called *density-of-states,* i.e. the electronic structure can be determined. Since the scattering length of the photoexcited electrons is very short, electron spectroscopy is particularly suited for various surface studies: chemisorption, oxidation, corrosion, catalysis, etc. The possibility to vary and control different parameters involved in the photoemission process has recently found extended use. In addition to the photon energy, the polarization and direction of the incident light can be varied, and the energy, direction, and spin-polarization of the emitted electron can be monitored. The binding energy for deeper lying core levels can be determined with high accuracy and are a sensitive probe of the local chemical environment. The field of electron spectrosopy, using visible, ultraviolet, and X-ray radiation as the excitation source, has seen the development of a number of commerical instruments which are now used routinely in a large number of laboratories. At the same time, there are still vital research efforts in understanding the basic mechanisms behind the photoionization processes in solids, liquids, and gases.

PHOTOGRAPHY

The history of photography spans more than a century, and embraces many techniques for producing photographic images. During the last half century, technological innovation has proceeded at an ever increasing pace. The most important advance of the past decade has been the computerized authomation of the basic photographic processes.

Every photographic technique includes an optical system, a photosensitive material, and a development process. Light from the subject passes through the optical system or camera and impinges on the photosensitive material to form a latent or invisible image. The latent image is transformed by chemical or physical means into a visible negative or positive image.

Most photographic processes use mixtures of the silver halides, i.e., silver bromide, iodide, and chloride, as the photosensitive materials. (The "speed" of a material depends on their relative proportions, with "fast" materials having a high percentage of silver bromide and little or no silver chloride.) These processes include conventional black-and-white and color photography, "instant" black-and-white and color photography, and lensless photography. A number of other processes are based on photochemical reactions of organic dyes, and of inorganic metal salts other than silver halides. Still other processes employ light-induced changes in the physical properties of materials, such as photoconductors, magnetic discs, or thermoplastics.

In conventional silver halide photography, the camera consists of a light-proof box with a lens for admitting and focusing light, a diaphragm for controlling the size of the effective aperture, a shutter for regulating length of exposure, and the photosensitive film. There must also be film-holding and film-transporting devices and a viewfinder. A simple box camera (Fig. 1) has only one lens aperture and one shutter speed. The distance from lens to film is fixed, and the lens has a short focal length so that all objects within the range six feet to infinity are in focus on the film. Other types of cameras have systems for varying the lens-to-film distance, the effective aperture, and the shutter speed.

The two most common types of shutter (Fig. 2) are the leaf shutter consisting of three or five interleaved blades, each pivoted on the outer end, and the focal plane shutter consisting of a slit which traverses the film plane during exposure.

Holography, or lensless photography, uses an unconventional image-forming system (Fig. 3a). Monochromatic light from a laser is split into two beams, one of which enters the lensless camera after reflection from a plane mirror, while the other enters after reflection from a three-dimensional object. The two beams combine to form a Fresnel diffraction pattern of the image, which is recorded on film. This recorded pattern is called a *hologram*. To reconstruct the image, a beam of laser light is transmitted through the hologram to generate a second diffraction pattern, a component of which is an exact duplicate of the original wave reflected from the object. This wave appears to come from the object, i.e., it yields a three-dimensional virtual image which appears suspended in space behind the hologram (Fig. 3b). Another component of the diffraction pattern forms a three-dimensional real image which appears suspended in front of the hologram. Holography has become an important scientific tool, with many unique applications (see HOLOGRAPHY).

Another process makes it possible to mass-produce a three-dimensional image known as a *parallax panoramogram* on a two-dimensional card.[1] The picture is coated with a plastic layer composed of vertical rows of cylindrical lenses which give the illusion of depth.

Ordinary photographic film is a suspension of microscopic silver halide crystals in gelatin coated on a supporting layer. Gelatin is a stable porous medium which permits processing solutions to reach the dispersed crystals. Gelatin contains organic sulfide impurities which react with silver halides to form sensitivity centers. These are tiny silver sulfide centers of at least

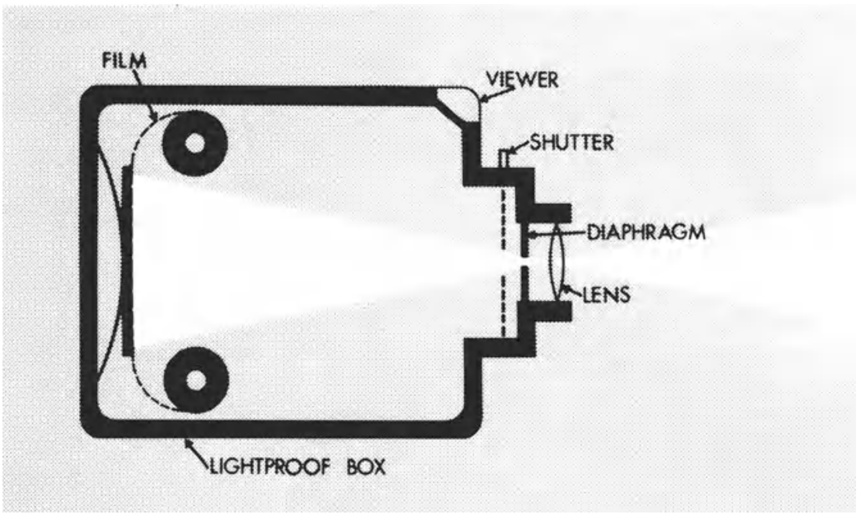

FIG. 1. Box camera. (Figures 1, 2 and 3 are redrawn from the "Encyclopedia Americana," International Edition, 1971.)

ten molecules each, which form on the surface of the crystals and catalyze the formation of the latent image by light.[2] When the film is exposed to light, the crystals absorb photons which generate mobile electrons. These electrons migrate to the sensitivity centers where they are trapped. They attract and neutralize silver ions, forming specks of metallic silver

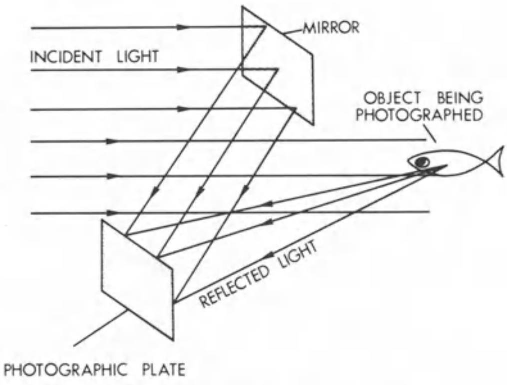

FIG. 3(a). Making a Hologram.

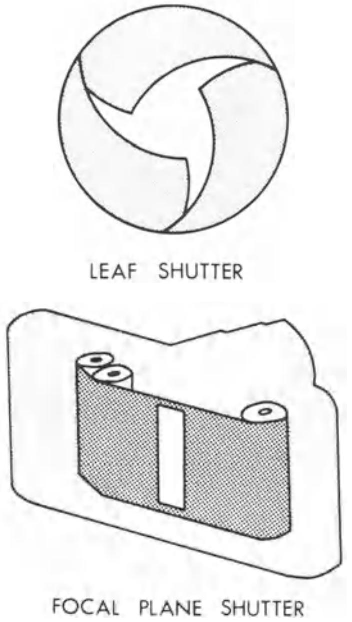

FIG. 2. Shutters.

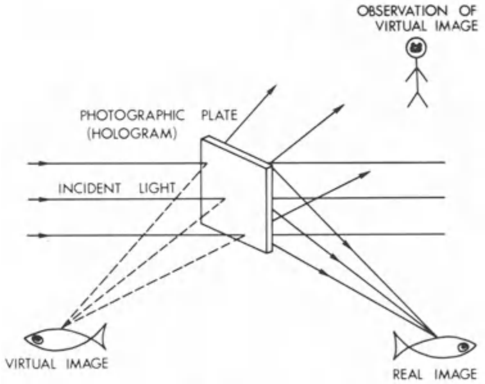

FIG. 3(b). Viewing a Hologram.

on the silver halide crystals at the sites of the sensitivity centers. These specks constitute the latent image. The smallest latent image speck that can make an exposed crystal develop during processing has from four to ten atoms of silver. Not all absorbed photons contribute to the latent image. Assuming that a typical speck of ten atoms formed by absorbing one hundred photons can cause development of a crystal with 10^{10} ion pairs, the amplification factor is about 10^8, which is higher than that of any other photographic material.

The developer reduces all the silver ions in an exposed crystal to silver atoms which deposit on the specks. The unexposed crystals are removed from the gelatin emulsion by a "fixing" solution to form the negative. A positive print is obtained by exposing an emulsion-coated paper to light through the negative, and developing it.

During development, the silver specks may grow until they merge to form irregular clusters. The image then is grainy; its contours are blurred, and its fine detail lost. This problem is amplified if enlarged prints are subsequently made. To solve the problem, the silver halide crystals are coated with developer inhibitor releasing (DIR) couplers by means of a process due to Kodak. As the metallic specks grow, the developer is oxidized in proportion to the silver reduced. The oxided developer reacts or "couples" with the DIR to release agents which limit the size of the specks, and thus prevent full development of the crystals. To compensate for this, a larger number of finer, more tightly packed crystals is now used in the emulsion. The image is well developed, but less grainy. Cubic crystals are preferred to hexagonal crystals, being smaller and more uniform in size and shape. Image sharpness is further enhanced by using very thin emulsions which minimize light scattering in the film.[3]

The Polaroid camera developed by E. H. Land in 1950 produces a positive black-and-white print ten seconds after exposure. In 1976, Kodak also entered the instant camera field. Instant photography requires rapid extraction of unexposed silver halide crystals from the exposed film, and rapid development of both the negative and positive images. Thus it was necessary to develop high speed film and very reactive agents. The negative emulsion layer is pressed against a nonsensitive layer of paper between metal rollers in the camera. Pods containing a viscous developer are ruptured as the two layers are pressed together, squeezing the developer uniformly between the layers. After forming the negative image, the developer then dissolves the unexposed crystals and transfers them to the paper layer which contains dry developer to produce the positive print.[4]

Silver halide emulsions are sensitive to ultraviolet and visible light, with maximum response in the blue at about 4200 Å. Their range may be extended to any wavelength up to 13,000 Å in the near infrared by sensitizing dyes which absorb light in the desired spectral regions and transfer the energy to the crystals. A mixture of two dyes often yields an increase in spectral sensitivity greater than the sum of increases due to each dye separately.[5] This is known as *supersensitization*. A common emulsion is that used in panchromatic film, which is sensitized to the visible spectrum up to 6200 Å.

In modern color photography, integral tripacks are used. An integral tripack is a film of three sensitive layers separated by gelatin. Each layer contains crystals sensitized to one of the primary colors for light mixing, i.e., red, green, or blue. After exposure, the three silver negatives in the nonseparable multilayered film are developed.

The most common method of forming the dye image is the dye coupling process. During development, the oxidized developer couples with a chemical to form a dye which produces a negative color image. A cyan dye in the red-sensitized layer absorbs red light, and reflects its complement, i.e., cyan, while the blue-sensitized emulsion acquires a yellow dye, and the green sensitized emulsion a magenta dye. The superposition of the three color negatives then transmits the colors complementary to those of the original image. To make color prints, the colors are reversed by exposing a three-layer emulsion coated on paper to white light through a color negative. To make positive transparencies, the color reversal is performed directly on the integral tripack film by changing the development procedure.

Infrared false color photography[6] is a process in which the film has three layers sensitized to green, red, and infrared (to 13,000 Å), instead of the normal blue, green, and red. A positive print or transparency then depicts the green, red, and infrared in the original scene as blue, green, and red, respectively. This process has important applications to mapping of earth resources from space, aerial reconnaissance, medicine, and many other disciplines.

Cameras come in many models employing various film sizes.[7] There are rangefinder cameras, single lens reflex (SLR), and double lens reflex cameras, each with different optics for viewing the subject scene. There are small cameras for hobbyists, large cameras for professionals, and special cameras for special applications.

Since 1970, advances in film chemistry, optics, electronics, and computer science have revolutionized camera design. Miniature cameras, simplified film loading, and very high-speed film are now available. In taking a picture, the effective aperture, shutter speed, and even the focal length may be adjusted in a fraction of a second by computer automation. Some cameras flash automatically under low ambient light conditions, while others flash during each exposure, thus softening harsh shadows in brightly lit scenes. Flash duration and intensity may be automatically controlled. The film may advance after each exposure, and rewind at the end. With a fully automatic camera, the user has only to compose the picture in the viewer, and press the shutter release button. Most such cameras are inexpensive, being priced between $30 and $150. A recent addition to the automatic camera field is the Canon line in the popular 35-mm film format, which features a full range of options in automation, and interchangeable accessories. These cameras were introduced during 1979–1982.

Techniques of automation vary. For example during auto-focus, the Kodak 980L instant camera and the Canon Sure Shot measure the object distance by infrared ranging, i.e., by sending an infrared pulse toward the object and timing its return. Fuji uses a pulse of white light for ranging, while Polaroid instant cameras now employ ultrasound. The Canon Super Sure Shot measures distance by triangulation, using ambient light reflected from the object.

Miniaturization has dictated the need for a short lens-to-film distance, i.e., a short focal length. This has the added advantage of increased depth of field, as illustrated in Fig. 4 for two focal lengths. Both lenses shown have the same *f*-number, which is defined as the ratio of focal length to aperture diameter. Point objects which are in focus on the film form point images; all other point objects form "circles of confusion," so that their images are blurred. A human observer can tolerate some degree of blurring before perceiving the image as "out of focus." The distance range for which objects appear in focus is called the *depth of field*.

In Fig. 4, the diameter of the circle of confusion formed on the film by the 12.5-mm lens is about one-tenth that of the 38-mm lens. The 12.5-mm lens also gives a smaller negative image. In making positive prints, this image must be magnified three times as much as the other to yield a print of equal size; however, the diameter of its circle of confusion is still only one-third of that on the other print. Thus the lens of shorter focal length provides greater depth of field. Depth of field may also be increased by using smaller apertures, i.e., larger *f*-numbers, which yield smaller circles of confusion. Faster film must then be used to compensate for the reduced exposure to light.

In 1972, Dr. Land announced a system of instant color photography which features the Polaroid SX-70, a miniature SLR camera. All operations except composing and focusing the picture are controlled electronically. There are few moving parts, so that essentially "only the electrons move." Within a minute of exposure, a hard, dry, scratch-resistant print emerges from the camera. It has a three-dimensional quality, "true" colors, and a luminous appearance as if internally lighted. Timing and waste disposal are eliminated. Pictures may be taken at the rate of about one per second. Provision is made for time exposures, and for flash bulb lighting. Fresh batteries are included

in each film pack. The system was developed by a large team of researchers over a 20-year period. In 1978, ultrasonic echo ranging and automatic focusing were added to the SX-70 system.

In 1981, Polaroid introduced the 600 line of folding instant cameras, featuring full automation, and one-button, no-decision operation. They flash during each exposure. Flash duration is adjusted to provide 75% ambient light and 25% strobe light for bright outdoor scenes, and 100% strobe light for dark scenes. All lenses are aspheric to minimize aberrations. Model 660 (Fig. 5) has ultrasonic echo ranging during autofocus, and automatic focal length selection, with one fixed lens and four supplementary lenses on a rotating disk. Exposure adjustments are based on detected ambient light levels. Model 640 has a fixed focal length. At low ambient light levels, its exposure adjustments are based on detected ambient infrared light levels, which give more accurate exposure information than low-level visible light.

A new line of instant cameras was marketed by Kodak in 1982. Three of the four models are folding cameras which flash during each exposure. Flash duration is adjusted so that strobe light mixes with ambient light. Model 980L features autofocus with infrared echo ranging, while Model 970L features a built-in auxiliary lens for object distances of 2-4 ft.

In 1982, Kodak introduced three miniature automatic "disc" cameras with a revolutionary film format, i.e., a rotating disc of film (Fig. 6). The disc has film for 15 exposures; each negative measures 8 X 10 mm, or one-tenth the area of a 35-mm negative. The disc has a rigid base which permits accurate film positioning during exposure and processing (Fig. 7). Thus images

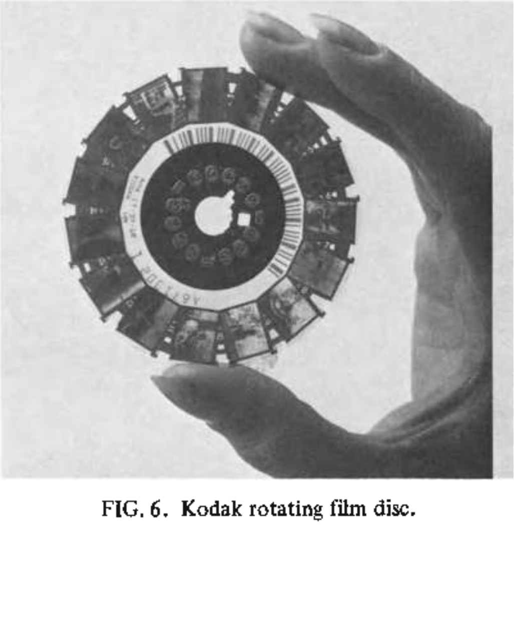

FIG. 6. Kodak rotating film disc.

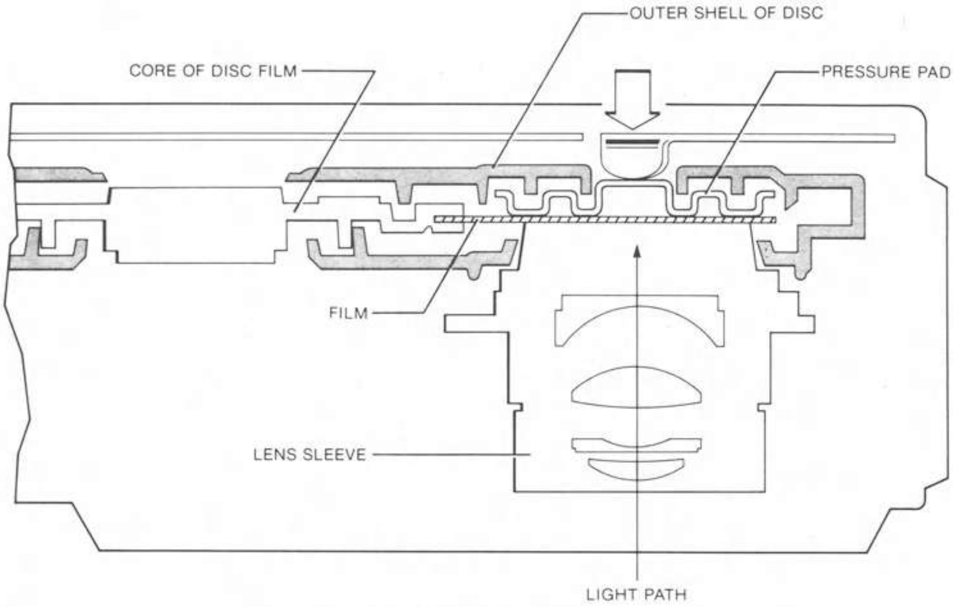

FIG. 7. Film positioning in a Kodak disc camera.

are sharper, and enlargements are of better quality. The disc is enclosed in a shell which is loaded into the camera in a fixed orientation (Fig. 8). The film is advanced automatically by a small motor, and is locked in place after a complete revolution. There are no rollers to damage the film. It is easily stored, and is processed outside the camera in the normal way. The disc has an iron oxide magnetic core which is used to store reorder information.

Each camera flashes automatically at low light levels. Each has a fixed focus, four-element lens (Fig. 7), one element of which is aspheric. The short (12.5 mm) focal length increases depth of field. Lens surfaces are computer-designed, and checked for microroughness by laser interferometry. The quality of the lens approaches diffraction limits, and the large aperture ($f/2.8$) reduces diffraction effects.

The disc film format has made possible a pocket-sized automatic camera. Model 4000 (Fig. 9) has dimensions of 7.5 × 12.5 × 2 cm (i.e., 3 × 5 × 0.8 in.). The somewhat larger Models 6000 and 8000 can accommodate object distances down to 45 cm (i.e., 18 in.). Model 8000 also allows the user to hold the shutter button down and thus to expose about three frames per second in daylight; at low light

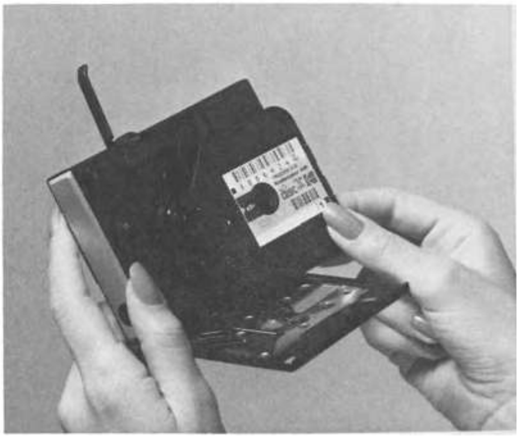

FIG. 8. Loading a Kodak disc camera.

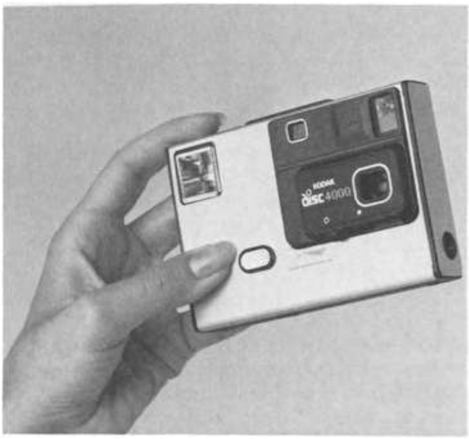

FIG. 9. Kodak pocket-sized camera.

levels, the exposure rate is limited to one per second by the recharging time of the automatic flash.

Many practical innovations have been made for darkroom hobbyists. Development trays have now been replaced by drums or tanks which permit development in full daylight. Kits are available for developing color slides, prints, or negatives under noncritical environmental conditions. Liquid concentrates with almost unlimited shelf life may be used to prepare small quantities of development solutions by simple methods. Instant photography techniques have been transferred to the darkroom, so that one solution may be used in a compact table top processor to develop negatives, slides or prints in minutes. Commercial developing systems are adapted for different volumes of picture processing, up to 10,000 prints per hour. They are controlled by microcomputers.

Photographic processes using photochemical systems other than silver halides have lower sensitivity to light, but may be used to achieve special effects.[8]

A class of processes known as *electrophotography* uses materials which show an increase in electrical conductivity during light exposure. Electrophotography is widely used for office copying machines. In one type of electrophotography, charges are sprayed on a selenium or zinc oxide layer by a corona wire charged to five or ten thousand volts.[2] During exposure, the charge leaks off image-wise through the photoconductive layer. The remaining charge pattern is the latent image, which is developed by applying an oppositely charged black resin powder which adheres to the charged areas. The image is fixed by slight heating to fuse the resin. This basic process has been modified by many recent innovations.

The Sony Corporation's expertise in magnetic tape technology has been applied in developing the Mavica camera, which records the latent image on a magnetic disc. In size and shape, the Mavica resembles a conventional 35-mm SLR camera. However, this new photographic process requires no film, and no chemical developers. Instead, the image is focused on a solid state imager called a *charge coupled device* or CCD, and converted into electrical signals which are recorded on the magnetic disc, called a Mavipak. The pictures may be viewed immediately on a home TV screen by means of a Mavipak viewer. They may also be transmitted over a telephone line at the rate of ten per second. Color prints may be made using the Mavigraph color video printer. The pictures may also be stored on video tape.

The new system, whose specifications are subject to change, will be marketed late in 1983. It is illustrated schematically in Fig. 10. It affords an image exposure rate of up to ten pictures per second, with a possible future rate of sixty per second. Through electronic means, the user can control the color tones, or produce composite pictures.

The magnetic disc is enclosed in a case measuring $6 \times 5.4 \times 0.3$ cm (i.e., $2\frac{3}{8} \times 2\frac{1}{8} \times \frac{1}{8}$ in.). It may be loaded, removed from the camera, and reinserted in daylight. It may be easily stored or mailed. The disc can store up to fifty color pictures; it has a frame counter, and a

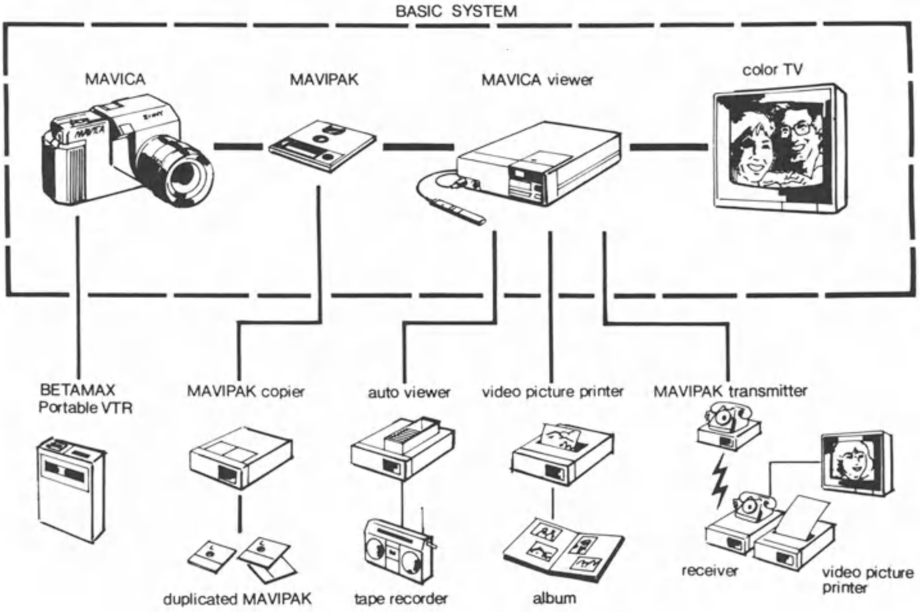

FIG. 10. Sony Mavica system.

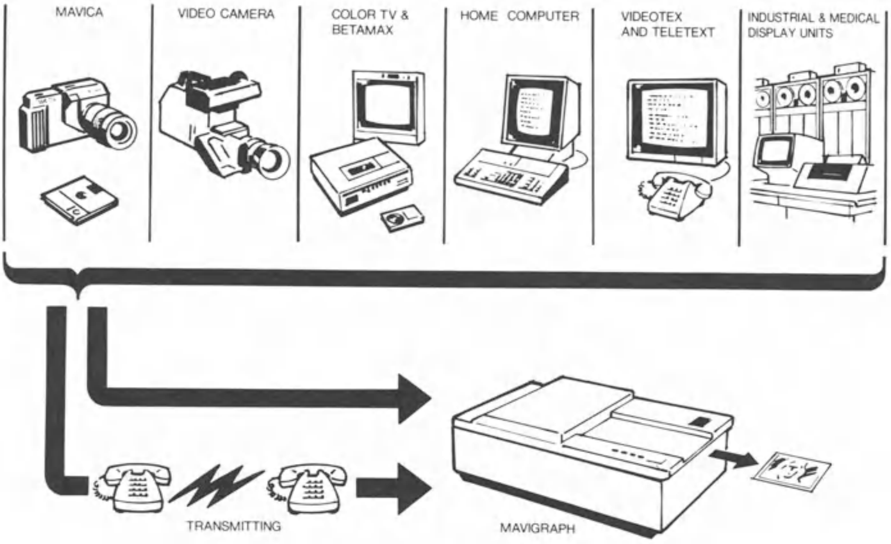

FIG. 11. Applications of Sony Mavigraph printer.

memory system which affords the user easy access to each picture. Although it is protected from accidental erasure, it may be erased and used again.

The color printer requires no chemical processing; instead, the dye is transferred to the paper image-wise by thermal evaporation. Color prints may be made from latent images stored on the magnetic disc or on videotape, and also from images transmitted by telephone. With the addition of a video camera, the printer can convert images on a TV, X-ray, or CAT scanning screen into hard copies. It may also be used as a printer for an office computer terminal. These applications are shown schematically in Fig. 11.

An image forming system for infrared wavelengths beyond the limit for sensitized photographic emulsions is now used in remote sensing from aircraft and spacecraft. This system requires no image-forming optics. Instead, a detector sensitive to infrared or microwave radiation scans the field of view, and the received intensity from each point in the scene is elec-

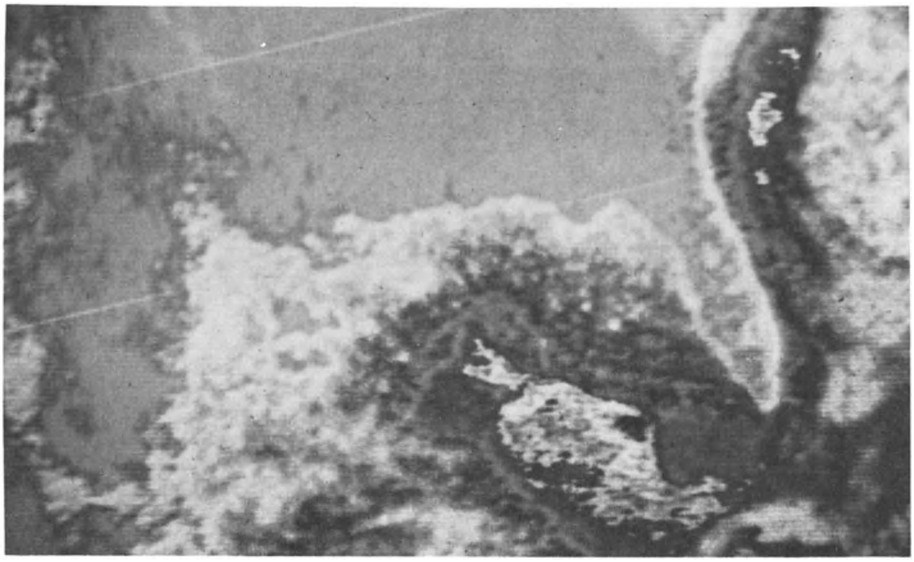

FIG. 12. Loop Current and Gulf Stream; infrared image.

tronically converted to a visible intensity at a corresponding point on a cathode ray screen. The visible image of the infrared or microwave scene is then recorded by conventional or instant photography. This system has many applications to medicine, geology, agriculture, forestry and oceanography.

Fig. 12 represents such an infrared photograph showing the warm Loop Current in the Gulf of Mexico, and the Gulf Stream. It has been processed so that bright areas in the center of these currents represent *very* warm water and dark areas represent *quite* warm water. Bright regions along the shore and outside of these currents represent very cold water. Thus bright areas depict both hot and cold water, while dark areas show the location of water at an intermediate temperature.[9]

The past decade has brought about these many innovations in photography. One can only speculate on the greater wonders which the future promises.

PHOTOMETRY

Photometry is concerned with the measurement of light, or much more frequently, of the time rate of flow of light. Light is the aspect of radiant energy to which the human eye responds, or more precisely it is Q_V in the equation:

$$Q_V = K_m \int V(\lambda) Q_{e\lambda} d\lambda$$

in which K_m is the maximum luminous efficacy of radiant energy (683 lumens per watt), $V(\lambda)$ is the CIE (International Commission on Illumination) spectral luminous efficiency function[1] which is curve 4 of the figure shown in the article on COLOR in this Encyclopedia, and $Q_{e\lambda}$ is the spectral distribution of radiant energy. Reference 1 is highly recommended as a short discussion of the basic principles of photometry.

The quantities with which photometry is concerned are luminous intensity and flux, illuminance and LUMINANCE, and luminous reflectance and transmittance.

The devices that are used to measure these quantities are called photometers. They fall into two general categories, namely, visual and physical. The making of brightness matches is a requisite in the use of visual photometers, while in physical photometers, which are usually of the photoelectric or thermoelectric type, luminous energy incident on a receiver is transformed into electric energy and the latter is measured by means of sensitive electric meters or devices. In visual photometry, observers with so-called normal color vision are used, it being tacitly assumed that the average spectral response of the observers used to make the observations approximates the standard CIE luminous efficiency curve. In physical photometry, the receiver should be equipped with a filter, the spectral transmittance of which when multiplied by the relative spectral response of the receiver, wavelength by wavelength, closely approximates the CIE luminous efficiency curve. In all photometric measurements that involve differences between the spectral distribution of the standard source used to calibrate the photometer and that of the test source, the accuracy of the results obtained is dependent on the degree of approximation of the spectral response curve of the photometer to the CIE spectral luminous efficiency curve.

The unit of luminous intensity (often called candlepower) is the candela. From 1948 until 1979 the candela was defined as being the luminous intensity of one-sixtieth of one square centimeter of projected area of a blackbody at the freezing point of platinum.[2] By action of the 16th General Conference on Weights and Measures[3] in 1979 "the candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540 × 10^{12} hertz and that has a radiant intensity in that direction of 1/683 watt per steradian." Radiation at other frequencies is also measured in candelas in accordance with the standard luminous efficiency, $V(\lambda)$, curve that peaks at 540 X 10^{12} Hz (yellow green). National standardizing laboratories, like the National Bureau of Standards in the United States, calibrate incandescent-lamp reference standards of luminous intensity in conformity with the international standard. The calibration for luminous intensity of other incandescent lamps relative to these reference standards or to other standards of luminous intensity is usually done on a bar photometer, which consists of a horizontal bar equipped with movable carriages, on one of which the standards and lamps to be calibrated are mounted in turn, while the photometric measuring device is mounted on the other carriage. The calibration involves the use of the inverse-square law which states that the illuminance at a point on a surface varies directly with the luminous intensity I of the source and inversely as the square of the distance d between the source and the point on the surface. If the surface at the point is perpendicular to the direction of the incident light, the law may be expressed as follows: $E = I/d^2$. In the measurement of the intensity I_2 of a source relative to the intensity I_1 of a standard, the illumination at the photometer from the two sources is made equal by varying the distance d, so that $I_2 = I_1 d_2{}^2/d_1{}^2$ in which d_2 and d_1 are the distances for the unknown and standard, respectively. The important precautions that must be taken in calibrating and using standards of luminous intensity are (1) that the distance between the standard and photometric receiver is sufficiently large relative to the size of the source and of the receiver so that the source and receiver act approximately as points,[4] (2) that the standard is accurately oriented with respect to the receiver,[5] and (3) that by the use of baffles no flux is incident on the receiver other than that which comes directly from the standard.

Illuminance is incident luminous flux per unit area. In the measurement of illuminance, a photometer, in this application often called an illuminometer, is used. The illuminometer is calibrated at n points by the use of a standard of luminous intensity I placed at n distances d from the test plate of a visual photometer or the surface of the receiver, thus yielding n illuminances E computed from the inverse-square law $E = I/d^2$. It is important that the geometric characteristics of the receiver of the illuminometer be such as to enable it to evaluate, without bias, luminous flux that is incident on the receiver from all directions; special precautions are usually necessary if flux incident at large angles to the perpendiuclar to the receiver is to be properly evaluated.

The unit of luminous flux is the lumen which is defined as the luminous flux in a unit solid angle (steradian) from a point source having a directionally uniform intensity of one candela. Standards of luminous flux are calibrated in terms of standards of luminous intensity by the use of a two-step procedure. In one step, the luminous intensity in a specified direction of the lamp to be calibrated is determined, and in the other step, by the use of a distribution photometer, the relative luminous intensity of this lamp in a multiplicity of directions is determined. To enable one to see how each of these intensities is effective in contributing luminous flux, one notes that each direction intersects a hypothetical sphere circumscribed about the lamp and that around the point of intersection on the sphere surface an area can logically be assigned which defines the solid angle in which the luminous intensity in that direction is effective in supplying luminous flux. These solid angles in steradians, by which the luminous intensity values must be multiplied to obtain the lumens incident on the respective areas, are called zonal constants. Such constants for various patterns of distribution measurements have been published and are thus readily available.[6,7] Reference standards of luminous flux are calibrated by this procedure, but in national standardizing laboratories reference standards of luminous flux are now generally calibrated by a similar procedure in which spectral radiant intensity is measured in step 1 and spectral irradiances are measured in step 2. The computed spectral radiant flux is then converted to luminous flux by the use of the $V(\lambda)$ function. Other standards are calibrated in terms of the reference standards or of other standards of luminous flux by the use of an integrating sphere, sometimes called an Ulbricht sphere. It is a spherical hollow enclosure with a uniform, diffusely reflecting inner surface. In such an enclosure, the illuminance due to reflected flux is the same at every point on the surface and is directly proportional to the flux emitted by a source in the sphere, independent of its angular distribution. The ratio of the fluxes emitted by two sources is thus the ratio of the illuminances at any point on the sphere surface that is shielded from receiving flux directly from the sources. The principal precautions in the use of spheres are (1) that the inner surface be a good diffuser, uniform in reflectance from point to point, and (2) that the spectral selectivity of the sphere throughout the visible region of the spectrum (0.4 to 0.7 μm) be compensated. This compensation is usually accomplished by the use of filters. It must be remembered that the effect of the spectral selectivity is greatly amplified because of the interreflections within the sphere so that the illuminance on the sphere wall by reflection only is $\rho/(1 - \rho)$ times the average illuminance by directly incident flux, where ρ is the reflectance of the sphere wall; thus if the reflectances at two wavelengths are, for example, 0.80 and

0.72, the spectral irradiance by reflection only at the wavelength of lower reflectance will be only 64 per cent of that at the wavelength of higher reflectance.

There are two related systems of units of luminance that have been and are still being used. In one of these systems the luminance is expressed in terms of luminous intensity per unit projected area or in terms of luminous flux per unit solid angle and unit projected area. The other system is that in which luminance is expressed in terms of the flux per unit area that would leave a perfect diffuser having the same luminance; the lambert and footlambert are units of this system and their magnitudes are such that one lumen per square centimeter and per square foot, respectively, would leave a perfect diffuser of unit luminance. Standards of luminance are usually combinations of luminous intensity standards and surfaces of known transmittance factor or reflectance factor (see below). The product of the illuminance of a surface by the appropriate one of these factors gives its luminance; for example, for each lumen per square centimeter incident perpendicularly on a freshly prepared surface of MgO, the luminance at an angle of 45° from the perpendicular will be approximately one lambert because the reflectance factor of MgO for this geometry is approximately 1.00. The reflectance factor of a more easily prepared $BaSO_4$ surface is approximately 1.01. In lieu of the MgO or $BaSO_4$ surface, use is more generally made of a highly diffusing glass or plastic plate of known transmittance factor for perpendicular incidence on one side of the plate and perpendicular viewing on the other side. The measurement of luminance relative to a luminance standard by visual photometry introduces no serious problems other than those inherent in photometry generally, because the receptor, in this case the eye, intercepts flux in a very small solid angle which can, for all practical purposes, be considered to be infintesimally small. In physical photometry, however, because of the need to collect flux in an amount that will result in adequate sensitivity, the solid angle of reception may be relatively large and cannot in general be considered to be infinitesimally small, so that there is introduced into the measurements an inaccuracy whose magnitude is related to the magnitude of the variation of the flux per infinitesimal solid angle within the solid angle of reception.

In addition to the measurement of the dimensional quantities discussed above, photometry is concerned with the measurement of the dimensionless quantities transmittance, transmittance factor, reflectance, and reflectance factor. Transmittance and reflectance are the ratio of transmitted and reflected flux, respectively, to incident flux. For a nondiffusing specimen, the measurement of transmittance or reflectance usually poses no great problem. For a diffusing specimen, the measurement of totally diffuse transmittance or reflectance (reception over a solid angle of 2π steradians) for specified modes of illumination of the specimen is usually made with instruments that incorporate integrating spheres;[8] for solid angles of reception smaller than 2π steradians, the measurement of the ratio of transmitted or reflected flux to incident flux yields what is designated as fractional transmittance or fractional reflectance, respectively, quantities which generally are not of as much interest as are the transmittance factor and the reflectance factor (formerly widely but inappropriately called directional transmittance and directional reflectance). These factors are defined[9] as the ratio of the flux transmitted (or reflected) in the solid angle of interest to that transmitted (or reflected) in the solid angle by the ideal perfect diffuse transmitter (or reflector) identically illuminated; the ideal perfect diffuse transmitter (or reflector) is one that transmits (or reflects) all of the luminous flux incident on it in accord with the Lambert cosine law, i.e., so that the flux per unit solid angle in any direction from it varies as the cosine of the angle between that direction and the perpendicular to the transmitter (or reflector). For a solid angle of reception of 2π steradians, the term transmittance (or reflectance) factor is synonymous with transmittance (or reflectance). For infinitesimal solid angles of reception and nonfluorescing specimens, the term transmittance (or reflectance) factor is synonymous with luminance factor which for any specimen is defined as the ratio of the luminance of the specimen to the luminance of a perfect diffuser identically illuminated.

The most commonly used photometric and related radiometric quantities, their defining equations and units, and symbols for them which are consistent with those agreed upon to date by the International Commission on Illumination, the International Electrotechnical Commission, the International Organization for Standardization, and the Commission for Symbols, Units, and Nomenclature of the International Union of Pure and Applied Physics are listed in Table 1.

TABLE 1. PHOTOMETRIC AND RELATED RADIOMETRIC QUANTITIES, DEFINING EQUATIONS, UNITS AND SYMBOLS

Quantity[a]	Symbol[a]	Defining Equation	Unit	Symbol
Radiant energy	Q		Erg	
			Joule[e]	J
			Calorie	cal
			Kilowatt-hour	kWh
Radiant density	w	$w = dQ/dV$	Joule per cubic meter[e]	J/m^3
			Erg per cubic centimeter	erg/cm^3
Radiant flux	Φ	$\Phi = dQ/dt$	Erg per second	erg/s
			Watt[e]	W
Radiant flux density at a surface				
Radiant emittance[b] (Radiant exitance)	M	$M = d\Phi/dA$	Watt per square centimeter	W/cm^2
Irradiance	E	$E = d\Phi/dA$	Watt per square meter[e], etc.	W/m^2
Radiant intensity	I	$I = d\Phi/d\omega$ (ω = solid angle through which flux from point source is radiated)	Watt per steradian[e]	W/sr
Radiance	L	$L = d^2\Phi/d\omega(dA\cos\theta)$ $= dI/(dA\cos\theta)$	Watt per steradian and square centimeter	W · sr^{-1} cm^{-2}
		(θ = angle between line of sight and normal to surface considered)	Watt per steradian and square meter[e]	W · sr^{-1} m^{-2}
Absorptance	α	$\alpha = \Phi_a/\Phi_i$[d]	None (dimensionless)	–
Reflectance	ρ	$\rho = \Phi_r/\Phi_i$[d]	None (dimensionless)	–
Transmittance	τ	$\tau = \Phi_t/\Phi_i$[d]	None (dimensionless)	–

NOTE: The symbols for photometric quantities (see below) are the same as those for the corresponding radiometric quantities (see above). When it is necessary to differentiate them the subscripts v and e respectively should be used, e.g., Q_v and Q_e.

(quantity of light)			Lumen-second (talbot)[e]	lm · s
Luminous density	w	$w = dQ/dV$	Lumen-second per cubic meter[e]	lm · s · m^{-3}
Luminous flux	Φ	$\Phi = dQ/dt$	Lumen[e]	lm
Luminous flux density at a surface				
Luminous emittance[c] (Luminous exitance)	M	$M = d\Phi/dA$	Lumen per square foot	lm/ft^2
Illumination (Illuminance)	E	$E = d\Phi/dA$	Footcandle (lumen per square foot)	fc
			Lux (lm/m^2)[e]	lx
			Phot (lm/cm^2)	ph
Luminous intensity (candlepower)	I	$I = d\Phi/d\omega$ (ω = solid angle through which flux from point source is radiated)	Candela (lumen per steradian)[e]	cd
Luminance (photometric brightness)	L	$L = d^2\Phi/d\omega(dA\cos\theta)$	Candela per unit area	cd/in^2, etc.
		$= dI/(dA\cos\theta)$	Stilb (cd/cm^2)	sb
			Nit (cd[e]/m^2)	nt
		(θ = angle between line	Footlambert (cd/πft^2)	fL
		of sight and normal to	Lambert (cd/πcm^2)	L
		surface considered)	Apostilb (cd/πm^2)	asb
Luminous efficiency	V	$V = K/K_{\max}$	None (dimensionless)	–
Luminous efficacy	K	$K = \Phi_v/\Phi_e$	Lumen per watt[e]	lm/W

[a] Quantities may be restricted to a narrow wavelength band by adding the word spectral and indicating the wavelength. The corresponding symbols are changed by adding a subscript λ, e.g., Q_λ, for a spectral concentration or a λ in parentheses, e.g., $K(\lambda)$, for a function of wavelength.

[b] Should be deprecated in favor of emitted radiant exitance.

[c] Should be deprecated in favor of emitted luminous exitance.

[d] Φ_i = incident flux; Φ_a = absorbed flux; Φ_r = reflected flux; Φ_t = transmitted flux.

PHOTON

The existence of the photon was first suggested by Planck's famous research, about 1900, into the distribution in frequency of blackbody radiation. He arrived at agreement with the experimental distribution only by making the drastic (for those times) assumption that the radiation exists in discrete amounts with energy $E = hf$. Here f is the frequency of the radiation and h is Planck's constant, $6.626(10)^{-27}$ erg sec. Confirmation of the existence of these quanta of electromagnetic energy was provided by Einstein's interpretation of the photoelectric effect (1905); he made it clear that electrons in a solid absorb light energy in the discrete amounts hf. The full realization that the photon is a particle with energy and momentum was provided by the Compton effect (1922), an aspect of the scattering of light by free electrons. Compton showed that features of the scattering are understood by balancing energy and momentum in the collision in the usual way, the light considered as a beam of photons each with energy hf and momentum hf/c.

The modern point of view is that, for every particle that exists, there is a corresponding field with wave properties. In the development of this point of view the particle aspects of electrons and nuclei were evident at the beginning and the field or wave aspects were found later (this was the development of quantum mechanics). In contrast, the wave aspects of the photon were understood first (this was the classical electromagnetic theory of Maxwell) and its particle aspects only discovered later.

From this modern point of view the photon is the particle corresponding to the electromagnetic field. It is a particle with zero rest mass and spin one. For a photon moving in a specific direction, the energy E and the momentum q of the particle are related to the frequency f and wavelength λ of the field by the Planck equation $E = hf$ and the de Broglie equation $q = h/\lambda$. As for all massless particles, the energy and momentum are related by $E = cq$ and the photon can only exist moving at light speed c. Another property of all massless particles is this: given the momentum, the particle can exist in just two states of spin orientation. The spin can be parallel or antiparallel to the momentum but no other directions are possible. The photon state with the spin and momentum parallel (antiparallel) is said to be right- (left-) handed and is a right- (left-) hand circularly polarized wave. In analogy with the neutrino, one can say that the state has positive (negative) helicity and can call the right-handed particle the antiphoton, the left-handed particle the photon. There is an operation, CP conjugation, that converts a photon state into an antiphoton state and vice versa. It is possible to superpose photon and antiphoton states in such a way that the superposition is unchanged by CP conjugation and so gives a type of photon that is its own antiparticle. The photons produced by transitions between states of definite parities in atoms or nuclei are their own antiparticles in this sense. As for all particles with integer spin, the photon follows Bose-Einstein statistics. This means that a large number of photons may be accumulated into a single state. Macroscopically observable electromagnetic waves, such as those resonating in a microwave cavity for example, are understood to be large numbers of photons all in the same state. The photon, among all the particles, is unique in having its states be macroscopically observable this way.

The electric and magnetic fields **E** and **B** describe the state of the photon and make up the wave function of the particle. Maxwell's equations give the time development of the fields and take the place, for the photon, that Schrödinger's equation takes for a material particle. Many of the remarks above follow as direct consequences of Maxwell's equations. In Gaussian units, where both **E** and **B** are measured in gauss or dynes per electrostatic unit of charge, the equations for the free fields are

$$\epsilon_{jkl}\partial E_l/\partial x_k + c^{-1}\partial B_j/\partial t = 0 \qquad (1)$$

$$\epsilon_{jkl}\partial B_l/\partial x_k - c^{-1}\partial E_j/\partial t = 0 \qquad (2)$$

$$\partial E_j/\partial x_j = \partial B_j/\partial x_j = 0 \qquad (3)$$

The particle aspect of the equations becomes evident when the equations are written in terms of the complex three-vector

$$\psi_j = E_j - iB_j \qquad (4)$$

in which case they become

$$\epsilon_{jkl}\partial\psi_l/\partial x_k + ic^{-1}\partial\psi_j/\partial t = 0 \qquad (5)$$

$$\partial\psi_j/\partial x_j = 0 \qquad (6)$$

Equation (6) is to be considered as an initial condition rather than as a equation of motion since it follows from Eq. (5) that

$$\partial(\partial\psi_j/\partial x_j)/\partial t = ic\epsilon_{jkl}\partial^2\psi_l/\partial x_j\partial x_k = 0$$

so if $\partial\psi_j/\partial x_j$ is zero at the start, it is zero forever. Equation (5) can be cast into Hamiltonian form. One writes the three components ψ_j as a column matrix ψ and introduces three, three-by-three, matrices by

$$(s_k)_{jl} = i\epsilon_{jkl} \qquad (7)$$

With this notation, Eq. (5) becomes

$$ic(s_k)_{jl}\partial\psi_l/\partial x_k = i\partial\psi_j/\partial t$$

or

$$H\psi = i\hbar\partial\psi/\partial t \qquad (8)$$

where

$$H = - c\mathbf{s} \cdot \mathbf{p} \qquad (9)$$

and $\mathbf{p}$ is $- i\hbar\nabla$. The Hamiltonian for the photon is thus $- c\mathbf{s} \cdot \mathbf{p}$. In detail, the matrices that occur here are

$$s_1 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix}, \quad s_2 = \begin{pmatrix} 0 & 0 & i \\ 0 & 0 & 0 \\ -i & 0 & 0 \end{pmatrix},$$

$$s_3 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \qquad (10)$$

They are Hermitian and, as is easily verified, they fulfill the commutation rules

$$[s_i, s_j] = i\epsilon_{ijk}s_k$$

and so are a set of angular momentum matrices. Evidently each has eigenvalues 0, ± 1 so they are a representation of spin one.

Next consider the plane wave solutions. Let them be propagating in the 3-direction; so substitute

$$\psi = u \exp\,[i\hbar^{-1}(p_3 z - Wt)]$$

into Eq. (8). Here the same symbol p_3 is used for the eigenvalue as for the operator. The system reduces to the matrix eigenvalue problem

$$- c\begin{pmatrix} 0 & -ip_3 & 0 \\ ip_3 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} u = Wu$$

The eigenvalues are found to be $W = 0, \pm cp$, where p is $|p_3|$, and the corresponding eigenvectors are

$$u_0 = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, u_\pm = \frac{1}{\sqrt{2}}\begin{pmatrix} \pm p_3/p \\ -i \\ 0 \end{pmatrix}$$

The $W = 0$ possibility does not satisfy the initial condition, Eq. (6), and so must be discarded. The solutions $u_\pm$ are valid for either sign of p_3; choose $p_3 = \pm p$ so both waves are propagating in the positive z direction. The two solutions of the problem are then

$$\psi_\pm = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ -i \\ 0 \end{pmatrix}\exp\,[\pm ip\hbar^{-1}(z - ct)] \qquad (11)$$

The subscript +(−) denotes a particle (antiparticle) solution with positive (negative) frequency of $W/h = + cp/h$ ($- cp/h$). Also $\psi_\pm$ are evidently eigenstates of the helicity operator $\mathbf{s} \cdot \mathbf{p}/p$ with eigenvalues ∓ 1. The electric and magnetic fields are the real and imaginary parts:

$$E_{\pm,x} = 2^{-1/2} \cos\,[p\hbar^{-1}(z - ct)] \qquad (12a)$$

$$E_{\pm,y} = \pm\, 2^{-1/2} \sin\,[p\hbar^{-1}(z - ct)] \qquad (12b)$$

$$B_{\pm,x} = \mp\, 2^{-1/2} \sin\,[p\hbar^{-1}(z - ct)] \qquad (12c)$$

$$B_{\pm,y} = 2^{-1/2} \cos\,[p\hbar^{-1}\,(z - ct)] \qquad (12d)$$

$$E_{\pm z} = B_{\pm\, z} = 0 \qquad (12e)$$

Here it is seen that the − 1(+ 1) helicity solution is left- (right-) hand circularly polarized with respect to the propagation direction.

The allowed states of the photon are eigenstates of the Hamiltonian H with eigenvalues $\pm cp$. Let $|H|$ be the operator which, applied to the same states, gives eigenvalue cp. The operators for the physical energy, momentum, and angular momentum of the photon are $|H|$, $(H/|H|)\mathbf{p}$, and $(H/|H|)(\mathbf{x} \times \mathbf{p} + \hbar\mathbf{s})$. One can understand these assignments for the energy and momentum by considering the plane wave states of Eq. (11). The states are eigenstates of the operators with energy eigenvalue cp and with momentum eigenvalue p in the positive z direction. As further justification for these operator assignments, the expectation values of the operators are directly related to the classical formulas for energy, momentum, and angular momemtum in the electromagnetic field:

$$(\psi, |H|\psi) = (8\pi)^{-1}\int d^3x(E^2 + B^2) \tag{13a}$$

$$\left(\psi, \frac{H}{|H|}\mathbf{p}\,\psi\right) = (4\pi c)^{-1}\int d^3x(\mathbf{E}\times\mathbf{B}) \tag{13b}$$

$$\left(\psi, \frac{H}{|H|}(\mathbf{x}\times\mathbf{p} + \hbar\mathbf{s})\,\psi\right) = (4\pi c)^{-1}\int d^3x\,\mathbf{x}\times(\mathbf{E}\times\mathbf{B}) \tag{13c}$$

where the rule for taking the inner product is

$$(\psi_1, \psi_2) = \frac{1}{8\pi c}\int d^3x\,\psi_1{}^{\dagger}\,\frac{1}{p}\,\psi_2 \tag{14}$$

These equalities apply for any solution ψ of Eqs. (6) and (8). The dagger denotes the Hermitian conjugate. The operation $(1/p)\psi$ in Eq. (14) is to be carried out by expanding ψ in the plane wave components like $\psi_{\pm}$ and replacing the operator $(1/p)$ by the number $(1/p)$ in each component. Proofs of Eqs. (13) will not be given here; they can be made by expressing each side of the equations in terms of the plane wave expansion coefficients. Accepting these operator assignments, one sees that the helicity operator $\mathbf{s}\cdot\mathbf{p}/p$ is the component of the spin of the photon $(H/|H|)\mathbf{s}$ in the direction of its momentum $(H/|H|)\mathbf{p}$.

The *CP* conjugation operation is related to the space reflection covariance of Maxwell's equations. Consider a primed and an unprimed coordinate system such that the coordinates of any point in space referred to the two axes are related by $\mathbf{x}' = -\mathbf{x}$. Suppose the electric field is axial and the magnetic field is polar so that the functions describing the fields are related by $\mathbf{E}'(\mathbf{x}', t) = \mathbf{E}(\mathbf{x}, t)$ and $\mathbf{B}'(\mathbf{x}', t) = -\mathbf{B}(\mathbf{x}, t)$. It is evident that Maxwell's equations have the same form in both coordinate systems and that the transformation rule for ψ is $\psi'(\mathbf{x}', t) = \psi^*(\mathbf{x}, t)$ where the asterisk denotes the complex conjugate. The fact that the equations have the same form in both systems implies further that if $\psi(\mathbf{x}, t)$ is any solution then $\psi'(\mathbf{x}, t)$, or equivalently $\psi^*(-\mathbf{x}, t)$, is also a solution. The operation that carries $\psi(\mathbf{x}, t)$ into $\psi'(\mathbf{x}, t)$ is called *CP* conjugation and one writes

$$\psi^{CP} = KP\psi \tag{15}$$

where K is the operation "take complex conjugate" and the operator P changes $\mathbf{x}$ into $-\mathbf{x}$. If ψ is a solution of Maxwell's equations so also is ψ^{CP}. However KP anticommutes with $\mathbf{s}\cdot\mathbf{p}$ so if the solution ψ has ∓ helicity, then ψ^{CP} has ± helicity. The *CP* conjugation thus converts the particle into the antiparticle. The *KP* operator also anticommutes with the physical momentum operator $(H/|H|)\mathbf{p}$ so for a state $\psi\pm(\mathbf{q})$ with definite helicity ∓ and physical momentum $\mathbf{q}$ one has

$$KP\psi_{\pm}(\mathbf{q}) = \psi_{\mp}(-\mathbf{q}) \tag{16}$$

Instead of the two states ψ_+ and ψ_-, one may consider the superpositions

$$\psi_1(\mathbf{q}) = 2^{-1/2}[\psi_+(\mathbf{q}) + \psi_-(\mathbf{q})] \tag{17a}$$

$$\psi_2(\mathbf{q}) = 2^{-1/2}[\psi_+(\mathbf{q}) - \psi_-(\mathbf{q})] \tag{17b}$$

The reason for introducing them is the property

$$KP\psi_1(\mathbf{q}) = \psi_1(-\mathbf{q}) \tag{18a}$$

$$KP\psi_2(\mathbf{q}) = -\psi_2(-\mathbf{q}) \tag{18b}$$

Thus the *KP* operation applied to ψ_1 or ψ_2 reproduces the state, only traveling in the opposite direction and with a change of phase for ψ_2. The states ψ_1 and ψ_2 in this way are their own antiparticles. These self-antiparticle states are plane polarized in perpendicular directions. For the states with momenta in the positive z direction, as given by Eqs. (11) and (12), the fields are seen to be

$$E_{1x} = \cos[p\hbar^{-1}(z - ct)] \tag{19a}$$

$$B_{1y} = \cos[p\hbar^{-1}(z - ct)] \tag{19b}$$

$$E_{2y} = \sin[p\hbar^{-1}(z - ct)] \tag{19c}$$

$$B_{2x} = -\sin[p\hbar^{-1}(z - ct)] \tag{19d}$$

with all other components zero.

The final point to be demonstrated here is that only a self-antiparticle type of photon is emitted or absorbed when a system makes a transition between states of definite parity. Consider for simplicity a spinless charged particle described by a Schrödinger wave function $\psi_m(\mathbf{x}, t)$. [The subscripts m and γ are used for the material particle and the photon.] Suppose the particle is bound in some system and makes a transition from an initial state i to a final state f, both eigenstates of parity P, with emission or absorption of a photon. As is well known, the transition probability is determined by the interaction integral

$$I = -(e/Mc)\int d^3x[\psi_{mf}{}^*(\mathbf{x}, t)\mathbf{p}\psi_{mi}(\mathbf{x}, t)]\cdot\mathbf{A}(\mathbf{x}, t) \tag{20}$$

where e and M are the charge and mass of the particle and $\mathbf{A}$ is the vector potential of the photon in the Coulomb or radiation gauge,

$$\nabla \cdot \mathbf{A} = 0 \qquad (21)$$

Here and below, the integrals extend over all space. The fields are found from the potential by the relations

$$\mathbf{E} = -c^{-1}\partial \mathbf{A}/\partial t \qquad (22)$$

$$\mathbf{B} = \nabla \times \mathbf{A} \qquad (23)$$

To make the argument, one first expresses the interaction explicitly in terms of the fields. The potential is found from the fields by integrating this way:

$$\mathbf{A}(\mathbf{x}, t) = \frac{1}{4\pi} \nabla \times \int d^3y \, \frac{\mathbf{B}(\mathbf{y}, t)}{|\mathbf{x} - \mathbf{y}|} \qquad (24)$$

It is easily verified that this expression for $\mathbf{A}$ satisfies Eqs. (21), (22), and (23) by using Eqs. (1), (3), and the fact that $\nabla^2 |\mathbf{x} - \mathbf{y}|^{-1} = -4\pi\delta(\mathbf{x} - \mathbf{y})$. In the verification it is assumed that fields of interest will be zero outside a finite region of space so that in making partial integrations there are no contributions from infinity. Then by using Eq. (24) and replacing $\mathbf{B}$ by $i(\psi_\gamma - \psi_\gamma^*)/2$, one can rewrite the interaction integral as

$$I = \frac{-ie}{8\pi Mc} \int d^3x \, [\psi_{mf}^*(\mathbf{x}, t) \mathbf{p} \psi_{mi}(\mathbf{x}, t)] \cdot \nabla \times \int \frac{d^3y}{|\mathbf{x} - \mathbf{y}|} \, [\psi_\gamma(\mathbf{y}, t) - \psi_\gamma^*(\mathbf{y}, t)]$$

However, if i and f are eigenstates of parity, then, by changing integration variables from $\mathbf{x}$ and $\mathbf{y}$ to $-\mathbf{x}$ and $-\mathbf{y}$ in the ψ_γ^* term, one sees that

$$I = \frac{-ie}{8\pi Mc} \int d^3x \, [\psi_{mf}^*(\mathbf{x}, t) \mathbf{p} \, \psi_{mi}(\mathbf{x}, t) \cdot \nabla \times \int \frac{d^3y}{|\mathbf{x} - \mathbf{y}|} \, (1 \mp KP) \psi_\gamma(\mathbf{y}, t)$$

where the factor is $(1 - KP)$ if i and f have the same parity, $(1 + KP)$ if i and f have opposite parity. Since

$$KP(1 \mp KP)\psi_\gamma = \mp (1 \mp KP)\psi_\gamma$$

only a type of photon that is its own antiparticle can be involved in the transition in either case. As examples, the electric dipole radiation field has $KP = +1$ and the magnetic dipole field has $KP = -1$.

For many calculations, especially in atomic physics, the electromagnetic field is quantized in the Coulomb gauge. Still in Gaussian units, the vector potential operator for the free field is written as

$$\mathbf{A}(\mathbf{x}, \mathrm{t}) = \frac{1}{\sqrt{V}} \sum_{\mathbf{k},\alpha} c \sqrt{\frac{2\pi\hbar}{\omega}} \, [a_{\mathbf{k},\alpha} \, \boldsymbol{\epsilon}^{(\alpha)} \cdot e^{i(\mathbf{k}\cdot\mathbf{x} - \omega t)} + a_{\mathbf{k},\alpha}{}^\dagger \, \boldsymbol{\epsilon}^{(\alpha)} \, e^{-i(\mathbf{k}\cdot\mathbf{x} - \omega t)}]. \qquad (25)$$

Here $V = L^3$ is the normalization volume, $\omega = ck$, and the wave vector $\mathbf{k}$ is quantized such that

$$(k_x, k_y, k_z) = (2\pi/L)(n_x, n_y, n_z),$$

where the n_i are positive or negative integers. The $\boldsymbol{\epsilon}^{(\alpha)}$ are two real polarization vectors such that $\boldsymbol{\epsilon}^{(1)}$, $\boldsymbol{\epsilon}^{(2)}$, $\mathbf{k}/|\mathbf{k}|$ form a right-hand orthogonal triplet of unit vectors. The $a_{\mathbf{k},\alpha}$ and $a_{\mathbf{k},\alpha}{}^\dagger$ are boson destruction and creation operators with commutation rules

$$[a_{\mathbf{k},\alpha}, a_{\mathbf{k}',\alpha'}{}^\dagger] = \delta_{\mathbf{k}\mathbf{k}'} \, \delta_{\alpha\alpha'}$$

$$[a_{\mathbf{k},\alpha}, a_{\mathbf{k}',\alpha'}] = 0. \qquad (26)$$

To understand the connection between this quantization and the previous discussion of photons, one starts with Eq. (25) and finds an expression for the field operator $\psi = E - iB$ in the standard form $\sum (a_+ \psi_+ + a_-{}^\dagger \psi_-)$ with normalization $(\psi_\pm, \psi_\pm) = 1$. Equations (22) and (23) provide the electric and magnetic field operators. For simplicity consider just one of the terms in the sum on $\mathbf{k}$ and choose $\boldsymbol{\epsilon}^{(1)}$, $\boldsymbol{\epsilon}^{(2)}$, $\mathbf{k}$ in the x, y, z directions respectively. The result is, for the sum on the two values of α,

$$\psi = i \sqrt{\frac{8\pi\hbar\omega}{V}} \left[\frac{(a_{\mathbf{k},1} + i a_{\mathbf{k},2})}{\sqrt{2}} \, \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ -i \\ 0 \end{pmatrix} \cdot e^{i(\mathbf{k}\cdot\mathbf{x} - \omega t)} + \frac{(-a_{\mathbf{k},1} + i a_{\mathbf{k},2})^\dagger}{\sqrt{2}} \, \frac{1}{\sqrt{2}} \cdot \begin{pmatrix} 1 \\ -i \\ 0 \end{pmatrix} e^{-i(\mathbf{k}\cdot\mathbf{x} - \omega t)} \right].$$

This is of the required form, as is seen by comparison with Eq. (11). The operators for destruction of photon or antiphoton with energy $\hbar\omega$, momentum $\hbar\mathbf{k}$, are identified as

$$a_{\mathbf{k},+} = (a_{\mathbf{k},1} + i a_{\mathbf{k},2})/\sqrt{2},$$

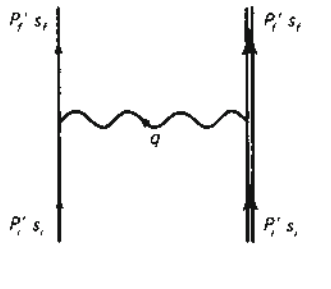
$$a_{\mathbf{k},-} = (-a_{\mathbf{k},1} + i a_{\mathbf{k},2})/\sqrt{2}. \qquad (27)$$

On the other hand, $a_{\mathbf{k},1}$ and $a_{\mathbf{k},2}$ are operators for destruction of self-antiparticle photons plane-polarized in the $\boldsymbol{\epsilon}^{(1)}$ and $\boldsymbol{\epsilon}^{(2)}$ directions. Many aspects of the interaction of photons with atoms may be understood on the basis of this quantization of the electromagnetic field, using the interaction as given in Eq. (20). For example, emission and absorption of light, Rayleigh and Thomson scattering of light by atomic electrons, the photoelectric effect, and the Raman effect may be treated this way. Limitations of this approach are that the electrons are considered nonrelativistic and that their spin is disregarded.

Relativistic calculations involving photons are almost always done with Feynman diagram techniques. For internal photon lines in the diagrams the propagator is

$$D_F(q^2)_{\mu\nu} = \frac{-g_{\mu\nu}}{q^2 + i\epsilon}. \tag{28}$$

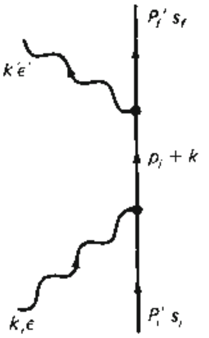
A simple example is the one-photon-exchange contribution to electron-proton scattering. The diagram is

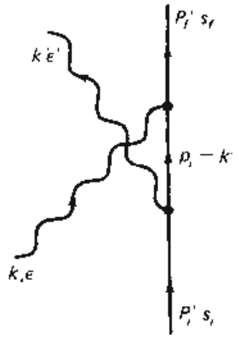


and the corresponding invariant matrix element is

$$M_{fi} = [\bar{u}(p_f s_f)\gamma_\mu u(p_i s_i)]\,\frac{e^2}{q^2 + i\epsilon}$$
$$\cdot\,[\bar{u}(P_f, S_f)\gamma^\mu u(P_i, S_i)]. \tag{29}$$

For external photon lines the polarization four-vector ϵ_μ, defined to be $(0, \epsilon)$, is used. As an example, in the Compton effect the two diagrams





contribute and the invariant amplitude is

$$M_{fi} = \epsilon_{\mu'}\,\bar{u}(p_f, s_f)\left[(-ie\gamma^\mu)\,\frac{i}{\not{p}_i + \not{k} - m + i\epsilon}\right.$$
$$\cdot\,(-ie\gamma^\nu) + (-ie\gamma^\nu)\,\frac{i}{\not{p}_i - k' - m + i\epsilon}$$
$$\left.\cdot\,(-ie\gamma^\mu)\right]u(p_i, s_i)\,\epsilon_\nu. \tag{30}$$

These two rules are the basis of a complete understanding of all photon interaction processes, including forces between charged particles, bremsstrahlung, pair production, the anomalous magnetic moment of the electron, and the Lamb shift.

plasts and blue-green algae H_2A is water and A is oxygen; for photosynthetic bacteria H_2A is often H_2S or other sulfur compounds, but is *never* water.

The primary action of light in photosynthetic systems is the excitation of pigment molecules. Singlet-state excitation is transferred from the light-harvesting pigment molecules to those few specialized molecules which participate in primary photochemistry at reaction centers. When excitation becomes localized in a reaction center, there is a charge separation in which an electron moves from an excited chlorophyll molecule to a primary acceptor molecule, thus leaving a chlorophyll cation radical which is easily detected by electron spin resonance techniques. All the known primary acceptors are either chlorophyll or pheophytin molecules. The array of light-harvesting pigments which deliver excitation energy to a single reaction center is called a photosynthetic unit. The size of photosynthetic units varies from roughly 50 to 2000 pigment molecules per reaction center in various systems; for plant chloroplasts 200 is a typical figure. The physical description of excitation transfer depends upon the structure of the photosynthetic unit in question. In most photosynthetic systems, there appears to be a heterogeneous arrangement of pigments with weak exciton coupling between closely spaced molecules (10 to 15 Å) and Förster resonance transfer between more widely separated molecules (e.g., 50 Å). In all cases energy transfer is a nonradiative process.

The pigments universally associated with photosynthesis are the chlorophylls. Chlorophyll *a* is essential for oxygen-evolving systems, and its close relatives, bacteriochlorophylls *a* and *b*, are characteristic of bacterial systems. Other types of chlorophyll as well as phycobilins and carotenoids function as accessory pigments which harvest light and transfer excitation to either chlorophyll *a* or bacteriochlorophylls *a* or *b*.

Reaction centers have been characterized most thoroughly in purple photosynthetic bacteria. The primary photochemical electron transfer shown in Fig. 1 can be driven by a single 880-nm photon (1.4 eV) with the storage of about 1.0 eV as electrochemical free energy in the primary products. The return of the electron to bacteriochlorophyll *a* via the intermediates (secondary acceptors Q_1 and Q_2, UQ·cytochrome *b*, and cytochrome *c*) in the cyclic transport chain is coupled to the formation of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic phosphate in which 0.5 eV per ATP is stored. Many bacteria also generate reducing power in the form of reduced nicotinamide adenine dinucleotide (NADH) from external hydrogen donors such as H_2S.

The formation of reduced organic compounds from CO_2 is driven by reducing power and ATP

in a series of enzymic reactions. No light is required for these reactions.

In blue-green algae and plant chloroplasts two distinct photochemical reactions in physically separate reaction centers are required to generate reducing power (NADPH) from water. Photochemical system 2 generates an oxidant powerful enough to extract electrons from water and evolve oxygen. Photochemical system 1 generates the powerful reductant for CO_2 reduction. As shown in Fig. 2, the flow of electrons from the top of system 2 to the bottom of system 1 is coupled to the formation of ATP. In addition to the noncyclic electron transport pathway shown in Fig. 2, most oxygen-evolving systems also operate a cyclic pathway similar to that shown for bacteria in Fig. 1.

PHOTOVOLTAIC EFFECT

The photovoltaic effect (PVE) is the generation of an emf as a result of the absorption of light. Three phenomena are involved in the effect. The first of these is photoionization, i.e., the generation of equal numbers of positive and negative charges by light absorption. The second is the migration of one or both of the photoliberated charges to a region where separation of the positive and negative charges can occur. The third is the presence of a charge-separation mechanism. The photovoltaic effect can occur in gases, liquids and solids, but it has been studied most intensively in solids and, therefore, this discussion will be limited to solids, especially semiconductors.

Photoionization Semiconductors and insulators are characterized by a threshold energy for photoionization equal to the energy difference between the bottom of the conduction band and the top of the valence band, i.e., the forbidden energy gap E_g. Only those photons whose energy exceeds E_g can cause photoionization. Values of E_g range from several electron volts, corresponding to an ultraviolet threshold, to small fractions of an electron volt corresponding to an infrared threshold.

The absorption of light follows Lambert's law, which states that

$$N(x) = N(0)\, e^{-\alpha x}$$

where $N(0)$ and $N(x)$ are the numbers of photons crossing unit area per second at a reference point (0) and at a distance x from the reference point along the direction of propagation of the light beam, and α is the absorption constant. Figure 1 shows how α changes with photon energy in a number of semiconductors used in photovoltaic cells. This dependence of α on photon energy $h\nu$ is intimately related to the dependence of the photovoltaic effect parameters on $h\nu$. It also has an important effect on the choice of semiconductors for solar cells. As is evident from Figure 1, the α vs $h\nu$ curves of semiconductors like silicon rise less rapidly toward values in the 10^4–10^5 cm^{-1} range than do the α vs $h\nu$ curves of semiconductors like GaAs and CdTe. Since the thickness of material x needed to absorb a photon is inversely proportional to the value of α, this means that a smaller thickness of a direct gap semiconductor is needed to absorb most of the photons with $h\nu > E_g$. Specifically, several microns of GaAs are sufficient, whereas a hundred microns of Si are needed for absorption of most of the solar photons absorbable in each of these two semiconductors. Consequently, direct gap semiconductors are preferred as the photovoltaically active semiconductors (PVAS) of thin film solar cells.

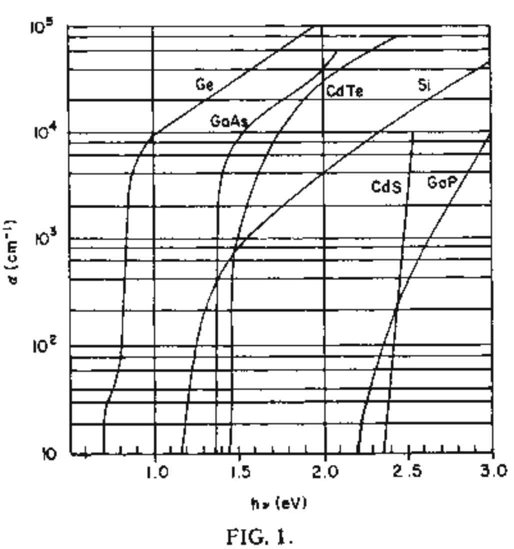

FIG. 1.

Migration of the Photo-Liberated Charges Because of Lambert's law, the photoliberated charges are distributed along the path of the light beam. Normally, they would move about at random until they recombine with carriers of opposite sign. This recombination process is characterized by a mean free lifetime τ of a pair which is of the order of microseconds in indirect gap semiconductors and of nanoseconds in direct gap semiconductors. As noted above, the PVE requires the presence of a charge separation region in the semiconductor. The magnitude of τ must be large enough to permit the carriers to move to this charge separation site before recombination occurs. Unproductive recombination can occur either in the bulk of the semiconductor or at its surface.

Charge-Separation Mechanism Charge separation requires a change in electrostatic potential between two regions of the solid, so that when a pair of opposite charges migrates to the region of the potential change, one of them can lower its potential by moving across this region. A large photovoltaic effect requires that the change in potential should be large and that it should occur over a distance which is short compared to the mean distance a free carrier can travel before recombination. These requirements imply the presence of a dipole layer which, in turn, implies an abrupt change in some property of the material. Such a dipole layer can occur either at the surface or in the interior of the material. A surface barrier usually involves a metal-simiconductor contact, a contact between the semiconductor and its oxide or, more generally, a contact with some other semiconductor. A barrier inside a material implies an abrupt change in the conductivity, which in the extreme case involves a change of conductivity type, as in a *p-n* junction. Figure 2 shows the diagrams of electron energy vs distance through the barrier for three such systems. The strongest photovoltaic effects are those which arise at *p-n* junctions, and therefore, the remainder of this article will be devoted to the *p-n* junction photovoltaic effect.

Photovoltaic Effect at p-n Junctions A *p-n* junction is formed by arranging the chemical impurity distribution in a single crystal of a semiconductor so that electric current is carried primarily by electrons on one side of the junction (the *n*-side) and primarily by holes on the other side (the *p*-side). The resulting electrostatic potential profile (Fig. 2) is such that excess holes can lower their energy by moving from the *n*- to the *p*-side while excess electrons lower their energy by moving in the opposite direction. Light absorption in either region leads to an increase in the concentrations of both holes and electrons, which are separated at the *p-n* junction. If a resistive load is connected between ohmic contacts to the *p*- and *n*-regions of a *p-n* junction illuminated by photons with energy $h\nu > E_g$, the current through the load I_L is related to the voltage across the load by the relation

$$I_L = I_s - I_0(e^{qV/kT} - 1)$$

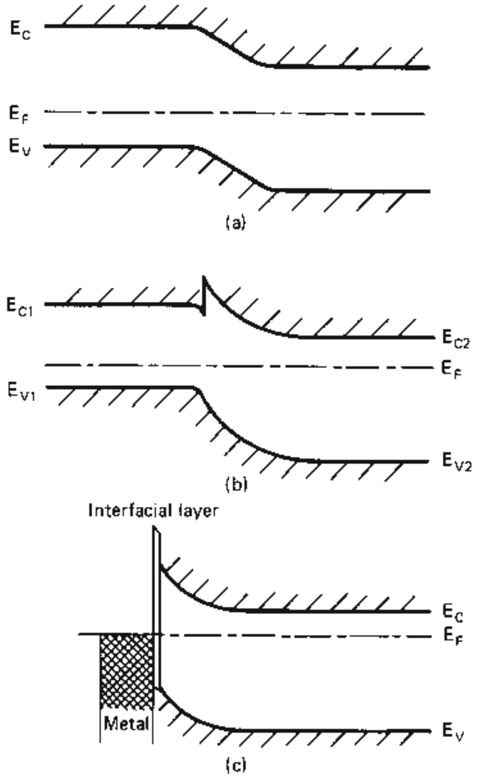

FIG. 2. Energy band diagrams of three charge collection barriers: (a) *p-n* homojunction; (b) *p-n* heterojunction; (c) MIS structure. The symbol E_C is the bottom of the conduction band; E_V the top of the valence band; and E_F is the Fermi energy.

where I_0 is the reverse saturation current of the *p-n* junction; q is the charge on the electron, k is Boltzmann's constant, T is the absolute temperature, and I_s is the photogenerated current which would flow if the load were a short circuit. The current I_s is a function of the absorption constant α, the spectral composition of the incident light, the pair lifetime and of the junction geometry. The $I_L - V$ characteristic of an illuminated PV cell is shown in Figure 3.

Applications The photovoltaic effect can be used to convert sunlight to electricity, and indeed *p-n* junction silicon solar cells have been the principal power sources on artificial earth satellites. Single crystal silicon solar cells having solar energy conversion efficiencies of about 12% are available commercially for prices in the \$5–10 per peak watt range. A peak watt is an amount of solar cells which, illuminated by unconcentrated, clear day sunlight having an intensity of 1 kW/m^2, produces 1 watt of electrical power. In the case of 12% efficient solar cells, the area covered by 1 peak watt is 83 cm^2. In 1983, the world production of such silicon cells was about 8 peak megawatts. While this is a substantial increase over the 50 peak

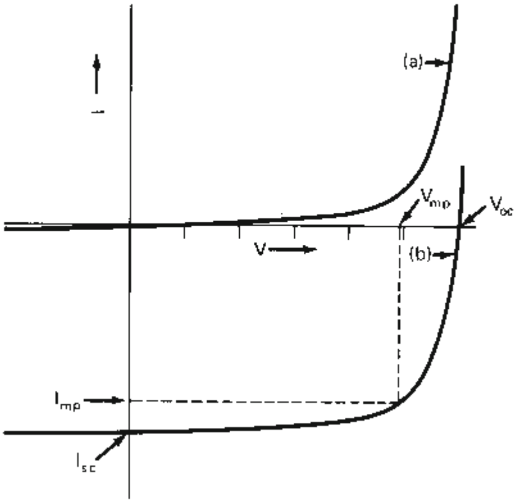

FIG. 3. Current-voltage characteristic of a solar cell in the dark (a) and under illumination (b). The symbol V_{oc} is open circuit voltage; I_{sc} is the short circuit current; V_{mp} is the voltage at maximum power and I_{mp} is the current at maximum power.

kilowatts produced in 1972, this amount of cells can produce an amount of electricity which is insignificant when compared to the world's production of electricity by fossil fuel and nuclear power plants.

Techno-economic studies of the feasibility of large-scale power generation by PV solar cells indicate that the price of solar cells must drop into the $1–2 per peak watt range before electricity produced by such cells can compete with electricity produced by conventional sources. Research programs aimed at achieving these price goals are underway, principally in the U.S., Japan and Western Europe. The research proceeds along two main paths. The first of these, which has had the greatest effort expended on it, aims at reducing the cost of single crystal silicon cells by introducing new methods for producing pure silicon and for producing sheets of silicon crystals suitable for solar cells. The second main path is aimed at alternative semiconductors for PVAS in solar cells. Among the most promising are gallium arsenide (GaAs), copper indium selenide ($CuInSe_2$), copper sulfide (Cu_2S) and amorphous silicon hydride. Cells having conversion efficiencies up to 22% have been fabricated from thin single-crystal GaAs, up to 10% from thin polycrystalline films of $CuInSe_2$ and Cu_2S, and up to 10% from thin films of amorphous silicon hydride. Research is also underway on tandem cell systems which require efficient cells made from PVAS having energy gaps between 1.0 and 2.0 eV. Calculations show that solar energy conversion efficiencies in excess of 50% are possible for such systems, whereas the upper limit efficiencies for solar cells utilizing a single PVAS are about 25%. While first generation terrestrial solar cells will be based on single PVAS, future cells will probably be of the tandem cell type because there is a high premium for high efficiency in photovoltaic solar energy conversion systems.

It should also be pointed out that PV cells have applications other than as solar energy conversion devices. The photovoltaic effect can also be used to detect small intensities of light. Since the ionizing radiation need not be light, the effect can be used to detect x-rays, beta rays, protons, etc. Studies of the spectral response of the photovoltaic effect can yield information about basic material parameters such as α, τ, and E_g. It can be used to study surface effects, radiation damage, and other phenomena in semiconductors.

PHYSICAL ACOUSTICS

Sound waves in the ideal sense are mechanical disturbances propagating in a continuous medium. The basic fact of interest from a physical standpoint is that these waves carry momentum and energy without a net transport of mass. In addition there are two other facts worth mentioning which are that sound waves propagate in almost all substances and that sound waves can be used to study the physical properties of, or to cause physical changes in the substances through which they propagate.

In practice, the approximation that natural materials are continuous fails when the wavelength is short enough to be comparable to interatomic or intermolecular distances—in a gas, the mean-free-path of a molecule; in a solid, the distance between atoms. The region of validity of the approximation that the waves are of small amplitude is more difficult to circumscribe since it depends on more than one property of the medium. In most cases, the approximation is valid when the disturbance in the velocity of the medium as the wave passes is small compared to the speed of sound in the medium. In air under normal conditions, this will occur when the pressure disturbance becomes an appreciable fraction of atmospheric pressure. In liquids and solids, however, pressure disturbances of hundreds or thousands of atmospheres propagate as small-amplitude waves. The low compressibility, or high "stiffness," of these media increase the speed of sound and at the same time require a larger pressure fluctuation to produce a given velocity fluctuation. If the medium is in a critical state, however, the definition of what constitutes a small disturbance can depend on other factors. For example, cavitation in a liquid occurs at particular sites that are called cavitation nuclei. While the reasons for the existence of these sites in a fluid are not completely understood, it is clear that they are regions that are subject to fracture at pressures far below those that would fracture the pure liquid.

The energy transported by the wave per unit area normal to the direction of propagation is called the intensity and can be measured in watts per square meter (the mixed unit, watt per square centimeter, is also in common use). A sound wave in air of intensity comparable to that of sunlight would be just beyond the pain threshold of the ear, and acoustic waves within the range of human tolerance do not produce a noticeable warming, as does sunlight. The heat generated when sound is absorbed can be measured, however, and in the design of absorbers for very high intensity sound the effect of the resulting heat production on the absorber may have to be taken into account. The principle of conservation of energy applied to energy transport by wave motion is a very useful tool, just as it is in mechanics.

The momentum transport per second per unit area is the intensity divided by the wave speed. Since this is also true for electromagnetic waves, it follows that a sound wave in air (speed 330 m/sec) of a given intensity transports about a million times more momentum than an electromagnetic wave of the same intensity. When the wave is absorbed or reflected, there is a radiation pressure on the absorber or reflector equal to the rate of change of momentum per unit area that is I/c on a perfect absorber and $2I/c$ on a perfect reflector, where I is the intensity and c the speed of sound. The measurement of this pressure is a fundamental method for measuring the amplitude of the wave.

The basic equations for a continuous medium are the continuity equation, which is an expression of the law of conservation of mass, and the Navier-Stokes equation, which relates the time rate of change of momentum in each volume element to the forces on the element. In differential form these equations are

$$\frac{\partial \rho}{\partial t} + \rho_0 \frac{\partial u}{\partial x} = 0 \quad \text{(continuity)}$$

$$\rho_0 \frac{\partial u}{\partial t} + \frac{\partial p}{\partial x} = 0 \quad \text{(conservation of momentum)}$$

The equations are presented here in one-dimensional form, and viscosity has been neglected. The inclusion of the two additional spatial dimensions and viscous effects is straightforward, and the complete equations can be found in most texts on acoustics. The dependent variables are p and ρ, the disturbances in pressure and density associated with the wave, and u, the disturbance in velocity. The parameter ρ_0 is the ambient density of the medium. In metric units (cgs) pressure is measured in dynes per square centimeter, density in grams per cubic centimeter, and velocity in centimeters per second. An additional equation is required that relates the scalar pressure to the other variables. While this third equation must be derived from the laws of thermodynamics, a relationship that is widely applicable is

$$\rho = \kappa \rho_0 p$$

where κ is the compressibility of the medium in units of inverse pressure. This relationship is useful as long as the wave does not change the value of κ appreciably. If there is no dissipation in the medium or if the dissipation is viscous, p and ρ will be in phase. In cases where dissipation exists due to irreversible heat flow, or the stress-strain relationship contains time derivatives, the equation can be retained by allowing κ to become complex. The three equations can be combined to give the wave equation

$$\left(\frac{\partial^2}{\partial x^2} - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right) f = 0$$

where $c = 1\sqrt{\kappa \rho_0}$ is the speed of propagation of the wave, and f stands for any of the disturbances, p, ρ, or u.

The wave equation is a second-order partial differential equation and as such has a unique solution only if certain boundary conditions are applied. In the case of an unbounded medium, the boundary condition is that all sources of sound must radiate energy outward, and this is sufficient to produce a unique solution. In a bounded region, reflections must be taken into account. A sufficient boundary condition is that the impedance of the boundary, defined as the ratio of the pressure disturbance to the normal component of the velocity disturbance, be specified at each point on the boundary. In simple cases, the boundary conditions can be satisfied by a superposition of elementary solutions. The impedance tube is an example of a case where plane waves are used to measure the reflective and absorptive properties of a sample placed at one end of the tube in terms of the incident and reflected waves. The details of the distribution of sound in an auditorium, however, can be a complex problem. Another approach is to reformulate the equations as an integral equation containing the boundary conditions explicitly. This integral equation, a mathematical expression of Huygens' principle, is known in acoustics as Kirchhoff's formula. A third approach is to include the boundary conditions in the differential equations. An example of this procedure is the propagation of sound in a duct of varying cross section. If the change in width of the duct per wavelength is small compared to the wavelength of sound in the duct, the shape of the duct can be introduced into the continuity equation. This procedure leads to the "horn equation" which describes sound propagation in flared ducts. The subject of boundary conditions is further complicated by the fact that waves may propagate in the boundary itself. A boundary characterized by the fact that each point behaves independently is called a locally reacting boundary. If neighboring parts of a boundary interact to support wave motion, the boundary is non-locally interacting, and if the wave speed in such a boundary is higher than in the medium, energy can propagate along the boundary and leak back into the medium. In such a case, the wave may find a shorter time travel path through the boundary than through the medium itself.

Sound waves are generated in regions where time-varying forces act on the medium. While in some cases it may be convenient to think in terms of boundary conditions, this is not always convenient or even possible. A moving piston, such as the cone of a loudspeaker, can be thought of as a boundary condition in that the normal velocity, or pressure gradient, is specified. Sound generated by a region of turbulence, however, cannot be treated in this fashion because the source strength is distributed over the entire turbulent volume and not restricted to a surface. In fact, in the region of turbulence it is difficult to separate the motion of the medium into hydrodynamic and acoustical components. If the mechanism of sound generation is confined to a definite region, it is natural to describe the sound field at a distance in terms of spherical harmonics, and the amplitudes of these harmonics can be related to integrals of moments of the motion of the medium taken over the source region. The most simple natural source, the monopole, can be described as a periodic injection and removal of mass at some point in the medium. In a stationary medium, the wave fronts are concentric spheres and the pressure disturbance is proportional to the time rate of change of mass flow. The next higher spherical harmonic, the dipole, is related to the net fluctuating force on the medium. For example, if an airfoil is subject to fluctuating lift and drag forces, there are equal and opposite forces exerted on the medium. These forces give rise to dipole sound radiation, and the sound pressure is proportional to the time rate of change of the forces. The sound fields generated by turbulence and by earthquakes are related to the integral of shear motions over the source volume and have a quadrupole distribution.

If the ambient properties of the medium are everywhere the same, the medium is said to be homogeneous. A uniform translational motion of the medium, however, deserves special attention. While a suitable coordinate transformation can remove a translational motion without changing the basic equations, such a transformation does not remove relative motion between the medium and any sources or receivers, and such motion causes the medium to be anisotropic. Although a receiver is never completely passive, the usual approximation is to assume that it is. In this case, the receiver has no physical effect on the medium and simply registers what it sees. A source, on the other hand, is contributing energy and momentum to the medium, and the distribution of these quantities is affected by the motion. Surfaces of constant phase are carried along by the medium in the same way as ripples from a pebble dropped in moving water, and for a monopole source at rest in a moving medium, they form spheres centered a distance RU/c downstream from the source, where R is the radius of the sphere, U the speed of the medium, and c the speed of sound in the medium at rest. The surfaces of constant pressure for such a source, on the other hand, are ellipsoids of revolution centered at the source with the minor axis in the flow direction. It follows that the pressure is greater to one side than it is at an equal distance either upstream or downstream. In general, the problem is complicated by the fact that the energy flow vector is not perpendicular to a surface of constant phase.

The dispersion relationship for acoustic plane waves relates the phase velocity and attenuation (or growth) of these waves to physical properties of the medium. Classically, the important parameters for a fluid are viscosity and heat conduction. While a general solution including these parameters leads to a sixth-order polynomial, in cases where they are small the problem can be solved to a good approximation by three pairs of roots representing two plane waves, two viscous shear waves, and two thermal waves. The plane waves, traveling in opposite directions, are attenuated slightly by viscosity and heat conduction. The shear waves and thermal waves are not excited in the bulk of the medium. At boundaries, the shear and thermal waves will exist, however, to satisfy tangential velocity and thermal boundary conditions. While the viscous and thermal waves exist only in thin boundary layers (the real and imaginary parts of the propagation constant are equal), they may be responsible for a major part of the absorption. For example, in the case of plane waves propagating in the air in a pipe the ratio of boundary absorption coefficient to bulk absorption coefficient is about $10^8/Lf^{3/2}$ where L is the ratio of the area of the pipe to its perimeter and f is the frequency. For very narrow pipes, the ratio is larger.

In general, the measured value of attenuation of plane waves exceeds the classical predictions based on heat conductivity and viscosity. The discrepancy varies not only from one substance to another but also may depend on the past history of the substance. The additional attenuation is caused by (and reflects) interactions between particles on a small scale compared to a wavelength—in other words, between individual atoms, molecules, or groups of molecules. The problems are as various as the chemical properties of matter.

In solids, it has been shown that dissipation usually is related to departures from ideal crystalline structure on a relatively large scale. Annealing greatly reduces the attenuation of sound. In fluids, it has been shown, however, that attenuation can be related to interatomic binding forces as well as the forces binding clusters of molecules. The vibrational relaxation of O_2 in air and of magnesium salts in water, for example, can account for the excess attenuation of sound waves in the atmosphere and in seawater.

PHYSICAL CHEMISTRY

Physical chemistry is that branch of chemistry concerned with the rationalization of chemical properties in terms of the underlying physical processes. A distinction is sometimes made between physical chemistry and chemical physics, the former being the behavior of matter in bulk, and the latter the study of individual molecules. The physical chemist is closely involved in devising techniques for and then interpreting the results from spectroscopy, measuring and accounting for the rates of chemical reactions and their response to the conditions, and determining (both experimentally and theoretically) the structures and properties of molecules. A convenient division of the subject is into studies of (a) equilibria, (b) structure, and (c) change, and this article is arranged accordingly.

The subject may be traced back to the earliest quantitative measurements on bulk matter (by Boyle). It developed particularly during the nineteenth century, largely through studies of solutions and the rates of reactions, and the first Nobel Prize in chemistry was awarded to a physical chemist (the Latvian Ostwald). The subject took its modern form only when quantum mechanics became established, and modern chemistry draws heavily on the techniques of quantum mechanics, statistical mechanics, and techniques of investigation often drawn from physics, but normally heavily adapted in the process.

Equilibrium By "equilibrium" is meant the application of classical thermodynamics to chemical systems. Initially this took the form of assembling a large body of calorimetric information on enthalpies and entropies of compounds. The justification and motivation of the former lies in the First Law of thermodynamics (that energy is conserved), and its implication that the energy change associated with a chemical reaction is independent of the reaction pathway. This means that from tabulated values of the internal energies (more usually, the enthalpies) of the compounds on each side of a chemical reaction (e.g., of the enthalpies of methane, oxygen, water and carbon dioxide in the reaction $CH_4 + 2O_2 = CO_2 + 2H_2O$) it is possible to predict the quantity of energy required for or available from the reaction, even though the reaction itself has not been studied. This is of importance for the analysis of biological and industrial processes. Modern techniques of calorimetry now permit the measurement of the enthalpies of microgram quantities of substances, a sensitivity important for the investigation of biochemically important compounds. Calorimetry is also an important technique for the measurement of the entropies of substances, a procedure motivated by the Second Law of thermodynamics (that entropy increases during a spontaneous change). This time the heat capacity of the substance is measured down to as low a temperature as possible, and the data manipulated to give a value of the entropy of the substance relative to its value at the absolute zero of temperature. The Third Law of thermodynamics (that the entropies of perfect crystals are identical at $T = 0$) enters chemistry at this point, for not only does it enable the entropies of perfect substances at absolute zero to be chosen as zero, it also permits the establishment of tables of the Gibbs function (G, which is also called the "free energy").

The Gibbs function is the most important thermodynamic function in chemistry. Its formal definition is $G = H - TS$, where H and S are the enthalpy and the entropy of the system and T its thermodynamic temperature (i.e., its temperature in the Kelvin scale). Since H and S may be measured calorimetrically, G may be tabulated. (The fact that we do not know H on an absolute scale is circumvented by dealing with the enthalpies of compounds relative to their elements: this entails the technicality of dealing with enthalpies of formation, and hence Gibbs functions of formation; but this is a detail that need not affect the present discussion.) The reason why G is so important is that it carries information about the direction of natural change of a reaction (e.g., as to whether the reaction $CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$ or $CO_2 + 2H_2O \rightarrow CH_4 + 2O_2$ is the spontaneous direction) under conditions of constant temperature and pressure. The basis for its ability to act as a signpost for spontaneity is the Second Law. This law, however, expresses the criterion for spontaneous change in terms of the entropy of the universe (in practice, the reaction system and its surroundings). The Gibbs function transforms this criterion into a statement involving the properties of the system itself, and the change of entropy of the surroundings does not have to be taken into account explicitly. This means that the table of values of Gibbs functions can be used, almost at a glance, to decide the natural direction of a reaction. The usefulness of this is partly that the ability can be assessed of one reaction to drive another which is spontaneous in the "wrong" direction, and this is particularly fruitful in the analysis of processes within living cells.

Another role for G is that it can be used to predict the composition of systems that have come to equilibrium (and show no further tendency to react). The explicit criterion is so important that it deserves to be stated here. First, the composition of a reaction $a\mathrm{A} + b\mathrm{B} = c\mathrm{C} + d\mathrm{D}$ that has reached equilibrium is expressed in terms of the quotient $K = [\mathrm{C}]^c[\mathrm{D}]^d/[\mathrm{A}]^a[\mathrm{B}]^b$, where $[\mathrm{X}]$ is the concentration of species X. K is called the *equlibrium constant* for the reaction. Next, one constructs from tables of Gibbs functions the quantity $\Delta G = (cG_\mathrm{C} + dG_\mathrm{D}) - (aG_\mathrm{A} + bG_\mathrm{B})$, but one uses the values appropriate to a particular set of standard conditions, and hence obtains a standard value of ΔG, denoted $\Delta G^\ominus$. The relation between K and $\Delta G^\ominus$ at the temperature of interest is then given by the *reaction isotherm:*

$$K = \exp(-\Delta G^\ominus/RT), \quad \text{or} \quad \Delta G^\ominus = -RT \ln K, \qquad (1)$$

where R is the gas constant. Therefore, not only can K be predicted from tables of data, since standard thermodynamic relations give the dependence of ΔG on the conditions, the dependence of K on the conditions of the reactions (e.g., its temperature) can be predicted. For example, the temperature dependence of K is given by the *van't Hoff equation:*

$$d \ln K/dT = \Delta H^\ominus/RT^2, \qquad (2)$$

where $\Delta H^\ominus$ is the enthalpy change under the appropriate standard conditions. Hence the effect of temperature (and other factors) can be predicted.

One complication with the direct application of these expressions is that the statement of the equilibrium constant in terms of the concentrations is only an approximation. The assumption has been made that the Gibbs function of a substance in a mixture depends on its concentration as $G = G^\ominus + RT \ln [\mathrm{X}]$. (The equation gives only the general form of the relation: we are avoiding precise details.) This relation is valid when the species do not interfere with each other; the more general relation is $G = G^\ominus + RT \ln a_\mathrm{X}$ where a_X is the *activity* of species X. When K is expressed in terms of activities Eq. (1) is thermodynamically exact; but it becomes useful only when a_X and $[\mathrm{X}]$ can be related. Much modern work has explained the connection between activities and concentrations, and has sought to find relations in terms of the intermolecular forces. The problem is particularly vexatious for reactions (and thermodynamic properties in general) of ions in solution, because the coulombic interactions between ions has a long range, and so deviations from ideality are large. An early attempt to relate a_X and $[\mathrm{X}]$ was made by Debye and Hückel, and in the case of a salt of the form $\mathrm{M^+A^-}$ they deduced that, in water at room temperature,

$$a(\mathrm{M^+})a(\mathrm{A^-}) = [\mathrm{M^+}]\,[\mathrm{A^-}]\,e^{-1.02\sqrt{c}} \qquad (3)$$
$$c = [\mathrm{M^+}] = [\mathrm{A^-}]$$

in the limit of low concentration. (In fact they deduced a more general limiting law; this is a special case.) Little further real progress of practical importance has been made in this direction, although techniques based on those developed for plasma physics have been explored.

The Gibbs function also plays a central role in the branch of equilibrium studies known as *electrochemistry.* A chemical reaction involving ions can be thought of as proceeding by the transfer of electrons from ions of one species to ions of another. When this takes place in bulk solution the direction of spatial motion is random. In an electrochemical cell the reacting species are separated, and the reaction proceeds when the donor ions deposit their electrons in an electrode, travel through an external circuit, and attach to the acceptor ions in its vicinity. The reaction proceeds as before, but the electronic motion has been channeled through a wire, and appears as an electric current. The Gibbs function determines the natural direction of change. In this application it is normally expressed in terms of the electromotive force (e.m.f.) of the cell, and that in turn is normally expressed in terms of the electronic potentials of the electrodes (and electrolyte) it is built from. Standard electrode potentials are tabulated, and so the standard e.m.f. of any cell can be predicted. Its e.m.f. under different conditions of concentrations of species in the electrolyte is expressed in terms of the *Nernst equation*, which for an electrode at which the reaction is $X^+ + e^- \rightleftharpoons X$ is

$$E = E^{\ominus} + (RT/F) \ln (a_{X^+}/a_X), \qquad (4)$$

F being Faraday's constant ($F = eL$), e the magnitude of the electron's charge, and L Avogadro's constant). The thermodynamic consequences of this equation are exact; the practical applications (the prediction and interpretation of cell e.m.f.'s) depend on the ability to relate a_X and $[X]$.

Equilibrium e.m.f. studies are of wide importance. Note only do they permit the elucidation and prediction of the potential difference between cell electrodes, but they also allow the assessment of the relative reacting power of ions (which is important, among other things, for studies of corrosion), and the measurement of the thermodynamic properties of ions in solution. Many biological processes depend on the electrical potential difference across membranes (even thinking about electrochemistry involves electrochemistry). The development of fuel cells, an important feature of modern technology, depends at least in part on an assessment of their electrical potential in terms of equilibrium-processes; but, as in all working devices, their effectiveness can be improved only on the basis of studies of their nonequilibrium behavior, and to that we shall return.

Structure The quantitative discussion of molecular structure (and the properties of individual molecules) required two stepping stones for its emergence. The first was the development of the concept of the atom, and the realization that it was not indivisible but had structure. The second was the establishment of quantum mechanics, and its application to calculations of atomic and molecular structures and properties.

Atomic structure is a part of physical chemistry in so far as a knowledge of the distribution of electrons and their binding energies is important for assessing their role in chemical bonding. The theory of the chemical bond—its strength, why atoms form a characteristic number of bonds, and the shapes of the resulting molecules—is called *valence theory*. It emerged with the emphasis put on the role of electron pairs by G. N. Lewis, and then took quantitative form with the theories of molecular structure known as *valence bond theory* and *molecular orbital theory*. Both theories are models of the structures of molecules; the latter has been much more richly developed, and we shall confine attention to it.

Molecular orbital theory adopts the view that the distributions of electrons in molecules can be regarded as described by wavefunctions (orbitals) spreading throughout the nuclear framework (which, as a first approximation, is assumed to be frozen into a static array). These orbitals are then obtained by solving the Schrödinger equation; but since there are numerous electrons present, approximation procedures are essential. A common procedure is to model the molecular orbital as a linear combination (sum) of atomic orbitals, the coefficients being determined by a self-consistency procedure. This gives rise to the Hartree-Fock (HF) self-consistent field (SCF) linear combination of atomic orbitals (LCAO) molecular orbitals (MO); or, in a word, HF-SCF-LCAO-MO's. While excellent progress has been made with absolute calculations of structures (the so-called *ab initio* approach, drawing on no empirical data), *semi-empirical techniques* (which use empirical data to estimate the magnitudes of some quantities, and neglect others) are widely and successfully used to account for molecular shapes, electron distributions, properties, and, increasingly, reactivities. This field is the branch of physical chemistry generally called *quantum chemistry*. Sometimes quantum chemistry itself is regarded as divided into computational quantum chemistry, which deals with the computational aspects of molecular structure, and noncomputational quantum chemistry, which is concerned with the mathematical as distinct from the numerical analysis of molecules.

Quantum mechanics is also inextricably interwoven with one of the most important of the modern branches of physical chemistry, the identification of molecules and the determination of their structures by spectroscopy. The physical chemist contributes to about half a dozen different classes of spectroscopic technique. *Microwave spectroscopy* is used to study the rotational transitions of molecules in the gas phase, and is used to obtain precise information about bond lengths and bond angles. *Infrared spectroscopy* is the study of vibrational transitions: its qualitative application is to the identification of species by interpreting their infrared fingerprint (their characteristic vibrational absorption spectrum), and its quantitative application is to the determination of the rigidities of bonds. *Optical and ultraviolet spectroscopy* studies electronic transitions, and is used to investigate excited electronic states of species. *Mass spectrometry* examines ions emerging from the fragmentation of molecules and, by monitoring their deflection in electric and magnetic fields, is used to determine their masses, and hence to infer the identity of the parent species. An offshoot of mass spectrometry is *photoionization spectroscopy*, in which the energies of electrons are measured after they have been ejected from a molecule by light of precisely controlled energy. Photoelectron spectra give information about the binding energies of electrons. The final principal class of spectroscopy consists of the *resonance techniques*. In a resonance spectroscopy experiment, a system of energy levels is tuned to the frequency of a transmitter and the power absorption increases dramatically when they match exactly (as in tuning a radio). Two cases involve using a magnetic field to tune the system. When the field acts on the magnetic moments of nuclei the technique is called *nuclear magnetic resonance* (NMR). When it is applied to electrons it is called *electron spin resonance* (ESR). The former has been richly developed to give a technique for identifying organic molecules (through the absorption patterns their protons give rise to), and its present development is to the determination of the structures of biological macromolecules, making use of the resonance of an isotope of carbon (^{13}C). Another resonance technique is *Mössbauer spectroscopy*, where the Doppler effect is used to tune nuclear energy levels to γ-ray emissions.

Apart from spectroscopy, the major techniques for studying molecular structures are those based on diffraction. Of these the most important is *X-ray diffraction*, which although it began with simple applications to simple inorganic crystals, is now (thanks to increases in computing power and improvements in techniques) capable of establishing the structures of biologically important molecules. Present day molecular biology could not have emerged without the existence of this technique. In one sense, diffraction techniques (which include electron diffraction and neutron diffraction) are complementary to spectroscopy, because while the later establishes energy levels (technically, eigenvalues) the former establishes electron distributions (technically eigenfunctions), and eigenvalues and eigenfunctions are the two aspects of the solution of the Schrödinger equation of a molecule.

Physical chemistry also provides techniques for the study of macromolecules, either synthetic (as in polymers) or natural (as in proteins). Size and shape are the principal targets of investigation, and both can be explored, at least in broad outline, by methods based on sedimentation rates and equilibrium, by light scattering, and by their effects on the viscosity of the solution. While these have been classical techniques of great usefulness, they are being displaced by techniques based on diffraction and magnetic resonance, for they can yield information of much better quality.

At this point in the survey we have two streams of information. One concerns the thermodynamic properties of bulk systems; the other concerns the characteristics of individual molecules. The fusion of the two streams is the domain of *statistical thermodynamics* (or *statistical mechanics*). Statistical mechanics deals with the energy levels of systems, and uses them to arrive at the thermodynamic properties. In effect, this means that it is possible to predict equilibrium constants of reactions (a typical "physical chemistry" property) on the basis of the spectroscopic data on the molecules involved (typical "chemical physics" properties). The key concept linking the two is the *partition function Q*, which can be expressed in terms of energy levels. For instance, if the system is a gas of N molecules with energy levels $E_1, E_2, \ldots$, the partition function at a temperature T is

$$Q = \left(\sum_n e^{-\beta E_n}\right)^N \Big/ N!, \qquad \beta = 1/kT \qquad (5)$$

where k is Boltzmann's constant. With Q known it follows that the internal energy and entropy are given by

Internal energy:

$$U(T) = U(0) - (\partial \ln Q/\partial\beta)_V \qquad (6)$$

Entropy:

$$S(T) = [U(T) - U(0)]/T + k \ln Q, \qquad (7)$$

and hence all the thermodynamic functions (e.g., G, and then the equilibrium constant) may be calculated. A particularly important field of statistical thermodynamics involves the evaluation of thermodynamic properties for systems consisting of interacting molecules. In particular, statistical techniques are used to study gas imperfections and, at higher densities, liquids. The interface between these two phases is of increasing interest in modern physical chemistry, where by "interface" we mean both the physical interface, the surface, between them and the thermodynamic interface, the characteristics of the transition between them (the *phase transition*).

Change Change takes a variety of forms. There is physical change, when a property is transported from one region to another. This is the domain of *transport properties*, the medium (for physical chemistry) being a gas (and giving rise, for instance, to viscosity and its dependence on intermolecular forces), an electrolyte solution (giving rise to ionic conductivity and being interpreted in terms of ionic mobility), and the transport of one phase past another (giving rise to the processes involved in the important preparative and analytical technique of *chromatography*). There is also the domain of chemical change, in particular, the measurement, and interpretation, and predictions of the rates of chemical reactions.

The rate of a chemical reaction is defined as the rate of change of the concentration of species (there are more sophisticated definitions). In general it varies during the course of the reaction, but extensive studies have shown that the rate is often proportional to the concentrations raised to various powers; for example,

$$d[\mathrm{A}]/dt = -k_2[\mathrm{A}][\mathrm{B}]. \qquad (8)$$

The quantity k_2 is called the *rate coefficient*. The role of empirical chemical kinetics is to establish the *rate law* for the reaction, to measure the rate coefficient, and to account for the rate law in terms of the *mechanism* of the reaction, the sequence of individual steps through which the reaction proceeds. The temperature dependence of the rate is also an important quantity, and it normally found that it can be expressed as the *Arrhenius law:*

$$k_2 = Ae^{-E_a/kT}, \qquad (9)$$

where E_a is the *energy of activation*. Modern physical chemistry is increasingly concerned with observations on very fast reactions, and its employment of laser techniques has enabled the time scale of studies to be reduced to the order of 10^{-12} s.

The parameters k_2, E_a, and A are investigated theoretically in a variety of ways. One way is to use statistical thermodynamics. This leads to the *Eyring equation* for the rate coefficient:

$$k_2 = (kT/h)K' \qquad (10)$$

where K' is related to the partition functions of the reactants and a weakly bound complex of them, the *activated complex*, they are presumed to form on the route to products (K' is closely related to an equilibrium constant between the activated complex and the reactants). There are numerous difficulties associated with the application of this expression (as well as doubts about its basis), and attention now centers on treating a chemical reaction in the gas phase as an aspect of a scattering event, when groups and atoms are exchanged between molecules during an energetic collision. The theoretical studies of such events are called *molecular reaction dynamics*, and the experimental studies center on *molecular beams*, which are low-density streams of molecules shot either at a target or at another beam.

More specialized rate studies include the role of surfaces (in *catalysis*), and it is now possible to discern the structure of species attached (*adsorbed*) to surfaces, often in a state (e.g., with bonds broken) where they are ripe for reaction. Studies of the effect of using surfaces as targets for molecular beams are also being used to discover details about the relation of surface structure and surface activity. A special class of reactions at solid surfaces are those involved in electrochemistry: an electrode in contact with an electrolyte is the site of the processes involved in power generation, and in recent years attention has turned to this aspect of electrochemistry, the details of the relation between the structure of the electrode/electrolyte interface and its role in the chemical (and photochemical) generation of electricity under conditions far from equilibrium.

Conclusion Physical chemistry stands squarely between physics and chemistry. It imports techniques and fundamentals from physics, and applies them to problems of chemistry. Increasingly it is becoming involved in biology, for its special ability lies in the quantitative procedures and understanding it can bring to the discussion of chemical, industrial, and now biological processes.

PHYSICS

Physics can be defined as the branch of natural science that treats those phenomena of material objects included in the subjects of mechanics, properties of matter, heat, sound, light, electricity and magnetism, and molecular and atomic processes. It describes and correlates energy and radiation, and has been defined as the study of matter and energy. It usually omits animate matter and processes involving changes in chemical composition. While such definitions attempt to distinguish between physics and other sciences, it should be stressed that physics is not set off by itself, but is very closely related to other sciences, and there is a good deal of overlap with their spheres of interest. In some cases the differences are partially matters of emphasis. Chemistry stresses the regrouping of atoms to form new compounds, while physics selects a particular substance and studies its behavior.

Biology restricts its interest to living organisms, while physics largely omits them from its consideration. Geology confines its investigations to the earth itself and the inanimate material of which it is composed. Astronomy, on the other hand, finds its major interest in the vast expanses of space that run on and on away from the earth.

The extent to which these sciences overlap is shown by the special branches of science dealing with borderline areas. Astrophysics treats physical phenomena as they occur in regions beyond the immediate vicinity of the earth. It includes studies of the physical processes in stars and of the nature of the radiations they emit. Physical chemistry, as its name implies, covers phenomena common to both physics and chemistry. Energy relations in chemical reactions and the effects of changes in temperature or pressure on the reactions are samples of the topics included. Geophysics relates physics and geology, and involves studies of the earth's magnetism and the effects of high pressure in the earth's interior. Biophysics deals with the physical processes that are of specific interest to the study of living organisms. Each of these fields has grown to include a vast array of scientific knowledge, and each is discussed in a separate article in this book.

The field of engineering is closely related to physics and other sciences. In general, it can be said that as knowledge about some specific topic grows to the point where use can be made of it in every-day life or in industrial processes, the topic passes over to engineering, and engineers develop and improve things using the basic information. Scientists concern themselves with the basic phenomena themselves, while engineers direct their efforts toward the solution of problems dictated by specific applications.

Historical Background The word "physics" can be traced to the Greek word *physos*, meaning nature. All studies about nature were grouped together by the Greek philosophers, but in many cases theories suffered from a lack of experimental research, so that the name, "natural philosophy" was more descriptive of their efforts than a name such as "natural science" would have been.

A summary of the important features in the development of physics from its early beginnings to the present advanced state can be found in the article on HISTORY OF PHYSICS.

Major Divisions of Physics For purposes of study, physics can be reasonably well divided into major areas, which will be discussed briefly here and in greater detail in other articles in this book.

Mechanics is the science of the motions of material bodies, the forces which produce or change these motions, and the energy relations involved. Newton's three laws of motion and his law of gravitation form the foundation of this study. Work, momentum, vibration, wave motion, pressure, elasticity, and viscosity are other topics considered to be parts of mechanics.

Heat is the energy which an object possesses by virtue of the motions of the molecules of which it is composed plus the potential energy resulting from interatomic forces. The field is of great importance to other areas of learning, as well as to physics, and appears as a topic in chemistry and engineering. The term heat is also used in a different but related sense to indicate energy in the process of transfer between an object and its surroundings because a difference exists between their temperatures. Thermodynamics is the name given to the study of the relationships between heat and mechanics.

Acoustics is the science of sound. Sometimes wave motion is studied under acoustics rather than under mechanics because sound provides good illustrations of wave motion. Objects which are in vibrating motion in a medium can set that medium in motion, and the disturbance can travel through the medium in the form of a wave. Energy is transferred without the transfer of particles of the medium. Sound is the type of wave motion which has such a frequency that, if it reaches a human ear, it can cause a stimulus to reach the brain and hearing results. Thus, to the physicist, sound is the wave motion itself. Sound can also be defined as the sensation produced when sound waves reach the ear. Because both definitions are in common use, care must be taken to avoid confusion.

Light is the particular part of the gamut of electromagnetic waves to which the eye responds. Here, varying electric and magnetic fields travel through a vacuum or a transparent medium. The energy travels in even multiples of specific small amounts called "quanta." Related to light are infrared radiations, those frequencies which are just too low to cause the sensation of light in the normal human eye, and ultraviolet rays, similar radiations whose frequencies are just too high for the human eye. Optics, which is the study of light, often includes infrared and ultraviolet radiation.

Electricity and magnetism are so closely related that neither topic can be studied in any depth without involving the other. Electricity deals with the forces which charged particles exert upon each other, the effects of such forces, and the phenomena caused by the motions of charged particles. Magnetism was first known in the form of the peculiar attraction which a mineral called lodestone exerted because of the particular electron orientations in the material. It was found that magnetic effects could be caused or altered by electric currents. Further, it is possible to use magnetic materials to advantage in producing electric currents, which are streams of charged particles. An important branch of electricity is electronics, and this area has attracted the attention of more physicists in this country than any other part of physics. This subject deals with the flow of electric currents in vacuum tubes, semiconductors, and associated circuits, and with the use of these circuits to form devices of many kinds.

Solid-state physics is a well established area cutting across some of the other areas mentioned above. It includes those phenomena which are exhibited by materials in the solid state, with emphasis on electronic properties and their relations to the composition of crystalline substances and to energy levels in these materials. The designation *condensed matter physics* has found favor recently to indicate solid state physics plus liquid state physics.

Modern physics is a title under which physicists sometimes group many topics of comparatively recent development involving or relating to atoms and other submolecular particles or radiation resulting from atomic processes. Subjects which are considered here include radioactivity (both natural and artificially induced), x-rays, atomic and molecular structure, the quantum theory, wave mechanics and matrix mechanics, and nuclear fission and fusion.

Experimental physics and theoretical physics are two general categories into which the entire field of physics can be divided. The experimentalist attempts to discover new phenomena through the manipulation of apparatus and to make measurements of old or newly discovered properties. The theoretical physicist attempts to correlate measurements and to simplify theories. He tries to predict new phenomena and to relate one effect to another. Mathematical physics uses mathematics to describe physical phenomena, and extends or adapts mathematics to make it applicable to specific theories.

General discussions of major areas of physics can be found in the articles listed as cross-references at the end of this article.

Future Trends It is of course impossible to predict major discoveries in science or to foretell which areas of it will receive increased emphasis. Theoretical physicists can suggest what the experimentalist should look for, and the results of experiments can provide a confirmation of a theory or suggest where theories need revision, but unexpected discoveries continue. Present trends lead one to expect that certain areas will receive emphasis, but a new discovery or even gradual progress in an area can open up vast new vistas. Computers and computer techniques are speeding calculations of nuclear forces and some of the riddles of their existence are yielding to intensive research. Fundamental-particle physics is an area in which recent progress has been highly significant. We are just now approaching an adequate theory for these particles. (See GRAND UNIFIED THEORY). Which, if any, of the particles we know now are truly "fundamental"? And what does "charged" imply? What will even more powerful accelerators reveal? The emission of coherent radiation and its behavior combine to form an area in which effort is being accelerated. The Fermi surfaces of metals, semiconductivity and superconductivity, and other cryogenic phenomena are fruitful, lively and interesting areas. Astrophysics is a very active area and many new experiments, discoveries, and theories may be expected from this field. Pulsars, quasars, neutron stars, and black holes are new concepts, and theories about them are still fairly nebulous, and mainly unproven. Undoubtedly more and more surprises are in store from exciting new research programs.

Physics Organizations Throughout the world there are many societies and other organizations that have the objectives of advancing physics and distributing knowledge of that science. In addition, other organizations deal with broader or related fields and include physics as part of their interests. Nine societies are members of the American Institute of Physics: The American Physical Society, Optical Society of Ameria, Acoustical Society of America, Society of Rheology, American Association of Physics Teachers, American Crystallographic Association, American Astronomical Society, American Association of Physicists in Medicine, and American Vacuum Society. Other groups are affiliated. The Institute was set up to assist the societies in their activities. Many other organizations are associated or affiliated with the Institute. It maintains an Information Center on International Physics Activities and publishes an "Information Booklet on Physics Organizations Abroad." Inquiries should be sent to the director of the Information Center, American Institute of Physics, 335 East 45th Street, New York, N.Y. 10017, U.S.A. In addition, scientific personnel attached to embassies in Washington, D.C. can provide information about activities in their respective countries.

PLANETARY ATMOSPHERES

Introduction All of the planets and a few satellites have atmospheres of some kind. Their diversity reflects the wide range of planetary radii, densities and rotation rates as well as the range of planet-Sun distances. As a rule, planets

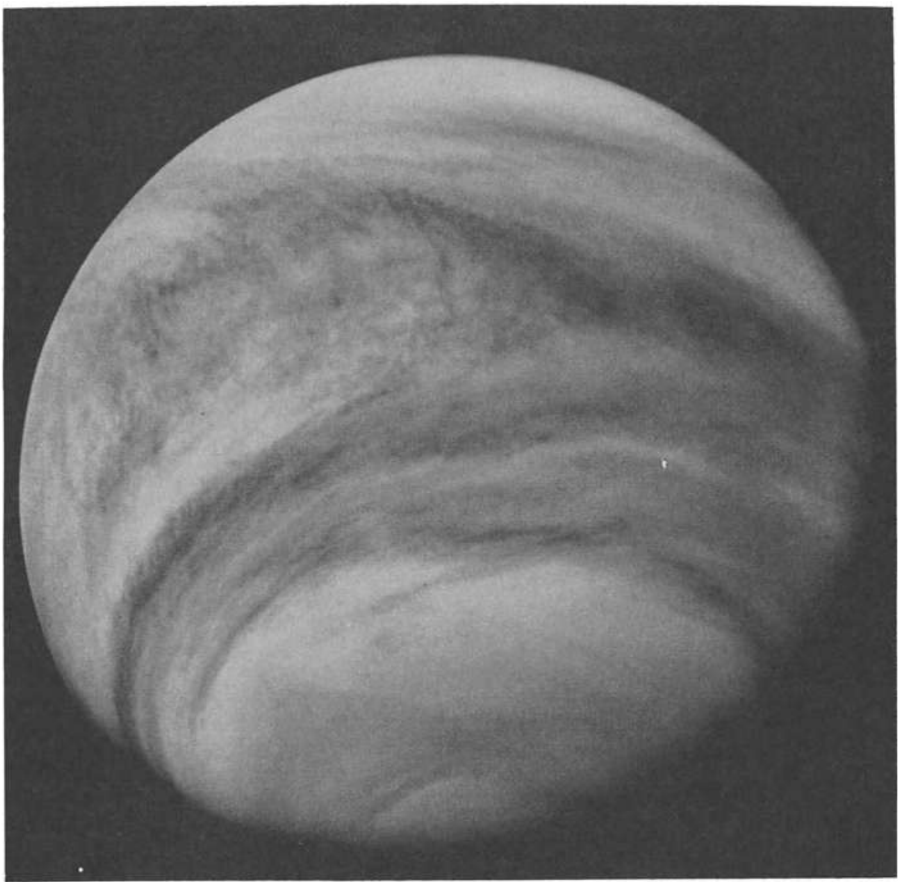

FIG. 1. Pioneer Venus image of Venus obtained on February 11, 1979 when the Pioneer spacecraft was at a point in its orbit directly above latutude 30°S. The cloud and haze patterns show the interaction between the high zonal and lower meridional winds.

stratus or cumulus clouds found on Earth. Much of the dynamics, weather, and climate of the Earth's atmosphere is driven by pressure gradiants resulting from temperature variations associated with variations in the insolation. By contrast, the surface temperature of Venus varies diurnally by less than 1 K and latitudinally by only several percent. Also, the coriolis forces on Venus are very low owing to the long rotation period (243 days, retrograde). The solar day is 117 days long so changes in insolation are very gradual. Therefore, temperature effects play a relatively minor role compared to chemical processes in the formation of the Venus clouds or weather.[4]

Most of the atmosphere is in radiative equilibrium and therefore stable against convection. Convection is found in two altitude regimes but only one of these is within the clouds. There appear to be three cloud layers: the upper cloud region, at 58–68 km altitude; the middle cloud region, at 52–58 km; and the lower cloud region, at 48–52 km. Below these, from 31 to 48 km altitude, a thin haze region exists. The regions of convective instability are 20–29 km and 52–56 km above the surface. The first is below the haze layer and produces no clouds. The latter is in the middle cloud layer and may be only indirectly related to the cloud formation by recycling evaporated aerosols to higher altitudes where chemical processes and coalescence produce large cloud droplets which precipitate to lower, hotter altitudes where they evaporate.

Cloud particle sizes appear to be trimodal in the middle and lower clouds and bimodal in the upper cloud. The biggest particles or droplets are found in the lower layers and have diameters of 7–8 μ. All layers have aerosols of 1.5–5 μ and up to 1.5 μ in separate modal distributions. The lower haze region has the smallest aerosols. The clouds consist of sulfur, various aerosols, H_2SO_4 solutions, and impurities.

Other features of the Venus clouds are their farther from the Sun are cooler. Temperature determines atmospheric bulk, composition, state and structure. Whether a volatile substance exists as a frost on the planet's surface, an ocean, a cloud, or a gas in the atmosphere depends on the temperature. Hot, small planets with low surface gravities are least likely to possess atmospheres and any long-term atmosphere on such bodies will not include gases of low molecular weight. This explains why Mercury and the Moon have no more than transitory atmospheres and why most satellites and all asteroids do not have detectable atmospheres. Mercury is too hot owing to its proximity to the sun, the Moon is too warm and too small, and the asteroids and most satellites are too small to possess appreciable atmospheres. High temperatures in the inner solar system explain why the terrestrial planets lost their primeval atmospheres during their formation and cooling. Their present atmospheres have been outgassed from their interiors after these planets had cooled substantially. By contrast, the Jovian planets formed in the cool outer solar system and so retained essentially all of their primordial gases and grew to large sizes.

Mercury Mercury, the closest planet to the Sun, rotates once relative to the Sun for every two revolutions about its elliptical orbit. Its solar day is therefore twice the length of its year. Because of its long day and proximity to the Sun (46 to 69 million km), Mercury is too warm to retain more than a very tenuous atmosphere. While the surface temperature drops to 90–100 K during Mercury's long night (88 Earth days), the dayside temperature gets as high as 700 K. At such high temperatures, most atmospheric gases which were present when Mercury was young should have since escaped.

Mariner 10 has detected an extended, tenuous, and transient atmosphere for Mercury consisting of at least H and He.[1] It is supplied by the solar wind and escapes rapidly. The residence time for the He atoms trapped in the atmosphere is only 200 days. Surface densities of He derived from the Mariner 10 measurements are 1.3×10^3 atoms cm^{-3} on the dayside and 2.6×10^5 atoms cm^{-3} on the nightside. The corresponding values for the Moon are 2×10^3 and 4×10^4 atoms cm^{-3}, respectively, so Mercury and the Moon have exospheres of similar density. Hydrogen is present only in trace amounts (~ 8 cm^{-3}). Mariner 10 set stringent upper limits on Ar, Ne, Xe, C, and O. Upper limits on CO_2 and H_2O emissions imply that Mercury's outgassing rates for these gases are four orders of magnitude less than the Earth's rates. Mercury's total surface pressure is less than 2×10^{-10} mbar and atmospheric column density is less than 2×10^{13} atoms cm^{-2}.

Venus Of all the planets and satellites in the solar system with solid surfaces. Venus has the thickest atmosphere (see Fig. 1). The Venera and Pioneer Venus probes[2,3] agree that the surface pressure is in the neighborhood of 90 atm, depending on the topography. The turbopause, where the lighter gases begin to separate from the heavier ones is 140 km above the surface. The exobase, where atoms escape to space, is at an altitude of 160 km. The dominant gas of Venus' atmosphere is CO_2; its concentration is 96.4% in the lower atmosphere and 95.4% in the upper atmosphere. The next most abundant gas is N_2 with concentrations of 3.4 and 4.6%, respectively. Water vapor is the third most abundant gas but its concentration varies with altitude. Results of the Pioneer Venus sounder probe suggests a maximum concentration near 42 km altitude of 0.52%. The Venus atmosphere is therefore very dry. Small amounts of O_2 have been detected as well as trace amounts of NH_3, SO_2, CO, Ar, Ne, H, HCl, HF and H_2SO_4. The atmospheric gases appear to be fairly well mixed. As for Mercury, the H in Venus's upper atmosphere is deposited by the solar wind rather than by photodissociation of H_2O. Unlike the Earth, Venus has no ozone layer; the solar UV radiation penetrates deep into the atmosphere and is absorbed mostly in and above the cloud regions. Nonradiogenic Ar in Venus' atmosphere is 200–300 times more abundant than in the Earth's atmosphere. Its abundance on Earth, in turn, is greater than its abundance on Mars. This trend suggests that the primordial nebula out of which these planets formed was not as hot near its center as supposed. Sulfur dioxide (SO_2) is the dominant sulfur-bearing gas. Solutions of sulfuric acid in water form a prime component of the clouds.

The atmosphere of Venus is one of the most chemically complex and dynamically active atmospheres in the solar system. Photochemical processes dominate in the upper atmosphere (at and above the clouds) owing to the relatively deep penetration of solar UV radiation as compared with the Earth's atmosphere with its protective ozone layer. Because of the thickness of the clouds, however, only 2% of the incident sunlight reaches the surface. Photochemical processes are therefore not important below the clouds. On the other hand, a very effective greenhouse mechanism operates in Venus' atmosphere as a result of the thermal opacity of the CO_2, SO_2, and H_2O present. They drive the surface temperature to 750 K, hotter than the sunlit side of Mercury! The high temperatures of the lower atmosphere cause thermochemical processes to dominate there. End products of these reactions may be a very corrosive acid rain capable of chemical weathering of the surface topographic features.

The clouds of Venus are fundamentally different from the clouds of Earth. They are produced by chemical processes rather than by convective uplifting coupled with phase changes. They are related more to smog than to the persistence and global uniformity. These reflect their chemical origin and the global near-uniformity of temperature at a given pressure level deep in the atmosphere. Venus' surface is never visible. There is probably little or no surface precipitation; the chemical products of the clouds apparently are not transported to the surface.

Lightning and thunder have been observed in Venus' atmosphere but these probably originate from processes other than thunderstorms since atmospheric processes which produce strong updrafts are unlikely on Venus. Again, chemical processes are probably the cause.

Above 90 km, Venus' winds are predominantly easterly and of high speed, 200 m s^{-1}. They flow around the planet in about four days. Within the clouds, where most of the solar energy is deposited, the circulation is meridional, as in Hadley cells, with speeds of about 25 m s^{-1}. Near the surface, the winds are calm. Near the top of the clouds, the zonal and meridional components of the wind cause these clouds to spiral around the planet towards the poles. The high speed zonal winds transport products of photodissociation of nitrogen and oxygen compounds to the night side of the planet where they recombine and cause the weak UV night-glow which is observed there.[4]

Mars The best information on the atmosphere of Mars has been obtained by Viking 1 and 2 orbiters and landers.[4,5] They measured an atmospheric composition of 95.3% CO_2, 2.7% N_2, and 1.6% ^{40}Ar. In addition, small quantities of O_2, CO, and H_2O exist in the Martian atmosphere. Trace gases include Ne, Kr, Xe, and O_3. The proportions of Ne, Kr, and Xe are the same as in the Earth's atmosphere. The heavier isotopes of Xe are probably absorbed onto surface material. Greater amounts of gas than are presently observed probably outgassed from the planet. Present escape rates of H to space from photodissociation of H_2O imply that as much as 10^4 g cm^{-2} of H_2O may have outgassed from the planet. Like the Earth, Mars has an upper layer of O_3 in its atmosphere. This results from the photodissociation of CO_2 and reaction of O atoms.

In contrast to the Earth's atmosphere, the atmosphere of Mars has very little solar heating of the stratosphere or thermosphere. Near the surface, the temperature ranges from 133 to 250 K over the globe. At the lander sites, the vertical temperature profiles are subadiabatic (fall off more slowly with altitude than the adiabatic lapse rate of 4.5 K/km) and are warmer than the CO_2 condensation temperature. Absorption of solar radiation by dust at low altitudes may help to stabilize the subadiabatic lapse rate. Over the polar caps, the surface temperature is essentially the temperature of CO_2 ice in the polar caps, except in northern summer when the residual north polar cap is mostly H_2O ice. This implies that the bulk CO_2 content of Mars' atmosphere is controlled by the temperature of the polar caps. This is supported by the seasonal variation in the daily average surface pressure at the Viking lander sites. Lander 1, located at latitude 22.5° N, observed the pressure to vary from a minimum of 6.7 mbar just before Mars' autumnal equinox to a maximum of 9.0 mbar at the winter solstice, which is close to perihelion. Lander 2, located at latitude 48° N, observed a parallel pressure variation of 7.4 mbar and 10.0 mbar, respectively. The terrain height difference explains the pressure differences. The minimum corresponds to the time of maximum CO_2 accumulation in the southern polar cap at the end of its winter. The seasonal variation in the pressure is asymmetrical because of Mars' large orbital eccentricity (0.093). It causes Mars to receive 40% more sunlight at perihelion than at aphelion. A long, cold southern winter and a short, warm northern winter result. Consequently, the southern polar cap grows to a greater size than the northern one does and the atmosphere actually has its greatest bulk during the northern winter! The diurnal pressure variation at the lander sites was typically 1–2% but doubled during the planetwide dust storms which reached a vertical optical depth of 3 and greater. These reflected changes in the amplitude of the thermal tides are due to heating by the dust and due to the winds generated.

The surface winds are diurnally variable and typically have small daily mean values. They vary from about 2 m s^{-1} at night to typically 7 m s^{-1} during the day. Dust storms imply wind speeds in excess of 50 m s^{-1} in order to raise the dust off of the surface. Wind speeds in excess of 75 m s^{-1} are required to form the sand dunes observed at high latitudes. Summer cloud motions at 15–25 km altitude reveal westward winds of 30–55 m s^{-1} in the tropics. An intense eastward jet at 20 km altitude and 48°S reaching 120 m s^{-1} was inferred from Mariner 9 orbiter infrared measurements. Meridional winds also exist. Indirect evidence supports an inferred circulation analogous to that in the Earth's tropics. During the solstice, a low flow towards the summer pole may occur, rising in the subtropics and returning to descend in winter midlatitudes.

The moisture content varies seasonally and latitudinally; it is maximum at high northern latitudes during its early summer. There appears to be a supply of H_2O somewhere in the northern hemisphere, perhaps in a permafrost reservior. Although the south polar cap is essentially all CO_2 ice, the residual north polar cap is largely H_2O ice. Water clouds, fogs, and frost have been observed along with CO_2 frosts. Clouds of H_2O and CO_2 form hoods over the polar caps in winter. Clouds sometimes form in the lee of mountains or volcanoes. Fogs and frost are transitory; they disappear soon after sunrise. Fogs form occasionally after sunrise as a result of H_2O being heated out of the soil and then condensing when it comes in contact with the cool air above.

The dust storms originate in the southern hemisphere during its summer where the heating rates are especially high. They may coalesce to become global storms, spreading to the northern hemisphere. They aid in the precipitation of H_2O over the polar caps by providing a nucleus for condensation. Dust storms are responsible for the dirty layers in these caps.

Large cyclonic storms have been observed near the edge of the north polar cap during early summer. These clouds were composed of H_2O ice and extended up to 6-7 km.

The presence of channels in the surface topography suggest the flow of H_2O at some time in the past. If this is the case, then the atmosphere of Mars must have been considerably denser at some past time. Long-term climatic changes may occur. As a result of gravitational perturbations of the Sun and other planets, the shifting longitude of perihelion and the precession of the equinoxes combine to give a climate cycle with period 51,000 years, which strongly affects the climate extremes between summer and winter.

Compounding these effects is a cyclic variation of the orbital eccentricity which varies from a nearly circular orbit to one which is highly elliptical where one hemisphere may receive 1.5 times more solar energy at perihelion than at aphelion. These effects combine to give climates much different than is observed today. In the past, H_2O could have been abundant.[4]

The Major Planets It is no coincidence that the major planets (Jupiter, Saturn, Uranus, and Neptune) all lie in the outer solar system (see Table 1). Their large mass is a consequence of the lower temperatures which have always existed in the outer solar system as a result of the great distance from the Sun. The outer protosolar nebula was cooler than the inner nebula so that the planets which condensed in the outer regions accreted even the lightest and most cosmically abundant elements, hydrogen and helium. The higher temperatures of the inner solar system caused the terrestrial planets to accrete the heavier elements preferentially. These are much less cosmically abundant than hydrogen or helium, so that the terrestrial planets are much smaller and denser than the major planets. The higher temperatures also caused the terrestrial planets to lose their primordial atmospheres and fluid envelopes, exposing their rocky crusts. As secondary atmospheres outgassed from the rocks, the higher temperatures caused gases with the lowest molecular weight to escape into space. Therefore, a distinguishing characteristic of the terrestrial planets is the presence of a solid surface underlying a relatively thin atmosphere in which gases of low molecular weight are absent. By contrast, the major planets have no solid surface. They are fluid except for possibly small, rocky cores. Molecular hydrogen and helium in approximately the solar abundance ratio make up most of their atmospheres and fluid interiors. Evidence for the lack of any solid surface is the differential rotation of these planets. The rotation periods are a function of the latitude with the shortest periods at the equator. The period of Saturn's atmosphere, for example, varies from 10 hours 2 minutes at the equator to 11 hours at 57° latitude.

The rotational periods of Jupiter and Saturn lie between 10 and 11, hours while those of Uranus and Neptune lie between 15 and 24 hours. The rapid rotation rates combined with the large size of the major planets causes coriolis forces to be strong at all but the lowest latitudes in these planets. Consequently, their atmospheres exhibit a zonal banded structure with the band widths typically decreasing with increasing latitude. At high latitudes, where the coriolis forces are strongest, the banded structure gives way to highly varied and less orderly structure. The zonal structure is characterized by dark belts and light zones with various

TABLE 1. PLANETARY DATA

Planet or Satellite	Distance from Sun (Earth = 1)	Orbital Eccentricity	Mass (Earth = 1)	Radius (Earth = 1)	Density (g cm^{-3})	Period of Rev.	Period of Rot.	Escape Velocity (km/sec)
Mercury	0.387	0.206	0.0554	0.381	5.53	87.97 d	58.6 d	4.3
Venus	0.723	0.007	0.815	0.950	5.25	224.70 d	−244 d	10.5

colorations, which are particularly evident for Jupiter. The belts are warmer regions, thought to be subsiding and representing relatively clear regions of the atmosphere. The zones are thought to be hazier, cooler regions produced by convective upwelling in the atmosphere. In addition to the zonal structure, there are vortex features such as white ovals, red spots and brown spots in these atmospheres which usually represent cyclonic or anticyclonic storms. Jupiter's Great Red Spot (see Fig. 2), located at 23°S latitude, is an anticyclonic feature currently 25,000 km by 14,000 km which has been in existence for over 300 years. Like the zones, it is cooler, higher, and hazier than its surroundings. The process causing the colors in these atmospheres is not understood but may involve red phosphorous formed photochemically from phosphine, PH_3. Alternatively, it may involve polmerized carbon suboxides, $(C_3O_2)_x$. Temperature differences may also explain the color differences.

Because the major planets condensed out of the protosolar nebula with relatively little fractional loss of the lighter elements, their composition reflects the solar abundance ratios of the elements. However, temperature and chemistry play an important role in governing the composition of the outer layers. The low temperature causes some of the elements to exist in molecular form and causes many common gases to freeze out. Consequently, their atmospheres consist largely of gases which have low condensation and freezing temperatures and which are made up of the more cosmically abundant elements. This explains the predominance of H_2, He, CH_4, and NH_3. Of these, NH_3 has the highest freezing point; it is frozen out of each upper atmosphere of these planets to a depth which increases with the planet's distance from the Sun. This explains its progressively lower visibility with increasing planetary distance from the Sun. In the atmospheres of Uranus and Neptune, the NH_3

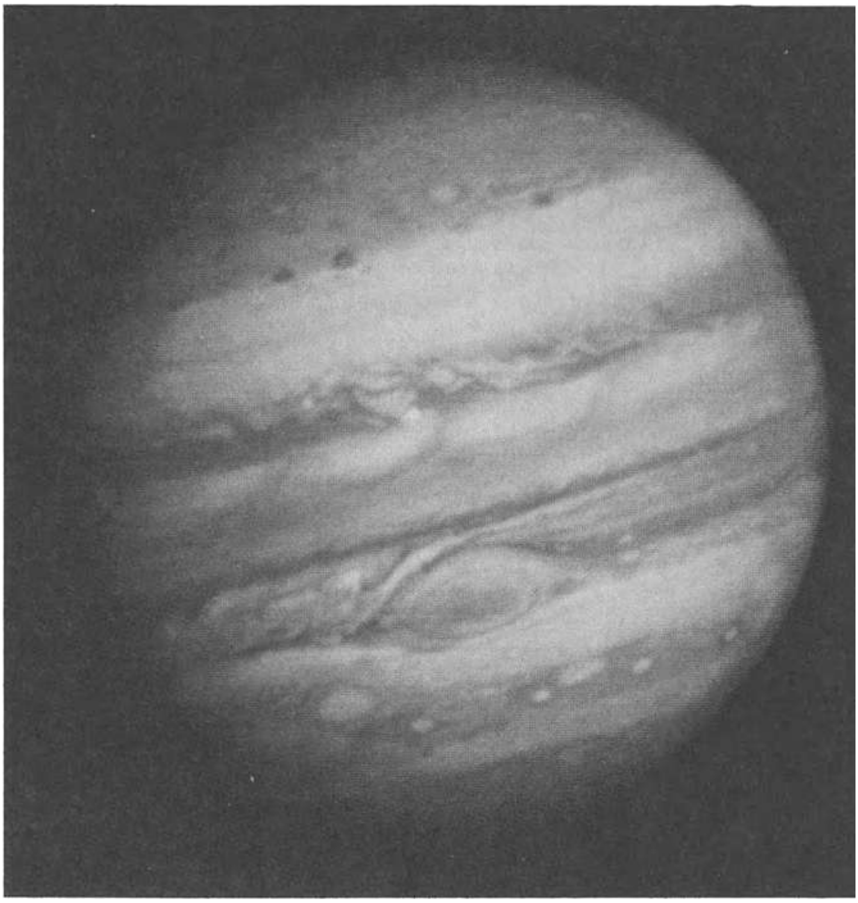

FIG. 2. Voyager 1 image of Jupiter obtained on January 26, 1979 showing the belts, zones, white ovals, dark spots, and Great Red Spot. The latter is near the central meridian at 23°S latitude.

abundance may be further reduced by conversion to NH_4HS clouds. Frozen NH_3 particles probably make up the upper cloud layers of Jupiter and Saturn.

In addition to the gases above, Jupiter's atmosphere contains HD, PH_3, H_2O, CO, C_2H_6, GeH_4, and probably H_2S and HCN. In Saturn's atmosphere, C_2H_4 has also been detected but H_2O, CO, GeH_4 and HCN have not yet been detected. In Uranus' atmosphere, the detected gases are H_2, HD, CH_4, and C_2H_6. The presence of He is inferred from observations. Many other gases, not yet detected, are probably also present in both atmospheres. Photochemical products and products of ion chemistry in the upper atmospheres of Jupiter, Saturn, and Titan are thought to be responsible for the dark UV albedos of these planets.[4]

All the major planets except Uranus have strong temperature inversions above the 10 mbar level. The temperature rises to over 100 K in some cases. This increase in temperature with altitude is caused by the heating of the upper atmosphere resulting from the absorption of sunlight by CH_4, C_2H_6, C_2H_2, and PH_3. The gases in this region of the atmosphere are poor thermal absorbers or radiators so the atmosphere heats up. Uranus' atmosphere may contain a thermal radiator which the other planets do not have.

Furthermore, all of the major planets except Uranus have strong internal heat sources which cause these planets to radiate about 1.7 times the absorbed incident sunlight (see Table 2). Uranus may have no internal heat source at all. These cause the temperature to increase with depth below the levels where sunlight penetrates, all the way to the source of the heat. In the tropospheric layers where sunlight penetrates, the thermal opacity from H_2-H_2 and H_2-He collisions causes the temperature to increase with depth at an ever increasing rate (the greenhouse effect) until the atmosphere becomes convectively unstable. In the convecting regions, the temperature lapse rate is about 2 K/km. Strong convection is especially evident in the cloud patterns of Jupiter. Lightning has been observed on Jupiter's night side by Voyager. Significant changes in the cloud features were observed in the four-month interval between the Voyager 1 and 2 flybys.[6] This occurred in spite of the much longer radiative time constant for the atmosphere because the convective time constants are quite short. Convection probably continues from the deepest layers penetrated by sunlight all the way to the source of the internal heating. For Jupiter, gravitational contraction suffices to explain the internal heating, but for Saturn, separation of He from H_2 is probably an additional important source of heat.

The internal heat sources moderate latitudinal and seasonal temperature variations. Jupiter has a small obliquity so its seasonal variation is small anyway. Saturn and Neptune have moderate obliquities but their strong internal heating limits seasonal effects to the uppermost layers of their atmospheres. Uranus has a large obliquity; its spin axis is nearly parallel to its orbital plane. Because of this and the lack of an appreciable internal heat source, Uranus' atmosphere should exhibit strong seasonal variations over its long orbital cycle.

Pluto In spite of its small size, Pluto has an atmosphere consisting of 27 m-Amagat CH_4 (1 cm-Amagat = 2.69×10^{19} molecules cm^{-2}). This gas is slowly escaping but is being replenished by the sublimation of the surface CH_4 ice. Adiabatic cooling of the escaping gas greatly slows the escape rate. Other gases have not yet been detected in Pluto's atmosphere; however, the presence of a heavier gas would help to stabilize the CH_4 atmosphere further. Since CH_4 gas on Pluto exists below its freezing point, its surface pressure is governed by the surface temperature. Pluto's atmosphere is apparently not cloudy because the light curve, which has a very large amplitude, has a very regular period.[7] The observed abundance therefore implies a surface temperature of 58 K, a value considerably higher than the solar equilibrium temperature. This suggests that a greenhouse mechanism is operating. However, CH_4 has no thermal opacity so the presence of a greenhouse would imply the presence of another bulk gas on Pluto.

TABLE 2. INTERNAL HEAT SOURCES FOR THE MAJOR PLANETS

Planet	Ratio of Internal Heat Source to Absorbed Solar Radiation
Jupiter	1.67 ± 0.09
Saturn	1.79 ± 0.10
Uranus	1.6 ± 1.0
Neptune	⩽0.03

TABLE 3. TITAN'S ATMOSPHERE

Gas	Mixing Ratio (%)
N_2	90
Ar	⩽10
CH_4	1
Ne	1
H_2	0.12
CO_2	7×10^{-10}
C_2H_2	2×10^{-4}
C_2H_4	4×10^{-5}
C_2H_6	2×10^{-3}
HCN	2×10^{-5}
C_3H_8	2×10^{-3}
C_3H_4	3×10^{-6}
C_4H_2	$10^{-6} - 10^{-5}$
HC_3N	$10^{-6} - 10^{-5}$
C_2N_2	$10^{-6} - 10^{-5}$

Unlike the terrestrial planets, Pluto's interior is largely icy rather than rocky; its density is low. It probably contains ices of volatile materials which supply volatile gases to the atmosphere.

The large ellipticity of Pluto's orbit (0.25) and Pluto's large obliquity cause a strong seasonal variation of Pluto's atmospheric bulk because of the sensitivity of the saturation vapor pressure to temperature for the volatile gases likely to constitute its atmosphere. Pluto's distance from the Sun varies from a current value of 30 a.u. near perihelion to 50 a.u. at aphelion 124 years from now. During this time, essentially all of the observed CH_4 and other volatile gases should freeze out of the atmosphere.

Titan The only satellite in the solar system known to possess a dense atmosphere is Titan, Saturn's largest satellite. Although a satellite, Titan is larger than the planet Mercury. Titan's surface temperature is 95 K, much cooler than Mercury's, so it is not surprising that Titan can retain an atmosphere. The Voyager flybys[8] obtained a surface pressure of 1.5 atm so that the column abundance of the whole atmosphere is about 100 km-Amagats. The major constituent is N_2, which accounts for 90% of the atmospheric molecules. Table 3 lists the other gases detected. The abundance of Ar could be as large as 10%. This implies that Ar is locked up in clathrates in Titan's interior which must have accreted from the protosolar nebula. The higher hydrocarbons are probably the products

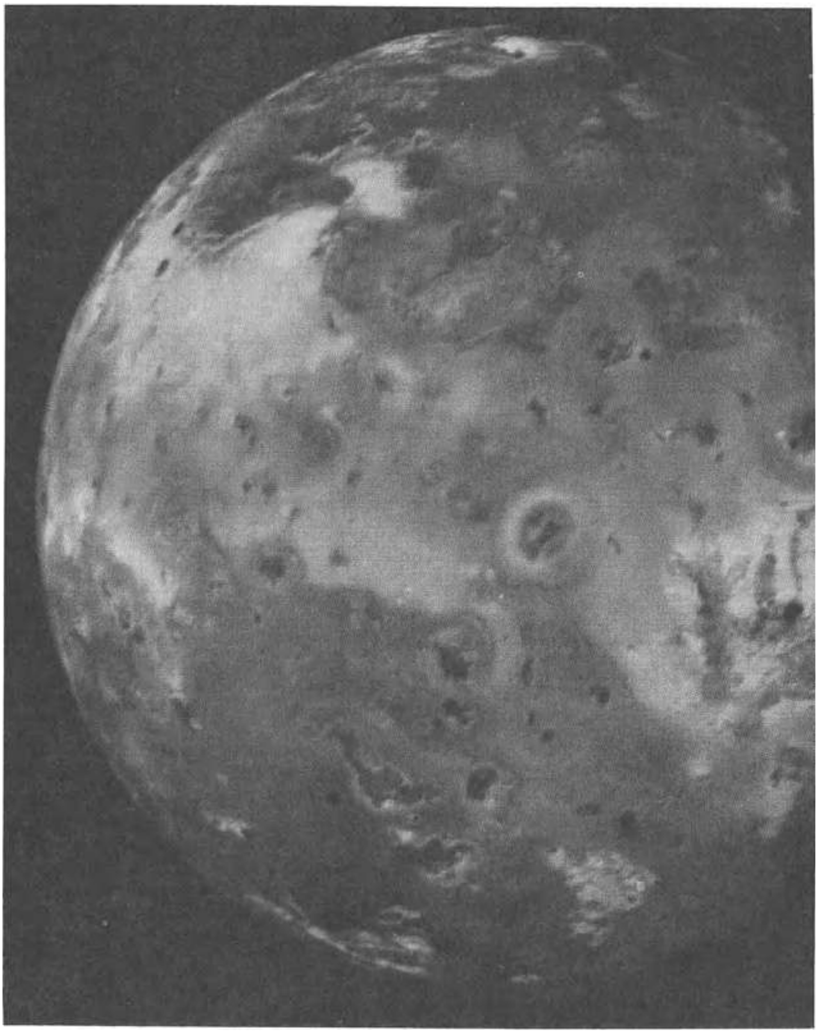

FIG. 3. Voyager 1 image of Io obtained on March 4, 1979 showing surface deposites of SO_2 frost and other material spewed from Io's volcanoes. The light circular region in the center of the satellite is the deposition site of an erupting volcano.

of photochemistry. Titan has no magnetosphere to protect it from the solar wind so charged particles and cosmic rays support ionospheric chemistry in Titan's spherically extended upper atmosphere. Owing to the abundance of H, C, and N in Titan's atmosphere, this leads to complex chemistry and possibly to organic molecules being formed. Titan's atmosphere may provide insights into the evolution of life or its precursors.

The atmosphere appears to be in radiative equilibrium except possibly for the bottom 2 km. The radiative time constant is long enough that diurnal effects should be negligible (Titan's day is 16 Earth days). There are, however, seasonal effects which cause a hemispherical asymmetry and seasonal cyclostrophic winds in the stratosphere. The dominant circulation pattern is Hadly cells, which transport heat polewards.

A detached haze layer appears high in the atmosphere over a deeper opaque cloud layer. It lies about 315 km above the surface, is nearly transparent, and is composed of aerosol particles with mean size 0.3 μ. These are probably the volatile products of photochemical reactions with CH_4 and N_2. At the time of the Voyager 1 flyby, the opaque cloud layer was 185 km above the surface in the north and 50 km higher in the south. It probably consists mainly of CH_4 crystals. The haze layer transitions into a north polar hood at high latitudes. Nowhere is Titan's surface visible.

Io Pioneer 10 detected an ionosphere on Io with a scale height of 100 km. This was the first compelling evidence that Io has an atmosphere. The innermost of the Galilean satellites, Io is immersed deep within Jupiter's magnetosphere and trapped radiation belts. Charged particles bombard its thin atmosphere and surface, causing atoms to sputter from Io into orbit around Jupiter, where they form thin toroidal clouds. Some of the atoms become ionized so that they are swept up by Jupiter's corotating magnetic field and join a plasma torus. These tori imply that S and O are the main constituents of Io's atmosphere and possibly its surface.

Io's atmosphere is very thin; the surface pressure is on the order of 0.1 μbar and is greatest on the sunlit side near the volcanoes discovered by Voyager.[6] These arise from the tidal heating of Io by interaction between Io's orbit and the other Galilean satellites. Voyager 1 observed eight large active volcanoes on Io. (See Fig. 3.) Four months later, Voyager 2 observed seven of these volcanoes and found six of them to be active. These volcanoes are believed to be the source of Io's atmosphere. They discharge primarily SO_2 gas into the atmosphere. A surface frost of SO_2 forms from the gas. Because of the rapid deposition rates, Io's surface is the youngest in the solar system.[6]

The column abundance of SO_2 observed near one of the hot vents was 0.2 cm-Amagat, a value consistent with the 130 K temperature of the sunlit surface for SO_2 gas in equilibrium with the surface frost. However, the IUE satellite observed only 0.008 cm-Amagats of SO_2, averaged over the sunlit hemisphere. Therefore, the global SO_2 atmosphere may be less abundant than if it were in equilibrium with surface frosts. The frosts, however, must have some "buffering" effect on the atmosphere bulk so that it cannot depart greatly from the saturation value.

PLASMAS

Solids, liquids and gases are the three familiar states of matter. When heated, solids, in general, turn to liquids and the liquids eventually become gases. When a gas is heated to sufficiently high temperatures such that the thermal energy of the atoms (molecules) is comparable to the binding energy of the electrons, violent interatomic (intermolecular) collisions tend to ionize the gas, i.e., the atoms are split into free electrons and ions. The dynamical properties of this gas of free electrons and ions are sufficiently different from the normal unionized gas that it can be considered a fourth state of matter, and is given a new name, *plasma*. It must be mentioned that the normal state of matter in this universe is plasma, although on the planet earth it is produced only under somewhat special and often extreme laboratory conditions.

The interiors of the stars, the Solar Wind, the Van Allen belts, and the ionosphere are a few examples of the plasma state.

The study of plasma state is needed to understand the properties of a large part of the universe. Thus the astrophysicists were the first to start investigating the phenomena peculiar to plasmas. In addition to this general scientific interest, manifold technical possibilities have given a tremendous boost to research in the physics of plasmas. A list of industrial applications must include welding and cutting through heliarcs, TIG welding and plasma torches, fluorescent lamps, dry plasma etching, plasma sputtering to deposit coatings, opening and closing power switches, generation of electromagnetic waves, and generation of useful energy.

The most important area of research, however, is the physics of confining and heating plasmas with a view to generating useful energy via controlled thermonuclear fusion of light elements (hydrogen isotopes, typically). This research, which has spanned theory as well as experiment, has played a large role in the considerable advances made in the past three decades in the description and understanding of plasmas, especially magnetically confined plasmas.

In general, the plasmas are overall charge neutral, that is, the total negative electronic charge equals the total positive ionic charge. However, the definition of a plasma has been extended to include even those systems where charge neutrality does not pertain. Thus, inherently unneutralized systems like electrons and ion beams also fall within the domain of plasma physics.

The primary characteristic of the plasma state is that the long-range Coulomb forces dominate the dynamics of the electrons and ions. Thus the constituent particles constantly interact with one another through the electromagnetic fields, which in turn are self-consistently generated by the motions of the plasma particles. Because of this constant interaction, the plasma particles tend to respond collectively to any perturbation. Collective behavior is, in fact, what distinguishes a plasma from a dilute neutral gas, whose particles move about essentially free, save for an occasional catastrophic collision with another particle. The immense extent and richness of plasma dynamics owes much to these very collective modes.

A theoretical formulation of the physics of plasma requires the simultaneous specification of the dynamics of the interacting electrons, ions and the electromagnetic fields. The electromagnetic fields are described by Maxwell's equations

$$\begin{aligned}&\nabla \cdot \mathbf{B} = 0, \qquad \nabla \cdot \mathbf{E} = 4\pi\rho\\ &\nabla \times \mathbf{E} = -\frac{1}{c}\frac{\partial \mathbf{B}}{\partial t}, \qquad \nabla \times \mathbf{B} = \frac{4\pi}{c}\mathbf{J} + \frac{1}{c}\frac{\partial \mathbf{E}}{\partial t}\end{aligned} \tag{1}$$

where **E** and **B** are the electric and the magnetic fields respectively, c is the velocity of light in vacuum, ρ is the charge density, and **J** is the current density. Notice that ρ and **J** are due to the motion of plasma particles in response to the electric and magnetic fields **E** and **B** (externally applied as well as self-consistently generated). The main task of the study of the dynamics of plasma particles then is to provide the so-called constituitive laws: expressions which determine ρ and **J** as functions of **E** and **B**, i.e.,

$$\rho = \rho(\mathbf{E}, \mathbf{B})$$

$$\mathbf{J} = \mathbf{J}(\mathbf{E}, \mathbf{B}).$$

Notice that ρ, **J**, **E**, and **B** are all functions of space (**r**) and time (**t**).

There are several levels of sophistication for the description of the dynamics of plasma particles. A microscopic theory would require a proper treatment as a problem in many-body physics. A fair number of phenomena, however, depend only on the macroscopic behavior of the plasmas, and can be studied within the framework of much simpler models. We describe two such frequently used models.

One-Fluid Model The plasma is treated as a single charged highly conducting fluid, and is described by a set of hydrodynamic equations. This is generally possible when the plasma is embedded in a strong external magnetic field. This of course is the case of greatest practical importance because the strong magnetic fields are the principal confining agents used for fusion plasmas. The set of hydrodynamic and Maxwell's equations together define the discipline of magnetohydrodynamics, hydromagnetics, or MAGNETO-FLUID-MECHANICS, and is characterized by a vastly rich variety of waves and flows that are not encountered in ordinary fluid mechanics. Historically, this is the oldest and the most well studied branch of plasma physics. The well known Alfvén wave, which is a transverse electromagnetic wave propagating along the direction of the ambient magnetic field, was discovered within this model. In toroidal confinement systems, one of the most notable discoveries called the *Kruskal-Shafranov criterion of stability* was also derived in magnetohydrodynamics. It states that if a certain quantity q, called the *safety factor*, fell below unity in the plasma, an instability will develop resulting in loss of confinement. This was subsequently verified experimentally in tokamaks. (The tokamaks is a doughnut-shaped machine which is, at present, the most advanced fusion system.)

Two-Fluid Description A slightly more detailed description of the plasma would be to treat the ions and electrons each as separate conducting fluids coupled through momentum transfer Coulomb collisions and, of course, Maxwell's equations. All results of the one-fluid theory are automatically contained in this model, and several new phenomena emerge. As an example, in this model one can show the existence of high-frequency longitudinal oscillations which are characteristic of a field-free, infinite, homogeneous plasma. These oscillations have a frequency $\omega = \omega_{pe} = (4\pi ne^2/m)^{1/2}$, where n is the density, m is the mass, and e is the charge of the electron. These oscillations are called *plasma waves* or *Langmuir waves*. (It was to describe these waves that Langmuir first coined the word *plasma*.)

Microscopic Description Fluid theories are unable to account for many microscopic phenomena, for which a detailed kinetic description is essential. Because of the long-range character of the Coulomb force, the plasma kinetic theory has to be quite different from that of a dilute gas in which the interaction is short range. However, it has been possible to systematically develop the statistical many-body description of a plasma as orders in an expansion in the small parameter $\epsilon = (1/n\lambda_D^3)$, where n is the average number density. The Debye shielding distance λ_D is given by

$$\lambda_D = \left(\frac{2kT}{4\pi ne^2}\right)^{1/2}$$

where k is the Boltzmann constant and T is the absolute temperature. The Debye shielding distance is a measure of the effective range of the Coulomb force acting on a test particle in the plasma. The potential seen by a test particle is given by

$$\phi(r) = \frac{q}{r}\,e^{-r/\lambda_D}$$

where r is the distance of the test particle from the charge q. The expansion parameter ϵ is the inverse of the number of particles in a Debye sphere, and for most plasmas of interest ranges from 10^{-2} to 10^{-9}. The smallness of this parameter really typifies the plasma state. It can be easily seen that the expansion parameter ϵ signifies the ratio of potential energy of interaction of one particle with its neighbor (separated typically by a distance $n^{-1/3}$) and the mean kinetic energy per particle,

$$PE/KE \simeq \frac{e^2 n^{1/3}}{kT} \sim (n\lambda_D{}^3)^{-2/3} = \epsilon^{2/3} \ll 1.$$

Thus the smallness of ϵ implies the smallness of the binary interaction as compared to the average collective many-body effect of all its neighbors within a Debye sphere.

How does the infinite-range Coulomb force become finite ranged? The answer can be given as follows. Let us suppose that a negatively charged test particle was introduced in the plasma. This test charge will immediately be surrounded by positively charged ions because they are attracted toward it. This cloud of surrounding positive charges tends to shield the test particle from other charges, so that it hardly interacts with charges separated from it by a distance larger than λ_D.

The plasma kinetic theory can be developed to the required order in ϵ. To order zero in ϵ, the plasma particles only interact collectively and no binary encounters are included. The binary encounters will come in order ϵ, and tertiary encounters in order ϵ^2, and so on. The leading order plasma dynamics, therefore, is an expression only of the collective behavior and is determined by the well known Vlasov or collisionless Boltzmann equation:

$$\frac{\partial f_s}{\partial t} + \mathbf{u}\cdot\frac{\partial f_s}{\partial \mathbf{r}} + \frac{e_s}{m_s}\left[\mathbf{E} + \frac{\mathbf{u}\times\mathbf{B}}{c}\right]\cdot\frac{\partial f_s}{\partial \mathbf{u}} + \frac{\mathbf{F}_{\text{ext}}}{m_s}\cdot\frac{\partial f_s}{\partial \mathbf{u}} = 0 \tag{2}$$

where $f_s = f_s(\mathbf{r}, \mathbf{u}, t)$ is the single-particle distribution function of s-species; e_s and m_s are the charge and mass, respectively; $\mathbf{E}$ and $\mathbf{B}$ are the self-consistent fields; and $\mathbf{F}_{\text{ext}}$ is an externally applied force, including, for example, an applied magnetic field. Notice that $f_s(\mathbf{r}, \mathbf{u}, t)$ is the particle density in six-dimensional phase space, and the Vlasov equation is an expression that f_s is conserved along the trajectory of the particle in phase space. From f_s one can construct the current and charge densities (needed in Maxwell's equations) by integrating over velocity space:

$$\begin{aligned}\rho(\mathbf{r}, t) &= \sum_s e_s \int d^3u\, f_s\\ \mathbf{J}(\mathbf{r}, t) &= \sum_s e_s \int d^3u\, \mathbf{u} f_s.\end{aligned} \tag{3}$$

Observe now that substituting Eq. (3) into Maxwell's equations (1) will allow us to determine $\mathbf{E}$ and $\mathbf{B}$ in terms of f_s. Thus Eq. (2) (where we have products of $\mathbf{E}$ and $\mathbf{B}$ with f_s) is essentially nonlinear, implying that even in the lowest order, the plasma dynamics is described by partial nonlinear integro-differential equations. It must be stressed that even in the simplified fluid models described earlier, plasma behavior is nonlinear.

The exact solutions of the Vlasov equation are exceedingly difficult to find. However, it is possible to determine the behavior of a small departure f_{s1} from some plasma equilibrium state f_{s0} by solving the linearized Vlasov equation. Much of the modern plasma theory is based on the investigation of the linearized Vlasov-Maxwell equations.

The dominant result of the linear theory (which is also called the *stability theory*) is the existence of a plethora of wave motions the plasma seems to be able to sustain. For example, a field-free plasma allows transverse electromagnetic waves in addition to the Langmuir waves and ion sound waves; the last requiring electron temperature for its existence. In the presence of electron temperature, the Langmuir wave becomes a propagating wave with a dispersion relation

$$\omega^2 = \omega_{\text{pe}}^2 + 3\left(\frac{kT}{m}\right)\kappa^2$$

where κ is the wave vector. The presence of an external confining magnetic field vastly increases the number of possible excitations. In addition to the Alfvén waves already mentioned, one can have ion and electron cyclotron waves, lower hybrid and upper hybrid waves, whistler waves, and so on. In confined fusion plasmas, because of the ever present temperature and density gradients, new wave motions which are generically called *drift waves* also become possible. A very important result of the linear theory is that in a plasma in thermal equilibrium (say a Maxwellian) the waves are damped even in this collisionless approximation. This phenomenon, called *Landau damping*, is one of the most important discoveries of plasma physics and is due to the interaction of the wave with particles traveling almost with the phase velocity of the wave. Landau damping has been experimentally confirmed.

If the equilibrium distribution f_{s0} has nonthermal features (an equilibrium current, a bump in its tail, anistropy in velocity) then the wave-particle interaction can lead to a growth of the waves. In inhomogeneous plasmas, there is always additional free energy available in the gradients to drive an instability. If the waves do grow in amplitude, the linear theory becomes invalid, and a nonlinear theory has to be invoked to determine the fate of the wave as well as the distribution function. The mechanism of instability can be understood as follows. The waves are created by perturbed motion of the plasma. If the electromagnetic fields thus generated happen to accentuate the perturbation, then the increased perturbation will create larger fields and an instability can build up.

The existence of the instabilities is one of the major difficulties in the controlled nuclear fusion program. It is believed that the very large electron energy losses observed in tokamaks are caused by the instabilities.

Hot plasmas are also capable of radiating in various modes. The magnetically confined hot thermonuclear plasmas are expected to copiously radiate at the cyclotron frequency $\omega_c = eB/mc$ and its harmonics and can be a serious source of energy loss.

Approach to Equilibrium In the linear theory, it was supposed that an equilibrium state f_{s0} existed. How does a plasma approach equilibrium? An ordinary gas does it through binary collisions, which for a plasma, can be investigated by including terms of order ϵ in the dynamics. These terms reflect the effects of particle discreteness, i.e., collisions between plasma particles. Since a plasma is characterized by numerous small angle collisions, a modified Fokker-Planck collision term is needed. In plasmas, there also exists another mechanism: the instability (an expression of the collective effects) which can rapidly take a nonequilibrium system towards equilibrium. It is instructive to mention here the "Langmuir paradox." In his experiments using electrostatic probes, Langmuir discovered that the electron distribution function was far more Maxwellian than warranted by the collisions. It is surmised that Langmuir oscillations described earlier may be behind this phenomenon.

POLAR MOLECULES

The term "polar" is applied to molecules in which there exists a permanent spatial separation of the centroids of positive and negative charge, or dipole moment. Such a moment was first postulated by P. Debye for molecules having structural asymmetry in order to explain certain of the observed electrical properties. He chose for his model an electrical dipole contained in a spherical molecule, free to rotate into alignment with an applied electric field, but subject to disorientation by collisions with other molecules due to thermal motion. At ordinary temperatures and field strengths, the electrical energy involved in the orientation is much smaller than the thermal energy kT so that only a small fraction of the dipoles are aligned with the field (k is Boltzmann's constant and T is the temperature in degrees Kelvin). The net dipole moment per mole (*molar polarization*) is then calculated statistically to be

$$P = \frac{4\pi}{3} N\left(\alpha + \frac{\mu^2}{3kT}\right) \tag{1}$$

where μ is the permanent dipole moment per molecule, i.e., the charge multiplied by the distance of separation, and N is Avogadro's number. The polarizability α represents the induced moment per molecule resulting from the temporary distortion of the electron orbits by the applied field. For nonpolar molecules, it is the only contribution; it corresponds to the optical polarizability as measured by the refractive index.

The molar polarization may be related to the dielectric constant ϵ by the approximate equation of Clausius and Mosotti

$$\frac{\epsilon - 1}{\epsilon + 2}\frac{M}{d} = P \tag{2}$$

where M is the molecular weight and d is the density. The permanent dipole moment of a molecule may therefore be determined by measuring the temperature coefficient of the dielectric constant as seen by combining Eqs. (1) and (2). Alternatively, a companion measurement of the optical refractive index may be made to determine α, and the dipole moment is then obtained as the difference between the total polarization and the optical contribution. The measurements are made in dilute vapor or solution phase, so that the individual dipoles are sufficiently far apart that they do not influence one another (see REFRACTION).

Equation (1) is valid in the low-frequency region where the dipoles are able to rotate in phase with the applied electric field. This rotation is subject to various restraints; in the simple case of a spherical molecule of radius a rotating in a fluid of viscosity η, this leads to a relaxation time

$$\tau = \frac{4\pi a^3 \eta}{kT} \tag{3}$$

corresponding to a frequency range of *anomalous dispersion* in which the molecules become unable to follow the oscillations of the applied field. This gives rise to an out-of-phase component of the dielectric constant representing a conductivity or *dielectric loss*, ϵ'', i.e., a dissipation of energy in the form of heat. Mathematically this is expressed as a complex dielectric constant.

$$\epsilon = \epsilon' - j\epsilon'' \tag{4}$$

$$\epsilon' - \epsilon_\infty' = \frac{\epsilon_0' - \epsilon_\infty'}{1 + \omega^2\tau^2} \tag{5}$$

$$\epsilon'' = \frac{(\epsilon_0' - \epsilon_\infty')\omega\tau}{1 + \omega^2\tau^2} \tag{6}$$

ω is $2\pi \times$ the frequency, and the subscripts 0 and ∞ refer to dielectric constant measured at very low and very high frequency, respectively. Cole and Cole showed for polar molecules having a unique relaxation time that a plot ϵ'' vs ϵ' is a semicircle centered on the ϵ'-axis. For more complicated molecules or high polymers, the center becomes depressed below the ϵ'-axis and the curve may be further distorted. This behavior is generally characterized by a distribution of relaxation times as a result of the orientation of molecular segments of various shapes and sizes. Information regarding the freedom of orientation within the molecules may thus be gained.

These simple relationships between dipole moment and dielectric constant fail for concentrated solutions or pure polar liquids because they do not take into account the interaction of the dipoles, both permanent and induced, with one another. The calculations have been extended by Onsager, Kirkwood, and others, to include these effects. It becomes necessary to include in the theory a correlation factor which is a measure of the extent of nonrandom orientation of the dipoles, i.e., the tendency of the dipoles to aggregate parallel or antiparallel to one another. Experimental determination of this quantity yields further insight into the structure of polar liquids.

In the solid state, most crystalline polar compounds exhibit low dielectric constants because the rotational freedom necessary for dipole orientation has been frozen out. A few compounds, however, do show a persistence of high dielectric constant to temperatures below the melting point, indicating rotational freedom in the solid. At some lower temperature the rotation ceases and the dielectric constant drops. This change in dielectric constant has frequently been used as a method of detecting second-order transitions in polar compounds.

Some success in the correlation of dipole moment with molecular structure has been achieved. A series of moments assigned to individual bonds was developed empirically by Smyth, Pauling, and others from measurements on simple molecules. They are intended for approximate calculation of dipole moments of complex molecules by vectorial addition along the bond directions as determined by other means. It is assumed that there is no interaction between bonds; this generally results in the calculated values being higher than the measured moment because of inductive effects, i.e., electrons being shared in a bond between two atoms are not wholly available to a neighboring bond, so that neither bond attains its full moment. An approximate correction for this effect has been made by Eyring and co-workers. Despite these inadequacies, the calculated moments are often helpful in determining molecular structures and have often applied in the case of various substituted benzene-ring compounds. Of special importance is the ability to decide between a polar or nonpolar, i.e., symmetrical, structure.

More detailed quantum mechanical calculations of dipole moments have been less successful. Rather the experimentally determined moments have been used to assign varying degrees of ionicity and covalency to the bonds in establishing the electronic hybridization structure. Quantum mechanics has also shown how it is possible to obtain extremely accurate measurements of the dipole moments from spectroscopic Stark splittings.

POLARIZED LIGHT

Polarized light is an especially simple form of light and can be defined easily in terms of either of the two prevalent theories of light: the wave theory and the photon theory (see LIGHT). According to the former, light consists of trains of electromagnetic waves whose wavelengths lie in the range from about 4×10^{-7} to 7×10^{-7} meters. A noteworthy feature of the waves is that two kinds of displacements are involved: electric and magnetic. Another significant feature is that, when the waves are traveling in empty space (or in glass, water, or other isotropic medium), the electric and magnetic displacements are perpendicular to the direction of propagation of energy; i.e., they are transverse, not longitudinal. Since the electric and magnetic displacements are always perpendicular to one another and have equivalent magnitudes, it is sufficient to specify just one of these quantities; most authors choose to deal with the electric displacement.

Consider, now, a slender beam of light that is traveling east, i.e., from left to right in Fig. 1. If it happens that the direction of electric displacement is everywhere up or down, but not north or south, the beam is said to be linearly polarized in the vertical plane. If, alternatively, the displacements were north and south, the beam would be called *horizontally* linearly polarized. The displacement might, of course, lie in some tilted plane specified by an angle α; in such case, any given displacement may be regarded as the resultant of a vertical displacement and a horizontal displacement. The *sectional pattern* of any such beam is conventionally indicated by a straight line segment at the appropriate azimuth α, as indicated in Fig. 2(c). Linearly polarized beams that have azimuths differing by 90° are said to have *orthogonal* polarization forms.

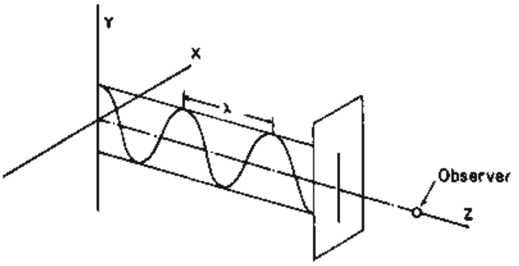

FIG. 1. Monochromatic beam of wavelength λ traveling horizontally to the right. Since, in this example, the electric displacement is vertical, the sectional pattern (indicated at right) consists of a vertical line and the beam is said to be vertically linearly polarized. The observer is situated far to the right, facing the light source.

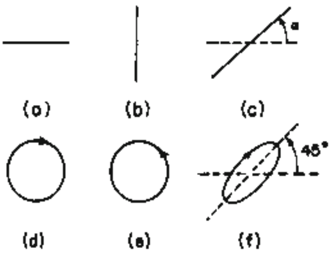

FIG. 2. Variety of sectional patterns of polarized light: (a) horizontally polarized; (b) vertically polarized; (c) linearly polarized at azimuth α; (d) right circularly polarized; (e) left circularly polarized; (f) right elliptically polarized at 45° azimuth and with ellipticity, or ratio of semi-axes, of approximately 3.

Circular and elliptical polarization forms exist also. Circularly polarized light may be regarded as the result of combining two linearly polarized beams that have the same wavelength and same intensity, are polarized in orthogonal directions (e.g., horizontal and vertical) and differ in phase by 1/4 cycle, or 90°. If the horizontally polarized component *lags* in phase by 90°, the sectional pattern of the combined beam is drawn as a circle executed clockwise, as judged by an observer facing towards the light source. If the horizontally polarized component *leads* by 90°, the circle has a counterclockwise sense and the light is called left circularly polarized. In the general case, the components may differ in magnitude and the phase difference may have any value; the general sectional pattern is an ellipse.

A different description of polarized light is required when the light is regarded as a stream of photons. This is the case when the photons are so infrequent and so energetic that they can be detected individually. In such case, it is the spin, i.e., the angular momentum, of the photon that constitutes the polarization. A right circularly polarized photon has a spin of +1 unit, and a left circularly polarized photon has a spin of −1 unit. Theory and experiment are in agreement that the magnitude of the unit in question is $h/2\pi$, where h is Planck's constant (see QUANTUM THEORY). Linearly and elliptically polarized photons may be regarded as combinations, in suitable proportions, of positive and negative spins.

Unpolarized light is more complex than polarized light, hence it is harder to describe. It consists of light in which the azimuth, ellipticity, and handedness of polarization vary rapidly and at random, so that no one type of polarization predominates. No simple diagram can depict the chaos and impartiality of the sectional pattern. If, in a given beam, one particular sectional pattern slightly outweighs all other patterns, the beam is said to be partially polarized; the degree of polarization may lie anywhere in the range from 0 to 100 per cent.

Polarization is not confined to visible light, but applies also to longer-wavelength radiations including the infrared and radio ranges and to shorter-wavelength radiations including ultraviolet light and x-rays. Nevertheless, the visual range deserves special attention in view of the variety of phenomena observed and the nicety of observation and wealth of applications.

Polarization was discovered by the Dutch scientist Christian Huygens in 1690, but it was not well understood until the transverse nature of the vibration, suggested by the English Physicist Robert Hooke in 1757, was confirmed by Thomas Young in 1817. Further clarification came in 1873 when Maxwell showed that light waves belong to the family of electromagnetic waves.

Today many simple methods of producing polarized light are known. Usually, an investigator starts with a beam of unpolarized light and then polarizes it by inserting a suitable optical device—a polarizer. However, the invention of the LASER makes it feasible to generate light that is polarized from the outset; no polarizer is needed. Various natural sources of polarized light exist, e.g. rays of light from a portion of the blue sky that is viewed in direction at 90° to the direction of the sun, also light from certain distant galaxies, such as the Crab nebula.

Conceptually, the simplest polarizer is the *micro-wire grid*, which consists of an array of parallel metallic wires each of which is less than a wavelength in diameter and is separated from its neighbors by comparably small distances. When a beam of unpolarized light strikes the grid, the component of the electric vibration that is perpendicular to the wires passes through readily, while the component that is parallel to the wires induces electric currents along them and is reflected or absorbed. The transmission axis of the device, defined in terms of the electric vibration of the transmitted component, is perpendicular to the wires. A far more economical type of polarizer is one that employs long, thin absorbing molecules, rather than wires. The most popular of the commercially produced polarizers, called H-sheet, contains large numbers of long, thin polymeric molecules consisting mainly of iodine atoms. These molecules are embedded in a plastic film that has previously been stretched unidirectionally so as to have a pronounced "grain"; the long slender molecules of iodine conform to this grain. Polarizers containing small absorbing units (whether wires or molecules) that show markedly different extents of absorption for different directions of electric vibration in the incident beam are called *dichroic* polarizers.

The first highly efficient polarizer was of birefringent type: it was made of the crystal *calcite* ($CaO{\cdot}CO_2$) which has two refractive indices and thus divides any incident beam into two beams. Each of these is linearly polarized, and the sectional patterns are orthogonal. Usually the crystal is artificially shaped so that one of the polarized beams is transmitted straight ahead and the other is deviated and disposed of by total internal reflection. The calcite prism designed by the Scottish physicist Nicol in 1828 was a basic piece of equipment in optics laboratories for over a hundred years. Types devised subsequently by Wollaston, Ahrens, and Foucault have proven to be superior in several respects.

Polarizers of reflection type are also well known. A typical reflection polarizer consists of a plate of glass that is mounted obliquely in the given beam of unpolarized light. The component that is transmitted is found to be partially polarized, and the reflected component is even more highly polarized—with the orthogonal sectional pattern. If the obliquity of the incident beam (measured from the normal to the plate) corresponds to *Brewster's angle*, defined as the angle that has a tangent of n, where n is the refractive index of the plate, the reflected beam is 100 per cent polarized. For ordinary glass, n has the value 1.5 and Brewster's angle is about 56°. Polarization by reflection is of common occurrence; yet few persons are aware of it; they are unaware, for example, that light reflected obliquely from the surface of a pond, a wet road, or a glossy sheet of paper is partially linearly polarized.

Asymmetric scattering is another process that polarizes light. The polarization observed in light from the blue sky is a consequence of scattering of the sun's rays, especially the short-wavelength or blue component thereof, by the molecules of the air.

Perhaps the simplest application of polarizers is in controlling the intensity of a light beam. For this purpose two polarizers are used, in series. If they are oriented so that their transmission axes are parallel to one another, the over-all transmittance is large. If they are oriented so that the two axes are crossed, i.e., at an angle $\theta = 90°$ to one another, the transmittance is zero; the beam is said to be extinguished. For intermediate angles-of-crossing the transmission is easily calculated from Malus' law, which affirms that the transmittance is proportional to $(\cos\theta)^2$. If the incident beam is already polarized, a single polarizer suffices to reduce the intensity to any desired extent. Polarizing sunglasses are effective in this manner thanks to the fact that light reflected obliquely from roads and most other nearly horizontal surfaces is partially *horizontally* polarized; since the polarizer lenses of the sunglasses are oriented with their transmission axes *vertical*, much of this reflected "glare" light is blocked. A polarizer that is employed to block an already polarized beam is called an analyzer.

Much of the interest in polarized light stems from the surprising convertibility of polarization form. By interposing an appropriate retardation plate, or *retarder*, in a given polarized beam, an experimenter can alter the polarization form at will, and with almost 100 per cent efficiency. A typical retarder consists of a thin flat crystal that exhibits birefringence, i.e., has two different refractive indices. Mica, being birefringent and being easily cleaved into thin plates, is often used. When a beam of polarized light enters a plate of mica, the beam is divided into two components and the phases of these are affected ("retarded") to different extents; thus when the components emerge from the plate and unite to form a single beam again, this latter is found to have a drastically altered sectional pattern. Especially versatile and accurate control of polarization form can be achieved with retarders of calcite or quartz. The effect of any given retarder on any given beam can be predicted accurately by various conventional means and, more recently, by a matrix algebra perfected by the American scientist, Hans Mueller; the procedure is to multiply the four-element vector representing the beam by the sixteen-element matrix representing the retarder. Since the vectors and matrices are tabulated in various books, the procedure entails little effort; indeed it is readily extended to cases in which there are several retarders arranged in series. In cases where high accuracy is not needed, predictions can be made especially rapidly with the aid of a kind of map, or spherical slide-rule, called the Poincaré sphere after its inventor Henri Poincaré.

When an object of glass or transparent plastic is subjected to a unidirectional stretching or compressing force, it becomes birefringent and thus acts like a retarder. Accordingly an engineer who wishes to evaluate the unidirectional strain within such an object can do so by directing a beam of polarized light through it and, with the aid of a calibrated retarder and an analyzer, measuring the change in the sectional pattern of the beam. Using conversion factors published in books on photoelastic analysis, he can interpret the change in terms of the direction and magnitude of the strain (see PHOTOELASTICITY).

Many microscopic biological objects, such as components of living cells, appear transparent and virtually invisible under a microscope. Yet such components often contain groups of aligned birefringent molecules and thus are capable of acting like miniature retarders. If the biologist illuminates a living cell with polarized light and examines it under a microscope that is equipped with an analyzer, he finds the birefringent components to be highly visible. Thus the use of polarizers renders visible a microscopic world that is normally invisible. Similarly, mineralogists find that the polarizing microscope greatly increases the visibility of small birefringent crystals.

There are many other applications of polarizers. Photographers use them to increase the contrast between white clouds and the (polarized) blue sky. Chemists use them to measure the extents to which various liquid solutions rotate the sectional pattern of a linearly polarized beam; the extent of rotation is a measure of the concentration of the solution. Electronics engineers use circular polarizers to trap and thus eliminate reflected flare from radar screens. Illumination engineers have devised systems of polarizing filters for automobile headlights and windshields that eliminate glare in night-time driving. Biologists have found that the direction of growth of certain algae can be controlled by illuminating the algae with polarized light of controlled sectional pattern. Bees and ants can detect linear polarization directly by eye, and they employ the polarization of blue sky light as a navigational aid. Even man can learn to detect the polarization of white light with the naked eye, and he can also distinguish right from left circularly polarized light.

Physicists use polarizers to study the emission of polarized light by atoms situated in regions of strong electric or magnetic field, to determine the strength of the sun's magnetic field by measuring the polarization of certain solar spectral lines, and to determine the pattern of magnetic fields within the Crab Nebula. They use polarizers to analyze the behavior of the remarkable light source *the laser* and to verify theoretical predictions as to the polarization inherent in the synchrotron radiation emitted by certain high-energy accelerators.

Because of light's puzzling dual character (waves and photons) and its central position in the growing field of physics, and because *polarized* light is a most elemental form of light, physicists are confident that polarized light will continue to be an outstandingly challenging enigma as well as a most versatile tool for many generations to come.

POLARON

An electron in the conduction band of an insulator (or a hole in the valence band) polarizes the medium in its neighborhood. This effect is particularly important in ionic crystals, on account of their high polarizability. The electron together with its associated cloud of lattice polarization is called a *polaron*. The subject has been of interest ever since Landau[1] suggested that an electron could become self-trapped by the lattice polarization it induces; this would mean that its effective mass would be very large compared with its "bare" mass (as given by band theory). The name *polaron* was proposed by Pekar.[2] Theoretical treatments of the polaron fall into two classes: the "dielectric" polaron of Pekar[2] and of Fröhlich, Pelzer and Zienau[3] (FPZ) and the "molecular " polaron, first described by Fröhlich and Sewell[4] and by Holstein.[5] (This terminology is due to Mott;[6] the names "large" and "small" polaron respectively are common in the literature, but are somewhat misleading.)

In FPZ, the dielectric polaron is described by a simple model Hamiltonian. The ionic medium is represented by a set of oscillators; each oscillator is characterized by a wave vector $\mathbf{q}$. However, the oscillator frequency ω is simply related to the Reststrahl frequency ω_t, and does not depend on $\mathbf{q}$. If $\mathbf{p} = -i\nabla$ is the electron momentum, and $\mathbf{r}$ its position, m the band mass, Ω the normalization volume, and if $a_\mathbf{q}^+, a_\mathbf{q}$ are canonical creation and annihilation operators for oscillator quanta ("optical phonons") then the FPZ Hamiltonian is

$$H = -\frac{1}{2}\nabla^2 + \sum_\mathbf{q} a_\mathbf{q}^+ a_\mathbf{q} + i\left(\frac{2\sqrt{2}\pi\alpha}{\Omega}\right)^{1/2} \cdot \sum_\mathbf{q} (a_\mathbf{q}^+ e^{-i\mathbf{q}\cdot\mathbf{r}} - a_\mathbf{q} e^{i\mathbf{q}\cdot\mathbf{r}}), \tag{1}$$

in units such that the electron band mass $m = 1$, $\hbar = 1$; the frequency ω of the "optical phonons" is assumed to be independent of the wave vector $\mathbf{q}$, and is taken as the frequency unit. The parameter α is defined as

$$\alpha = \frac{e^2}{\hbar}\left(\frac{1}{\epsilon_\infty} - \frac{1}{\epsilon_0}\right)\sqrt{\frac{m}{2\hbar\omega}}, \tag{2}$$

where ϵ_∞ is the high frequency dielectric constant. The FPZ model is one of a particle interacting in a very simple way with a (nonrelativistic) field—the only parameter is the dimensionless coupling constant α. The problem is therefore of fundamental field-theoretical interest, as well as being interesting for its applications to real ionic crystals.

For $\alpha \lesssim 1$, a perturbation-theoretical and a Tamm-Dancoff type of variational calculation agree that Landau self-trapping does *not* occur. The binding energy (in units of $\hbar\omega$) is

$$E_0 = -\alpha + O(\alpha^2), \tag{3}$$

and the effective mass is

$$m^* = 1 + \tfrac{1}{6}\alpha. \tag{4}$$

The "intermediate coupling" theory of Lee, Low, and Pines[7] extends the range of validity to $\alpha \lesssim 5$, without changing the essential character of the results. It is based on a canonical transformation which partially decouples the electrons from the phonons.

For very large α ("strong coupling," $\alpha \gtrsim 10$), a variational treatment by Pekar[2] *does* lead to very large effective masses:

$$E_0 = -\gamma\alpha^2, \tag{5}$$

$$m^* = 16\alpha^4/81\pi^2, \tag{6}$$

where[8]

$$\gamma = 0.108513. \tag{7}$$

However, for $5 \lesssim \alpha \lesssim 10$, neither the LLP nor the Pekar method is good. A method due to Feynman[9] provides a bridge between the strong- and intermediate-coupling regimes. The electron propagator (for states with no free phonons) is expressed as an integral over all possible paths of the exponential of an action functional. The oscillator coordinates do not appear explicitly, but the action contains a term which represents the Coulomb interaction of the electron *with itself at earlier times:*

$$(\mathbf{r}_1, t'|\mathbf{t}_2, t'') = \int \mathfrak{D}(\mathbf{r}(t)) \exp S; \tag{8}$$

$$S = -\int_{t'}^{t''} \tfrac{1}{2}\dot{\mathbf{r}}^2\,dt + 2^{-3/2}\alpha \iint_{t'}^{t''} dt_1\,dt_2 \cdot |\mathbf{r}(t_1) - \mathbf{r}(t_2)|^{-1} \exp - (t_1 - t_2). \tag{9}$$

(For convenience, Feynman uses an imaginary time variable.) Feynman makes the variational *Ansatz* for the action

$$S_0 = -\tfrac{1}{2}\int_{t'}^{t''} \dot{\mathbf{r}}^2\,dt - C\iint_{t'}^{t''} dt_1\,dt_2 \cdot (\mathbf{r}(t_1) - \mathbf{r}(t_2))^2 \exp - w(t_1 - t_2), \tag{10}$$

where C and w are parameters to be determined. This trial action is the exact action for a model system in which the electron is coupled to a fictitious particle of mass $M = 4C/w^3$ through a spring constant $K = 4C/w$, after the coordinates of the fictitious particle have been eliminated. An upper bound for the energy is found and minimized with respect to w and C. For general α, this bound has had to be evaluated numerically. However, analytic expressions exist in the limit of small and large α. When $\alpha \lesssim 3$, Feynman's expression reduces to the LLP solution (3). When $\alpha \gtrsim 10$ it reduces to Pekar's[2] solution (5), except that the constant γ takes the value $1/3\pi$, about 2% too small. Gerlach and Leschke[8] have shown how the Feynman theory can be refined in the strong-coupling limit, to bring it into complete agreement with Pekar.

The effective mass and the mobility of the Feynman polaron have been calculated;[10] they vary smoothly with α. Higher-order corrections[11] are $\lesssim$ 2% for all α.

When α is large, the radius of the dielectric polaron is small. A measure of the radius R is the amplitude of the zero-point oscillations of Feynman's model system:

$$R = \sqrt{3}(4Cw + w^4)^{1/4}/2\sqrt{C}, \qquad (11)$$

where the unit of length is $\sqrt{(\hbar/m\omega)} \simeq 10$ Å. For large α, R is found to be $\sim\alpha^{-1}$, which can become less than the lattice spacing. When this occurs the dielectric model is no longer appropriate and we have the "molecular" (or "small") polaron. Frohlich and Sewell[4] have proposed the use of a Bloch tight-binding model; polarons localized on adjacent lattice sites are assumed to have small overlap integrals. The polaron mass can then become very large. Conduction occurs by a mixture of quantum-mechanical tunneling and thermally activated electron hopping. Holstein[5] has developed a perturbation theory in which the nearest-neighbor overlap integral J is the expansion parameter. His expression for the rate of hopping from site i to site $i + 1$ is

$$\nu_{i\to i+1} = \frac{J^2}{2\hbar}\sqrt{\left\{\frac{2\pi}{E_a\hbar\omega_0 \operatorname{csch}(\hbar\omega_0/2kT)}\right\}} \cdot \exp\left\{-\frac{4E_a}{\hbar\omega_0}\tanh\frac{\hbar\omega_0}{4kT}\right\}, \qquad (12)$$

where E_a is the barrier height and ω_0 is the characteristic frequency of the bound electron (the binding being modeled by a harmonic-oscillator potential). At high temperature ($kT \gg \hbar\omega_0$), thermally activated hopping is dominant, and the exponential function in (12) reduces to the usual thermal-activation expression $\exp(-E_a/kT)$. In this high-temperature regime, the molecular polaron is characterized by a mobility $\mu \propto T^{-1}$.

Experimental evidence for dielectric polarons is extensive—especially for electrons in alkali halides[12]—but it has been suggested that holes in alkali and alkaline earth halides and in some oxides[13] show polaron localization. Mott[6] suggests that in amorphous SiO_2, dielectric polarons are formed rapidly (i.e., a time scale of $\sim 10^{-12}$ s), but that formation of molecular polarons is delayed ($\sim 10^{-5}$ s).

POLYMER PHYSICS

Polymers are long-chain molecules with molecular weights of from thousands to many millions (generally between 20,000 and 10^7 for materials of practical interest). The molecules may be linear, branched, or crosslinked to give a gel structure.

The size and shape of polymer molecules are generally determined from measurements in dilute solution. Molecular weights are obtained from osmotic pressure (number average molecular weight), light scattering (weight average molecular weight), and intrinsic viscosity measurements. Dissymmetry of light scattered by dilute solutions gives the size of molecules. Extent of chain branching can be estimated from light scattering or solution viscosity measurements by comparing the branched polymer with a linear polymer of the same molecular weight. The degree of cross-linking can be determined from the extent of swelling in a solvent or from the elastic modulus by using the kinetic theory of rubber. Swelling decreases and modulus increases as cross-linking increases. Solution properties are sensitive not only to molecular weight but also to the interaction between the polymer and solvent molecules. Most polymers have a distribution of molecular weights. In addition to the results from fractionations, the width of the distribution can be estimated from the ratio of weight average to number average molecular weights. This ratio is 1.0 if all the molecules are the same; it is around 2 for most polymers, but may be much greater for some highly branched polymers.

More recently it has been possible to determine the size and shape of individual polymer molecules in the bulk using the technique of small angle neutron scattering. The successful application of this technique depends on the fact that deuterium and hydrogen have very different coherent neutron scattering cross sections. Thus a small amount of deuterated polymer is dissolved in a protonated matrix and this provides contrast. One of the most important results from these studies is that polymer chains in the bulk assume their "unperturbed" dimensions as predicted by theory.

The molecular structure of polymers is unusually complex since the molecules can assume many conformations; more than one type of monomeric unit can make up the chains to give an infinite variety of distribution of sequence lengths, or the monomeric units can be arranged in different types of stereoregularity—isotactic, syndiotactic, or atactic forms. Nuclear magnetic resonance and infrared spectroscopy are especially powerful techniques for studying the structure of polymers. For polymers capable of crystallizing, x-ray diffraction is another useful tool.

The most important quantity determining the mechanical and many other physical properties of polymers is the *glass transition temperature.* If the glass transition temperature T_g is below ambient temperature, the molecules have extensive freedom of movement, so the material is either a viscous liquid or a rubbery material with a low elastic modulus. If T_g is above ambient temperature, the movement of the molecules is frozen in, so that the polymer is a rigid solid with a high elastic modulus of the order of 10^9 Pa. The glass transition temperature is not sharply defined but depends to some extent on the time scale of the experiment—the faster the experiment, the higher the apparent T_g. Glass transitions may be measured by many techniques, such as where breaks occur in the slope of volume or refractive index vs temperature curves or by the rapid change in elastic modulus with temperature in the transition region. The position of T_g on the temperature scale is largely due to the stiffness of the polymer chains. Flexible molecules such as polybutadiene and silicone rubbers have low T_g, while stiff molecules such as polystyrene and polymethyl methacrylate have high transition temperatures. Cohesive energy density or polarity is another important factor in determining T_g. Symmetry plays a secondary role. Glass transitions can be regulated by copolymerization or by addition of a plasticizer which lowers T_g.

Many polymers including polyethylene and isotactic polypropylene are semicrystalline. In their bulk behavior such polymers behave as though they are a mixture of amorphous and crystalline materials, but the exact nature of the crystalline state is not yet clearly defined for such materials. In the crystal lattice, some types of polymer chains assume a zig-zag conformation while others crystallize in the form of helices. Single crystals of some polymers have been grown from dilute solutions. In these single crystals the chains are perpendicular to the faces making up the thin lamellar crystals, so that each polymer chain must fold back on itself several times. There is some morphological evidence, based on electron microscopy studies, that even in the bulk polymer cooled down from the melt there is extensive chain folding in the crystalline phase. In terms of a two-phase model, the degree of crystallinity may be determined by x-ray, density or heat capacity measurements. Different techniques generally give similar but not identical values for the degree of crystallinity; typical values vary from 40% crystallinity for low-density polyethylene to 85% for high-density polyethylene. Crystallinity is greatly affected by chain perfection. Copolymerization and branching greatly reduce crystallinity. High stereoregular polymers such as isotactic polystyrene tend to be crystalline, while the random atactic polymers are noncrystalline. The melting point also depends upon chain perfection—the greater the degree of imperfection, the lower the melting point.

Many polymers of commercial importance are not linear polymers consisting of a single type of monomeric unit. Copolymers contain two or more kinds of monomers. If one type of monomer makes up the backbone and another type side chains, the polymers are called *graft polymers*. If two polymers are mechanically mixed together, the mixture is called a *polyblend*. Most, but not all, polyblends are two-phase systems. Block polymers, consisting of long sequences of one kind of polymer chain attached to the end of another kind of polymer chain, are also generally two-phase systems in which parts of a single molecule can be in two phases simultaneously. Two-phase systems are important commercially because of their great toughness.

Even at high temperatures where linear polymers are liquid, they tend to be very viscous. The melt viscosity is especially high if the molecular weight is above a critical value where chain entanglements can occur. At molecular weights above which entanglement occurs, the melt viscosity at low rates of shear depends approximately on molecular weight. These viscous polymer melts are also more or less elastic in nature and behave somewhat like rubber. If the molecules are crosslinked to one another, the elastic behavior becomes dominant and true vulcanized rubbers result. Polymer melts are generally non-Newtonian, and the properties are very dependent upon the rate of shear. Molecular theories have been developed by Rouse, Zimm, and Bueche which explain quite well many of the rheological properties of melts and solutions.

The Rouse, Bueche, and Zimm theories do not explain the long-range motions of entangled polymer chains such as those that occur in the melt under processing conditions. De Gennes, Edwards, and Doi have developed a theory based on scaling laws taken from the renormalization group approach which has proved so successful in elementary particle physics. In this theory the motion of an entangled polymer chain is confined along its contour length so that it moves as if it were inside a tube. This process is called *reptation*. The reptation concept has been successful in explaining the molecular weight dependence of the flow of entangled polymer molecules.

The usefulness of polymers depends primarily upon their mechanical properties. The elastic modulus of rubbers is explained quite satisfactorily by the kinetic theory of rubber elasticity. No satisfactory theory is yet available for rigid polymers. Dynamic mechanical measurements using oscillating stresses or strains have been especially useful in relating mechanical properties to molecular structure; such tests are generally made to measure the elastic modulus and mechanical damping over a wide range of frequencies and temperatures. Generally the effects of temperature and frequency (or time) can be made equivalent by a superposition treatment such as the one developed by Williams, Landel, and Ferry. The phenomenological theory of viscoelasticity has developed to the stage where it is possible to interconvert data from one type of test (say dynamic mechanical) to other types of tests such as creep, stress relaxation and, to a lesser extent, stress-strain data. On heating a rigid organic polymer, the modulus drops from about 10^9 Pa to a low value of about 10^6 Pa in a small temperature interval near the glass transition temperature, unless the polymer is highly crosslinked or crystalline. Both crystallinity and crosslinking can greatly increase the modulus above T_g, but they have little effect on the modulus below T_g. Polymers are unique in that some of them can be elongated over 1000% before they break.

The dielectric constant and power factor or electrical loss depend upon the number and type of dipoles. At low temperatures (or high frequencies) where the dipoles are frozen in, the dielectric constant and electrical loss are both low. At high temperatures (or low frequencies) where the molecules have high mobility, the dielectric constant is high while the electrical loss is often low. At intermediate temperatures or frequencies, where the main relaxation times for dipolar motion are approximately the same as the applied electrical frequency, the electrical loss goes through a pronounced maximum, and the dielectric constant changes rapidly with either frequency or temperature. Since the mobility of the chain backbone is related to the ease with which dipoles can move, there is often a good correlation between electrical and mechanical properties. Impurities in polymers can be very detrimental to good electrical properties, especially at high temperatures where conductivity can be relatively high.

Most pure amorphous polymers are transparent. Crystallinity often makes a material milky or white in appearance. Long chain molecules can be oriented by stretching in the molten state or by cold-drawing in some cases. Such oriented materials are generally highly birefringent, since the polarizability along the chain is usually quite different from the polarizability perpendicular to the chain. The mechanical properties of oriented polymers such as fibers are also highly anisotropic. For instance, the modulus and tensile strength are generally much greater parallel to the chain axis than perpendicular to it.

An interesting development has been to ultra-orient polymers by various techniques to produce high modulus, high strength fibers. In some cases this has led to the production of materials with a strength greater than that of steel. In order to accomplish this, liquid-crystal-forming polymers may be spun into fibers from anisotropic solutions or various high drawing processes may be used, including solid state extrusion.

Polymers have very high coefficients of thermal expansion compared to most rigid materials. The coefficients of expansion shows a distinct break at the glass transition temperature—the coefficient being greater above Tg. Most polymers would be classed as thermal insulators rather than as thermal conductors.

The discovery of high electrical conductivity in organic polymers such as polyacetylene when doped by arsenic pentafluoride has led to a great deal of experimental and theoretical activity to explain the phenomenon. Conduction is postulated to proceed by means of solitons but many questions remain obscure. This is at present a very active field and at least one superconducting polymer, sulfur nitride, $(SN)_x$, has been identified. Although major technological developments involving conducting polymers remain to be realized, a storage battery using polyacetylene has been described.

POSITRON

The positron is one of many fundamental bits of matter. Its rest mass (9.109×10^{-31} kg) is the same as the mass of the electron, and its charge ($+1.602 \times 10^{-19}$ coulomb) is the same magnitude but opposite in sign to that of the electron. The positron and electron are antiparticles for each other. The positron has spin 1/2 and is described by Fermi-Dirac statistics as is the electron (see ELECTRON).

The positron was discovered in 1932 by C. D. Anderson at the California Institute of Technology while doing cloud chamber experiments on cosmic rays. The cloud chamber tracks of some particles were observed to curve in such a direction in a magnetic field that the charge had to be positive. In all other respects, the tracks resembled those of high-energy electrons. The discovery of the positron was in accord with the theoretical work of Dirac on the negative energy states of electrons. These negative energy states were interpreted as predicting the existence of a positively charged particle.

Positrons can be produced by either nuclear decay or the transformation of the energy of a gamma ray into an electron-positron pair. In nuclei which are proton-rich, a mode of decay which permits a reduction in the number of protons with a small expenditure of energy is positron emission. The reaction taking place during decay is

$$p^+ \rightarrow n^0 + e^+ + \nu$$

where p^+ represents the PROTON, n^0 the NEUTRON, e^+ the POSITRON, and ν a massless, chargeless entity called a NEUTRINO. The positron and neutrino are emitted from the nucleus while the neutron remains bound within the nucleus. Although none of the naturally occuring radioactive nuclides are positron emitters, many artificial radioisotopes which decay by positron emission have been produced. In fact the first observed case of positron decay of nuclei was also the first observed case of artificial radioactivity. An example of such a nuclear decay is

$$_{11}\text{Na}^{22} \rightarrow {}_{10}\text{Ne}^{22} + e^+ + \nu \text{ (half-life} \approx 2.6 \text{ years)}$$

This particular decay provides a practical, usable source of positrons for experimental purposes.

The process of pair production occurs when a high-energy gamma ray interacts in the electromagnetic field of a nucleus to create a pair of particles—a positron and an electron. Pair production is an excellent example of the fact that the rest mass of a particle represents a fixed amount of energy. Since the rest energy ($E_{\text{rest}} = m_{\text{rest}}c^2$) of the positron plus electron is 1.022 MeV, this energy is the gamma energy threshold and no pair production can take place for lower-energy gammas. In general, the cross section for pair production increases with increasing gamma energy and also with increasing Z number of the nucleus in whose electromagnetic field the interaction takes place.

The positron is a stable particle (i.e., it does not decay itself), but when it is combined with its antiparticle, the electron, the two annihilate each other and the total energy of the particles appears in the form of gamma rays. Before annihilation with an electron, most positrons come to thermal equilibrium with their surroundings. In the process of losing energy and becoming thermalized, a high-energy positron interacts with its surroundings in almost the same way as does the electron. Thus for positrons, curves of distance traversed in a medium as a function of initial particle energy are almost identical with those of electrons.

It is energetically possible for a positron and an electron to form a bound system similar to the hydrogen atom, with the positron taking the place of the proton. This bound system has been given the name "positronium" and the chemical symbol Ps. Although the possibility of positronium formation was predicted as early as 1934, the first experimental demonstration of its existence came in 1951 during an investigation of positron annihilation rates in gases as a function of pressure. The energy levels of positronium are about one-half those of the hydrogen atom since the reduced mass of positronium is about one-half that of the hydrogen atom. This also causes the radius of the positronium system to be about twice that of the hydrogen atom. Thus positronium is a bound system with a radius of 1.06Å and a ground state binding energy of 6.8eV. As mentioned previously, the positron has an intrinsic magnetic moment and an intrinsic angular momentum, or spin. In positronium, the spins of the electron and positron can be oriented so they are either parallel or antiparallel. These two states, called ortho-positronium and para-positronium respectively, have very different annihilation characteristics. Most positrons entering a medium do not form positronium, but the general annihilation characteristics show the same dependence on orientation of the spins, regardless of whether the annihilation occurs in a collision or from the bound state.

For many years all attempts to observe positronium through the emission of its characteristic spectral lines were unsuccessful. These lines are similar to hydrogen's except that the wavelengths of all corresponding lines are doubled. Finally in 1975 the Lyman-α line (the radiation emitted when the first excited state of positronium decays to the ground state) was observed in the laboratory. In another recent development the long-predicted positronium negative ion, consisting of two electrons and one positron bound together by electrical attraction, was detected experimentally in 1981. Both of these experiments were made possible by the discovery that positronium can be formed efficiently in a vacuum when a solid target is bombarded by a slow positron beam.

Positronium is also the ideal system in which the calculations of quantum electrodynamics can be compared with experimental results. In fact measurements of the fine-structure splitting of both the ground state and the first excited state have served as important confirmations of the theory of quantum electrodynamics.

It is possible for a positron-electron system to annihilate with the emission of one, two, three, or more, gamma rays. However, not all processes are equally probable. One-gamma annihilation requires another particle to participate to conserve momentum. This process is a very infrequent type decay. The most probable decay is by the emission of two gamma rays, directed in opposite directions, with each possessing about one-half the energy of the system. The presence of these 0.511-MeV ($=mec^2$) gamma rays is always found when positrons are present. Whether annihilation is to be by the emission of one, two or three gammas depends on the orientation of the spins of the positron and electron. Conservation of charge parity and angular momentum requires that the number of gamma rays emitted be an even number (most likely 2) if the spins are antiparallel, and be an odd number (most likely 3, but possibly 1) if the spins are parallel.

If formed in free space, positronium exhibits two characteristic lifetimes against self-annihilation. These are $\tau_1 = 1.25 \times 10^{-10}$ second for the anti-parallel spin case (also called the singlet state) and $\tau_3 = 1.39 \times 10^{-7}$ second for the parallel spin case (called the triplet state). Another lifetime, characteristic of the physical surroundings of the positron, is found when positronium is formed in certain condensed materials. This lifetime (known as τ_2) is longer than the singlet free space lifetime τ_1, but is much shorter than the triplet free space lifetime τ_3. In general, this τ_2 lifetime is a measure of the rate of "pickoff" of atomic electrons with antiparallel spins by the positrons in triplet positronium. In this process, the positron enters the material and forms triplet positronium with an electron, but then annihilates with an electron belonging to one of the surrounding atoms, whose spin is oriented opposite to that of the positron. That the probability of "pickoff" and the subsequent two-gamma annihilation depend on the properties of the surroundings is to be expected. Indeed, the τ_2 lifetime is a function of the material, the temperature, the density, the degree of crystallinity, the phase, etc. It has been found in some cases that even in the same material not all positrons in triplet positronium have the same "pickoff" probability, a fact revealed by the presence of more than one τ_2 component. Positron lifetimes have been measured in a great variety of substances in an effort to correlate trends in the τ_2 lifetime values with chemical or physical properties.

The angular correlation of the annihilation gammas has been measured for both the two-gamma and three-gamma cases. In three-gamma annihilation, the gammas are coplanar as predicted, and azimuthally correlated such that their energies and directions are consistent with the conservation laws of energy and momentum. Two-gamma annihilation studies have been extensive, the results showing that the two gammas are emitted within a few milliradians of 180° from each other. The width of the two-gamma angular distributions is a measure of the linear momentum of the positron-electron system when annihilation occurs. These measurements can be used to gain information on the momentum distribution of the electrons with which the positrons annihilate. The development of high resolution semiconductor gamma-ray detectors has provided a faster but less accurate method of investigating the electron momentum distribution in materials by positron annihilation. This method is based on measurement of the Doppler shift in the energy of the annihilation gamma rays caused by the motion of the positron-electron pair at annihilation.

In recent years several applications of positrons have been developed. For example, a positron annihilation has been used to determine Fermi surfaces and to study defects in metals and metallic alloys. It has also become possible to produce slow monochromatic positron beams which show promise of being useful in the study of the solid surfaces to complement the well-established technique of low-energy electron diffraction (LEED). A recent medical application of positrons is positron-emission tomography (PET). This is a process by which a patient's metabolic activity, often metabolism in the brain, is observed. This technique gives a fundamentally different result from that obtained by x-rays or CAT scans, which display density differences rather than the chemical activity levels as does PET.

POTENTIAL

The concept of potential has developed in several fields in physical phenomena from either one or another of two viewpoints. One idea is that there can be the storage of some entity which results in energy storage in the system. This stored energy may be released for dynamic use. The energy so stored can thus be considered as potential energy.

The other idea from which the concept of potential has been developed is that it is some scalar function whose space rate of change yields a vector force which may be useful for mathematical analyses or for the development of other physical quantities. As will be shown, these two ideas are compatible.

From one, the other, or both of these general viewpoints has developed the concept of potential as an entity in the subjects of gravitation, electricity, magnetism, heat conduction, fluid flow, elastic stress, and others. The early analysis of entities in many of these subjects began through experimental observations and mathematical hypotheses of various sorts, but the concept of potential eventually became apparent if it was not in the original analysis.

The concept of potential as a significant entity for the analysis of electric phenomena was developed by Simeon Poisson, George Green, and others in the period from about 1813 to 1827. It was realized that energy could be released from electrically charged bodies, and the concept of potential was developed as one characteristic of such a charged system that measured the ability of the system to release this energy. The energy stored in the system was and is called *potential energy* and is a scalar quantity.

The discussion of this article is phrased in electrical terminology, although many of the interrelationships among entities discussed here are applicable to the subjects of gravitation, heat conduction, fluid flow, and other subjects. The concepts of scalar magnetic potential and vector magnetic potential are included here so that the basic concepts in electromagnetism are complete.

Closely associated with the concept of electric potential was the concept of *charge* that had been formulated by Charles Augustin de Coulomb and others over about a 100-year period starting about 1737. The electric scalar potential of a macroscopic system is defined as the electric energy of the system divided by the electric charge. This simple definition presumes a basic two-conductor, statically charged system. The mathematical expression for the definition of the potential Φ is

$$\Phi = \frac{W}{Q}$$

where W is the energy of the system and Q is the charge (see list of units at end of article).

Modern electric systems employ the concept of potential for much more sophisticated forms through the use of summations of charge effects either in discrete or in distributed forms. The complete expression for electric potential caused by the accumulation of a number of concentrated charges Q_k, surface charge density σ over a surface S, and volume charge density ρ in a volume V, all being located in a dielectric medium of uniform permittivity ϵ, is

$$\Phi = \sum_{k=1}^{n} \frac{Q_k}{4\pi\epsilon r} + \frac{1}{4\pi\epsilon}\int_S \frac{\sigma ds}{r} + \frac{1}{4\pi\epsilon}\int_V \frac{\rho dv}{1}$$

where r measures the magnitude of the distance from the point at which the electric potential is evaluated to each charged particle or element of charge.

The difference in electric potential from one point a to another point b in a static electric field is related to a vector function called the electric field intensity $\mathbf{\mathcal{E}}$ (a characteristic of the space related to the negative of the gradient of the electric potential) through the line integral relationship

$$\Phi_{ab} = - \int_a^b \mathbf{\mathcal{E}} \cdot d\mathbf{l},$$

where $\mathbf{l}$ is a vector direction measured along the path in the direction from the point a to the point b, and the scalar product between $\mathbf{\mathcal{E}}$ and $d\mathbf{l}$ is denoted by the dot or scalar product notation.

The inverse form of this integral expression is the gradient form for the static electric field intensity, namely

$$\mathbf{\mathcal{E}} = - \nabla \Phi$$

where the ∇ symbol is a vector differential space operator which, when applied to the scalar electric potential Φ, yields the electric potential gradient.

An extension of spatial derivative operations yields another function of the scalar electric potential Φ, known as the scalar Laplacian, as $\nabla^2 \Phi$. This term, when equated to the negative of the volume space charge density ρ divided by the permittivity of the space, is known as Poisson's equation. Thus,

$$\nabla^2 \Phi = - \rho/\epsilon$$

If the electric volume charge density is zero, the above relationship becomes

$$\nabla^2 \Phi = 0$$

and is known as Laplace's equation.

Electric charges in motion produce magnetic effects, which result in a magnetic field intensity vector $\mathbf{H}$, somewhat analogous to the corresponding vector $\mathbf{\mathcal{E}}$ in electric field phenomena. The line integral relationship between this vector $\mathbf{H}$ and the vector direction measured along a path in space from point a to b establishes an analogous scalar magnetic potential Ψ_{ab} as

$$\Psi_{ab} = - \int_a^b \mathbf{H} \cdot d\mathbf{l}$$

This function is useful in the evaluation of magnetic field geometric relations for locations in space where the electric current density is zero.

For regions in magnetic fields where current densities exist, a designation of a magnetic potential relation can only be made through a function called the *vector magnetic potential*. This vector is defined in a form similar to the expression for scalar electric potential caused by a volume distribution of electric charge density as given earlier. Thus, the vector magnetic potential $\mathbf{A}$ at a point in space, caused by a distribution of current density $\mathbf{J}$ over a volume V is

$$\mathbf{A} = \frac{\mu}{4\pi} \int_V \frac{\mathbf{J}\, dv}{r}$$

where μ is the permeability of space and r is the magnitude of the distance from the point at which $\mathbf{A}$ is evaluated to each element of current density of the system. The point under consideration can be a point within the region of current density.

The vector magnetic flux density $\mathbf{B}$ in such a space is related to the vector magnetic potential $\mathbf{A}$ through a spatial differential function called the curl and symbolized by the operational form as

$$\mathbf{B} = \nabla \times \mathbf{A}$$

An extension of spatial derivative operations upon the vector magnetic potential also yields another function of this potential known as the vector Laplacian, $\nabla^2 \mathbf{A}$. This term is related to the current density $\mathbf{J}$ at a point in the field as

$$\nabla^2 \mathbf{A} = - \mu \mathbf{J}$$

This expression is analogous to the similar scalar Laplacian of the electric potential which was related to the electric charge density at the point of evaluation.

For systems in which the charges are moving in such a manner that the vector magnetic potential is not constant with respect to time, the elementary form of the relationship between the electric field intensity $\mathbf{\mathcal{E}}$ and the scalar electric potential Φ must be modified to include a function of the vector magnetic potential, namely

$$\mathbf{\mathcal{E}} = - \nabla \Phi - \frac{\partial \mathbf{A}}{\partial t}$$

This is the general expression that is valid at a point in space for all conditions. As action at a distance is considered, the elementary forms for the evaluation of the scalar electric potential Φ and of the vector magnetic potential $\mathbf{A}$, however, must recognize the time delay in action with respect to the causes.

If the scalar electric potential at a point P is to be evaluated at some time t, the *retarded potential* must consider the finite velocity of propagation that occurs in the path length r between the point P and the location of the charge that causes the electric potential.

Depending upon the nature of the charge, the retarded potential expression can be expressed in terms of the retarded time $t - r/c$, where c is the velocity of the propagated effect in free space. For the case in which the charge is distributed over a volume, the expression becomes

$$\Phi_{P,t} = \frac{1}{4\pi\epsilon}\int_V \frac{[\rho]_{t-r/c}dv}{r}$$

The symbol $[\rho]_{t-r/c}$ indicates that the charge density at the source of the field is that evaluated at an earlier time $t - r/c$. If the charges are discrete or distributed over surfaces, the corresponding forms of the potential function for these geometries would be used.

In a similar manner, the retarded vector magnetic potential can be expressed for a volume distribution of current density as

$$\mathbf{A}_{P,t} = \frac{\mu}{4\pi}\int_V \frac{[\mathbf{J}]_{t-r/c}dv}{r}$$

All preceding relations are expressed in a form that results if a rationalized system of units is used. The internationally accepted metric (SI) units that conform with these preceeding relationships are:

Entity	*Symbol*	*Unit*
Energy	W	joule
Potential (electric)	Φ	volt
Charge	Q	coulomb
Length	r, l	meter
Area	S	meter^2
Volume	V	meter^3
Surface charge density	σ	coulomb/meter^2
Volume charge density	ρ	coulomb/meter^3
Permittivity	ϵ	farad/meter
Electric field intensity	$\mathcal{E}$	volt/meter
Magnetic field intensity	$\mathbf{H}$	ampere/meter
Scalar magnetic potential	Ψ	ampere
Vector magnetic potential	$\mathbf{A}$	weber/meter
Permeability	μ	weber/meter-ampere
Magnetic flux density	$\mathbf{B}$	tesla
Current density	$\mathbf{J}$	ampere/meter^2
Time	t	second
Velocity	c	meter/second

PRESSURE, VERY HIGH

In 1950 high pressure research in physics was associated primarily with the macroscopic measurements of classical physics and the geophysics of the outer crust of the earth. The higher pressures now available permit extensions of these studies. However, the most far reaching development has been the use of modern instrumentation to study high pressure effects on atomic and molecular properties. Thus high pressure, like low temperature, has become an integral tool of modern science. This transformation in high pressure research took place first in solid state physics and geophysics. In recent years it has extended to chemical physics and biophysics. (See FLUID STATICS for a discussion of the concept of "pressure" and methods for measuring it.)

For the purposes of this article, "very high pressure" will imply pressures above a few kilobars (1.0 kbar = 987 atm. = 0.1 GPa.). This lower limit permits the discussion of recent significant experiments in chemical and biophysics in the 10–12 kilobar range.

Only a brief outline of techniques for generating pressure is included. Piston and cylinder devices are used to virtually all work below ~20 kilobars and for many applications to 50 kilobars where samples larger than a few milligrams are required. For higher pressure work the tapered anvil pistons developed by P. W. Bridgman are very widely employed, as well as the modification wherein support is applied also to the taper. The use of diamond anvils in a Bridgman configuration is very wide spread. Improved alignment techniques permit pressures of the order of 500 kilobars, though with frequent breakage of the diamonds. With appropriate liquid mixtures pressures are hydrostatic to 90 kilobars, and the use of solidified rare gases extends the hydrostatic range. An important development in calibration has been the discovery (at the National Bureau of Standards) that the emission of ruby at 692 nm shifts linearly with pressure to several hundred kilobars at least. The diamond cells are especially useful for x-ray, Raman, and Brillouin scattering, and optical absorption at wavelengths longer than 300–350 nm. Since essentially all diamonds luminesce when exposed to intense UV radiation, their usefulness for fluorescence studies is limited to systems which can be excited in or near the visible region of the spectrum.

Bundy and coworkers at General Electric have used a supported taper cell with sintered diamond pistons to make extensive electrical resistance studies to 500 kilobars pressure. Other devices claim static pressures of a megabar or so, but experimental results in this range are very limited at present.

The use of dynamic pressure devices (shockwave) permits pressures in the multimegabar region, accompanied by very high temperatures, but a discussion of shock experiments is beyond the scope of this article.

To give some flavor of the breadth of current high pressure research the discussion contains a section on electronic phenomena, with briefer outlines on structural studies, the liquid state, geophysics, and biophysics.

Electronic Phenomena Probably the most generally significant application of high pressure research in the past 30 years has been the study of electronic phenomena. The basic discovery is that with increasing compression one perturbs different electronic energy levels in different degrees. This "pressure tuning" of electronic energy levels has proved to be a very powerful tool in understanding the behavior of matter and in discovering new electronic phenomena.

High pressure studies have been essential to the testing of numerous theories of electronic phenomena. A few examples are given here:

(1) In the simple form first proposed by Bethe, ligand field theory predicts that the *d* orbitals of transition metal ions will be split in energy by an amount which increases as R^{-5}, where R is the ion-ligand distance. High pressure studies where R is decreased continuously have established the possibilities and limitations of this analysis. Van Vleck predicted that when this splitting gets sufficiently large the normal high spin configuration would rearrange to permit spin pairing. As discussed below, this electronic transformation has been confirmed by high pressure studies.

(2) Electron donor-acceptor complexes occur widely in solutions of chemical and biological interest. Mulliken developed a theoretical description in which the ground state is held together primarily by van der Waals forces, whereas the excited state involves a transfer of charge from the donor to the acceptor. Compression should stabilize the charge transfer state. Indeed, for a number of complexes this stabilization has been verified by the observation that the charge transfer peak shifts rapidly to lower energy with increasing pressure and increases dramatically in intensity.

(3) Many luminescent and related processes have an efficiency which depends strongly on the transfer of excitation between species in a crystal, a solution, or a macromolecule. This transfer is basic in fluorescent lighting, rare earth lasers, photosynthesis, and the photographic process. The effectiveness of the energy transfer depends strongly on the difference in energy between the donor and acceptor (or activator and sensitizer) states. The pressure tuning of energy levels is an ideal scheme for testing theories of this efficiency. The Förster-Dexter theory has been confirmed quantitatively and a number of theories involving lightning and laser materials have been tested effectively by means of high pressure luminescence measurements.

The relative shift of electronic energy levels can provide a new electronic ground state for a material with changes in electrical, magnetic, optical or chemical properties. One of the most dramatic results of "pressure tuning" is that these electronic transitions are found to be as ubiquitous as structural phase transitions.

The most widely studied transitions involve a change in electrical properties. In the early 1960s, insulator-conductor transitions were observed in molecular crystals such as I_2, Se, As, and some organic materials; in ionic compounds like the thallous halides; and in Si, Ge, GaAs, GaSb, InP, InAs, InSb, ZnS, ZnSe, ZnTe, CdS, CdSe, CdTe, etc., all having the zinc blende or related structures. A few more such transitions have been observed since, but much of the more recent effort has been towards a more detailed understanding of the insulator-conductor transition. Groups at Bell Telephone Laboratories have made thorough studies of such transitions in transition metal oxides and rare earth chalcogenides.

A recent extension of the early studies on I_2 indicates that at ~160 kilobars it becomes a diatomic metal and at 200–210 kilobars it becomes a monatomic metal. These results have been used by theorists as a model for the behavior of diatomic molecular crystals, in particular for hydrogen. Calculations now indicate that hydrogen will become a diatomic metal near 2–2.5 megabars and a monatomic metal at ~5.5 megabars. These pressures, especially the latter, are beyond the foreseeable range of static experiments.

Other types of electronic rearrangements which are detected from electrical properties involve the alkali, alkaline earth, and rare earth metals. In the heavy alkali metals an *s* electron is promoted to the *d* band, giving transition metal character to these materials. In the rare earths a $4f$ electron is delocalized into the d band, while calcium and strontium transform from metals to semiconductors at high pressure.

It is of interest that many of these metallic phases which appear at high pressure are superconductors. The study of these materials has, in fact, contributed measurably to the understanding of superconductivity.

Electronic transitions involving magnetic properties include transformations of transition metal ions from high spin to low spin configuration with increasing ligand field, transformation of iron from a ferromagnet to a paramagnetic phase at 115 kilobars, the appearance of ferromagnetism in FeO near 60-80 kilobars, and a variety of transformations in ferromagnetic insulators. High pressure neutron diffraction has proved to be a very elegant technique for these latter studies.

Electronic transitions can also have chemical consequences. As mentioned earlier the excited (charge transfer) state of electron donor-acceptor complexes is stabilized vis-à-vis the ground state with pressure. At sufficiently high pressure a significant fraction of the molecules are in this state, forming radicals which can react in the solid state geometry to form compounds which have never been made by any other approach.

Structural Research The measurement of the effect of high pressure on lattice parameters for simple structures from x-ray powder patterns is an art which is at least 20 years old. The advent of rotating anode electrodes and especially synchrotron radiation, plus improvements in the hydrostaticity of the diamond cell, have made possible single crystal x-ray studies to 100 kilobars or higher, as well as resolution of degrees of ordering in compounds at high pressure, etc. Most of the studies possible on inorganic crystals at one atmosphere can now be performed at high pressure. Organic crystallography under pressure is less advanced.

Recently Brillouin scattering has proven to be a very useful tool for establishing elastic constants of materials under extreme conditions. It has been applied primarily to materials of geological interest.

P. W. Bridgman established many years ago that first-order structural phase transitions were common phenomena at high pressure. With x-ray crystallography it has been possible to establish the structures of the new phase in situ. The most exciting advance in the past decade has been the use of laser Raman scattering to follow the lattice vibrational modes as a phase transition as approached. With increasing pressure most vibrational modes stiffen (shift to higher energy). However, as one nears the pressure at which a structural phase transition occurs, one mode softens and the lattice "comes apart" and rearranges by this mechanism. There has been a great deal of study of various kinds of lattices and characterizations of the relevant soft modes so that the mechanics of structural phase transitions is, for the first time, understood. This research is an excellent example of how a new tool extracts new' and exciting science from an old field.

Liquid State Studies High pressure research has impinged most strongly on modern chemical physics in the areas of properties of and processes in the liquid state. Studies include molecular motion and relaxation processes, luminescence, and chemical reaction rates and synthesis. Much of this research has become possible in the past decade due to the availability of high field NMR equipment, lasers, photon counters, and high speed electronics.

With respect to diffusion and relaxation processes the major conclusion is that in order to test theories adequately it is necessary to study the temperature coefficient of these processes *at constant density*. This coefficient is, in general, very different from the coefficient at constant pressure which is obtained from experiments at one atmosphere.

One of the important aspects in understanding fluids involves the relationship between macroscopic properties such as viscosity or dielectric constant and molecular properties. Pressure induces very large changes in the bulk properties without changing the temperature (thermal energy) or the chemical composition of the system. It has been demonstrated from pressure experiments that the Stokes-Einstein relation between viscosity and molecular diffusion holds remarkably well over ranges of 10^4 in viscosity. Unequivocal relations between dielectric constant and rate of emission of luminescence, and between viscosity and thermal dissipation of molecular excitation have also been established.

The study of pressure effects on chemical reaction rates has long been used to establish the mechanism of chemical reactions. The analyses have been based on the classical Eyring picture of the central role of the transition state. A stochastic theory whose modern development is based on early work of Kramers predicts a different rate controlling step in fluids of moderate viscosity. Recently, high pressure experimentation has provided a clear proof of the applicability of the stochastic theory.

Geophysics The field of high pressure geophysics is one of the oldest aspects of high pressure research and one which is continuing and increasing in intensity. There are numerous active laboratories in the United States as well as in Japan, Australia, and Europe. It is beyond the scope of this article as well as the expertise of the author to review this activity thoroughly so only the barest outline is given.

In the period up to about 1965-70 most high pressure geophysics was concerned with pressure-volume-temperature measurements and changes in crystal structure in the crust and top of the mantle. The usual method was by quenching in the high pressure–high temperature phase. Today one can investigate these phenomena in situ via x-ray diffraction to pressures which correspond to those in the lower mantle. In addition Brillouin scattering permits the determination of elastic constants at high pressure–information of importance in seismology. Magnetic properties of high pressure forms can be established via Mössbauer resonance. High pressure high temperature studies involving laser heating have shown that complex silicates tend to decompose into SiO_2, FeO, MgO, etc. under conditions near the upper mantle–lower mantle boundary. High pressure studies have also contributed to our understanding of mantle dynamics. Finally, recent studies have been made on the equation of state of rare gas solids to ~500 kilobars. This information contributes to our picture of conditions in the outer layers of the Jovian planets.

Biophysics Optical, and, in particular, fluorescent properties of proteins have proved over the past 25 years to provide a powerful probe of protein conformation, of unfolding during denaturation and of rapid localized motion of protein segments. In the past decade high pressure fluorescence studies of proteins in solution have been undertaken and have revealed both reversible and irreversible changes in conformation. These experiments have contributed considerably to our understınding of segmental motion and the denaturation process. High pressure studies of rates of chemical reactions at active sites have also been significant. Biophysics (and biophysical chemistry) constitutes one of the newest but most rapidly growing areas of modern high pressure research.

This brief outline of a variety of high pressure studies is intended to convey some feeling for the power and versatility of high pressure as a tool for understanding the physics of condensed systems.

PROPAGATION OF ELECTROMAGNETIC WAVES

The equations governing electromagnetic theory–Maxwell's equations–have special solutions that describe electromagnetic wave propagation. Such solutions provide for the transport of energy by wave propagation from regions of space containing moving charged particles or currents through regions completely devoid of matter. Wave propagation in free space (vacuum) occurs with a wave velocity $c = 2.9979 \times 10^8$ m/s; this velocity is independent of frequency and thus applies to the complete electromagnetic spectrum: radio waves, microwaves, infrared radiation, visible light, x-rays, etc.

In the presence of matter, wave propagation can be substantially altered, in some cases propagating with a velocity much smaller than c. The type of wave propagation is characterized by its dispersion relation (relation between wave number and frequency); the various types of wave behavior are referred to by names: e.g., *helicon waves*, *Alfvén waves*, *surface plasma waves*, etc. Propagation through inhomogeneous materials or through regions containing different materials gives rise to the phenomena of *reflection*, *refraction*, and *diffraction*. Wave propagation in anisotropic solids is the source of phenomena such as *double refraction* and *birefringence*.

Maxwell's equations of electromagnetic theory provide a relationship between the electric and magnetic field vectors **E**, **B** and the charge and current densities ρ, **J**. These equations, together with appropriate boundary conditions are sufficient to describe a full range of electromagnetic phenomena, including wave propagation. In the presence of a material medium some of the charge and current density arises from atoms, molecules, ions and/or electrons making up the medium; these latter densities both influence and are influenced by the electromagnetic field quantities (**E** and **B**). The situation is most conveniently handled by introducing two auxiliary field quantities, the electric displacement **D** and magnetic intensity **H**, and constitutive parameters ϵ, μ, and σ which characterize the medium. The *permittivity* ϵ, the *permeability* μ and the *conductivity* σ will be defined and discussed in more detail below.

Maxwell's equations are conventionally written:

$$\nabla \times \mathbf{E} = -\dot{\mathbf{B}} \tag{1}$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \dot{\mathbf{D}} \tag{2}$$

$$\nabla \cdot \mathbf{D} = \rho \tag{3}$$

$$\nabla \cdot \mathbf{B} = 0. \tag{4}$$

These differential equations, supplemented by the constitutive relations for the medium in which the fields are to be calculated,

$$\mathbf{D} = \epsilon \mathbf{E} \tag{5}$$

$$\mathbf{B} = \mu \mathbf{H} \tag{6}$$

$$\mathbf{J} = \sigma \mathbf{E} \tag{7}$$

provide a macroscopic phenomenological description of electromagnetic phenomena which is the most appropriate formalism for treating wave propagation. The effect on the electric field by free and bound charges of the medium is accounted for by the permittivity ϵ. The transport currents produced by the motion of free charges in the medium are taken into account through the conductivity σ, whereas the magnetic field produced by these currents as well as by atomic and molecular currents derives from the permeability μ.

Plane Wave Fields; Dispersion Relations A simple medium is defined as one containing no charge or current density (ρ, $\mathbf{J} = 0$) and being characterized by constant values of ϵ and μ (vacuum is a particular simple medium with $\epsilon = \epsilon_0$ and $\mu = \mu_0$). Taking the curl of Eq. (1), combining with the time derivative of (2), and eliminating **D** and **B** by means of (5) and (6) yields

$$\nabla \times \nabla \times \mathbf{E} = -\mu\epsilon\ddot{\mathbf{E}}. \tag{8}$$

By substituting a vector identity and noting that $\nabla \cdot \mathbf{E} = 0$ in a simple medium, we find that (8) reduces to the *wave equation*. It is convenient to introduce a specific time dependence for **E**, namely, $\exp(-j\omega t)$, where ω is the impressed frequency of the electromagnetic disturbance:

$$\nabla^2 \mathbf{E} + \omega^2 \mu\epsilon \mathbf{E} = 0. \tag{9}$$

The wave or phase velocity is given by $v_p = 1/(\epsilon\mu)^{1/2}$; in the case of free space or vacuum the wave velocity is $c = 1/(\epsilon_0\mu_0)^{1/2}$.

Equation (9) has a solution in the form of a plane wave, i.e., one in which the field quantity **E** (or **H**) has a space and time dependence given by $\exp(j\mathbf{k}\cdot\mathbf{r} - j\omega t)$, with **k** equal to the wave vector, $\mathbf{k} = k\mathbf{n}$, where **n** is a unit vector normal to the wavefront (i.e., the direction in which the wave is propagating) and $k \equiv |\mathbf{k}| = 2\pi/\lambda$ (λ is the wavelength). When we substitute the exponential solution into (9), we get the dispersion relation $\omega^2 = v_p{}^2k^2$ (an algebraic relationship between ω and k). Examination of the Maxwell equations shows that **H** also satisfies (9), and that **E**, **H**, and **n** are mutually perpendicular. The energy transported per unit time per unit area is most conveniently expressed in terms of the Poynting vector $\mathbf{S} = \mathbf{E} \times \mathbf{H}$; for a plane electromagnetic wave **S** has the direction of the unit normal **n**.

The case of a conducting medium with constant conductivity σ is not much more difficult to handle. Eq. (9) gets an extra term

$$\nabla^2 \mathbf{E} + \omega^2\mu\epsilon\mathbf{E} + j\omega\mu\sigma\mathbf{E} = 0 \tag{10}$$

or

$$\nabla^2 \mathbf{E} + \omega^2\mu\epsilon^*\mathbf{E} = 0 \tag{11}$$

with

$$\epsilon^* \equiv \epsilon + j\sigma/\omega. \tag{12}$$

Thus through the introduction of the complex permittivity ϵ^*, Eq. (11) takes on the same form as (9). Using the plane wave expression $\exp(j\mathbf{k}\cdot\mathbf{r})$ in Eq. (11) gives the dispersion relation

$$k^2 = \omega^2\mu\epsilon(1 + j\sigma/\omega\epsilon). \tag{13}$$

Wave Propagation in Plasmas; the Ionosphere Gases which are highly ionized are good conductors of electricity. An ionized gas in which the positive and negative space charges are nearly balanced is called a *plasma*. Plasmas play an important role in many areas of physics: e.g., physics of the upper atmosphere, theoretical astrophysics, the problem of ion containment in thermonuclear (fusion) reactors, and solid state plasmas.

Wave propagation in a plasma is governed by Eqs. (11) and (12), or equivalently by (13). The conductivity of the plasma is due primarily to free electrons, since the more massive ions contribute much less to electrical transport; for most non-solid-state plasmas of interest, $\epsilon \approx \epsilon_0$ and $\mu \approx \mu_0$. The conductivity contains a contribution from the damping force of electron-ion collisions as well as an out-of-phase inertial contribution. In certain cases, such as the ionosphere or a tenuous plasma, the damping term is very small; then the "conductivity"

$$\sigma_{\text{plasma}} \approx jN_0e^2/m\omega, \tag{14}$$

where N_0 is the free electron density, m and e are mass and charge of the electron, respectively. The "conductivity" is purely imaginary in this case (with the electric field and current out of phase). Substituting into (12) and (13), we obtain

$$\epsilon^* = \epsilon_0(1 - \omega_p{}^2/\omega^2), \tag{15}$$

and

$$k^2 = (\omega^2/c^2)(1 - \omega_p{}^2/\omega^2), \tag{16}$$

where the plasma frequency

$$\omega_p \equiv (N_0 e^2/m\epsilon_0)^{1/2}.$$

This simple picture of a plasma is sufficient to explain the role of the ionosphere in the propagation of radio waves. The ionosphere is a plasma with typical maximum electron density of $10^{12}/\text{m}^3$ (corresponding to a plasma frequency of the order of $\omega_p \approx 6 \times 10^7\ \text{sec}^{-1}$) at a height of some 100 km above the earth. According to Eq. (15), however, the plasma turns into an ordinary dielectric at frequencies above the plasma frequency; below ω_p the ionosphere has a negative permittivity (equivalently, a negative dielectric constant), thus acts like any electrical conductor and is capable of reflecting electromagnetic waves. For vertical incidence, the cutoff is about 10 MHz, but with oblique incidence this is extended out to about 40 MHz. Reflection from the ionosphere was responsible for all long-distance radio communication in the world up to the time when a sufficient number of communication satellites were placed in orbit to provide direct line-of-sight radio transmission links. For higher electromagnetic frequencies—microwaves, visible light—the ionosphere is essentially transparent.

Propagation in Bounded Regions At the boundary or interface between two media, Maxwell's equations require a definite relationship between the field components in the two media. Let us call the two media 1 and 2. The tangential components of **E** and **H** are continuous across the boundary, the normal component of **B** is continuous, and

$$\epsilon_1^* E_{1n} = \epsilon_2^* E_{2n} \tag{17}$$

at the boundary (E_n stands for normal component). Imposition of these boundary conditions gives rise to the well-known phenomena of wave *reflection* and *refraction*.

In general when an electromagnetic wave is incident on a boundary separating two media, part of the wave is reflected and part is transmitted. If the wave is incident on the boundary obliquely, then the transmitted wave is refracted, i.e., its propagation direction is deflected (toward the normal to the boundary if the second medium is optically more dense, i.e., if ϵ^* is larger in this medium). If the second medium is highly conducting then very little energy is transmitted and almost all of the energy is reflected back into the first medium.

Electromagnetic waves can be propagated in a bounded region by surrounding the propagation medium with walls made from a good electrical conductor. Such a bounded region is called a *waveguide*. Waveguides with rectangular or circular cross sections are used extensively for the transmission of microwave power. Propagation of the electromagnetic wave in the guide can be visualized as a wave which is being continuously reflected by the walls back into the bounded region. Consider, for example, a rectangular waveguide of cross section $a \times b$ where $b \gg a$; further, consider wave propagation in a plane perpendicular to the dimension b and which is transversely polarized (i.e., **E** parallel to the b dimension). Detailed analysis shows that all frequencies with wavelength $\lambda < 2a$ are propagated; but if $\lambda > 2a$ the wave is exponentially damped. $\lambda_c = 2a$ is called the *cutoff wavelength*.

Electromagnetic waves can also be confined by a boundary between two media with substantially different indices of refraction. (The refractive index is defined as the square root of the normalized permittivity, ϵ/ϵ_0.) A wave propagating in a high index material, surrounded by a low index medium, will be totally internally reflected for a range of obliquely incident rays. Thus, light can be confined and transmitted with very little attenuation by thin optical fibers of glass or by channels of high refractive index; this forms the basis of the modern technologies of "fiber optics" and "dielectric waveguides."

Surface Plasma Waves An interesting case of wave propagation occurs at the boundary between a dielectric and a conductor. Consider, for example, a solid-state plasma (a metal or a semiconductor) in contact with vacuum ($\epsilon = \epsilon_0$). The permittivity of the plasma is given by (15) and we consider frequencies below ω_p where ϵ^* is negative. We assume that a wave—$\exp(jkx - j\omega t)$—is propagating in each medium parallel to the boundary; the **E**-field has one component in the direction of propagation and one normal to the boundary, the **H**-field has only one component—parallel to the boundary. Ensuring that the fields satisfy Maxwell's equations requires, among other things, that the fields on both sides of the interface be damped exponentially as one moves away from the boundary. Using the boundary conditions of the preceding section yields the dispersion relation:

$$(k^2 - \omega^2/c^2)^{1/2}\epsilon^* = -\epsilon_0(k^2 - \epsilon^*\omega^2/c^2\epsilon_0)^{1/2}. \tag{18}$$

At small values of k, $\omega \approx ck$; but at large values of k, $\epsilon^* \approx -\epsilon_0$, or

$$\omega^2 \to \omega_p{}^2/2. \tag{19}$$

This type of wave propagation is called a *surface plasma wave*.

Propagation in the Presence of a Static Magnetic Field In the presence of a static magnetic field $\mathbf{B}_0$, electromagnetic wave propagation through materials takes on a new dimension. The reason for this is that the conductivity (and hence the complex permittivity) of the medium becomes anisotropic due to the fact that all current densities **J** experience magnetic forces at right angles to both current direction and $\mathbf{B}_0$: $\mathbf{F}_{\text{mag}} = \mathbf{J} \times \mathbf{B}_0$. For an anisotropic material, the conductivity σ can no longer be treated as a scalar quantity, but is in fact a tensor; assuming the z-direction to be that of the magnetic field, we find:

$$\sigma = \begin{pmatrix} \sigma_1 & \sigma_{12} & 0 \\ -\sigma_{12} & \sigma_1 & 0 \\ 0 & 0 & \sigma_z \end{pmatrix}. \tag{20}$$

The conductivity in the direction of the magnetic field, σ_z, is unaltered; the off-diagonal element σ_{12} is often referred to as the *Hall conductivity*.

Two types of electromagnetic waves are commonly encountered in plasmas in a magnetic field; these are called *helicon waves* and *Alfvén waves*, and they are seen both in gaseous (atmospheric or galactic) plasmas and solid-state plasmas. Helicon waves are dominated by the off-diagonal Hall conductivity; the waves are circularly polarized and they propagate in the direction of the static magnetic field $\mathbf{B}_0$. Atmospheric helicons have been called "whistlers;" these propagate in the ionosphere along the earth's magnetic field. Alfvén waves also propagate along the direction of $\mathbf{B}_0$ but are governed by a different dispersion relation; they occur in compensated plasmas (e.g., electron-hole systems with equal numbers of electrons and holes) and in systems so dominated by collisions that the Hall term is very small. They are named for Nobel laureate Hannes Alfvén who first predicted their behavior.

We consider solutions to Eq. (11) for waves propagating along the z-direction (the direction of $\mathbf{B}_0$), but note that ϵ^* is a tensor quantity in this case. Since displacement currents play no role in helicon and Alfvén wave propagation (these are low frequency waves), we can neglect $\omega^2\epsilon$; Eq. (12) thus becomes $\epsilon^* \approx j\sigma/\omega$. μ will be taken as μ_0. Using Eq. (20) for the conductivity, we obtain the general dispersion relation:

$$k^2 = \omega\mu_0(j\sigma_1 \pm \sigma_{12}). \tag{21}$$

Let us consider an electron-ion plasma in a magnetic field. Equation (14) is no longer adequate for σ_1; we must keep the collisional term, as well as new terms depending specifically on the magnetic field $\mathbf{B}_0$:

$$\sigma_1 \approx \sigma_0(1 + j\omega\tau)/[(1 + j\omega\tau)^2 + \omega_c{}^2\tau^2], \tag{22}$$

$$\sigma_{12} \approx \sigma_0\omega_c\tau/[(1 + j\omega\tau)^2 + \omega_c{}^2\tau^2]. \tag{23}$$

Here $\sigma_0 \equiv N_0e^2\tau/m$, with N_0, e, and m as defined in (14), τ the electron-ion collision time, and $\omega_c \equiv eB_0/m$ the Larmor frequency in the magnetic field B_0. $\omega_c\tau$ may also be written as $\sigma_0 RB_0$, where R is the Hall coefficient.

Helicon wave propagation is dominated by the σ_{12} term; if we neglect the $j\omega\tau$ term in both numerator and denominator of (22) and (23), and then substitute these conductivity terms into (21), we obtain the helicon dispersion relation:

$$k^2 = j\omega\mu_0\sigma_0/(1 \pm j\omega_c\tau), \tag{24}$$

or

$$\omega = (k^2/\mu_0)(RB_0 - j/\sigma_0). \tag{25}$$

The waves are circularly polarized: $E_x = \pm jE_y$.

For Alfvén waves the Hall term either vanishes or is negligible. Since we are interested in large magnetic fields, we neglect everything in the denominator of (22) except $\omega_c{}^2\tau^2$. Substituting in (21), we obtain the Alfvén dispersion relation:

$$\omega^2 = k^2B_0/\mu_0N_0m(1 - j/\omega\tau). \tag{26}$$

The dominant term in (26) gives a wave velocity $v_p = (B_0/\mu_0N_0m)^{1/2}$. Since there are usually more than one group of charge carriers participating in Alfvén wave propagation, it is more appropriate to use the total plasma mass density $\sum N_im_i$ for N_0m.

Propagation in Anisotropic Media In the preceding section we encountered one example of an anisotropic medium, namely, a conducting medium in the presence of a static magnetic field. However, many naturally occurring crystalline materials are anisotropic as a consequence of their crystal structure. Although both cubic crystals and amorphous materials are isotropic for electromagnetic wave propagation, crystalline materials with lower symmetry (tetragonal, orthorhombic, monoclinic, etc) show anisotropic behavior in their constitutive parameters ϵ, μ, and σ.

With the exception of magnetic-field-induced anisotropy, the most important examples of anisotropic behavior are those associated with the permittivity (or dielectric behavior) of nonconducting, nonmagnetic, crystalline solids. The electromagnetic (or optical) properties of such crystals depend primarily upon the symmetry of the permittivity tensor ϵ_{ij}. In this regard, the various crystals fall into three types: cubic, uniaxial and biaxial. In uniaxial crystals, one of the principal axes of ϵ_{ij} coincides with a symmetry axis of the crystal; this is called the *optic axis* of the crystal. A uniaxial crystal has two independent permittivity values, one for propagation along the optic axis and one for propagation at right angles to it; the difference between these two values is a measure of the *birefringence* of the crystal. Two types of electromagnetic waves can be propagated in a uniaxial crystal; with one, called the *ordinary wave*, the crystal behaves like an isotropic body. With waves of the second type, called *extraordinary waves*, the magnitude of the wave vector k depends on the direction it makes with the optic axis.

Two different refracted waves are formed when a wave impinges on a uniaxial crystal, a phenomenon known as *double refraction*. The two waves have different polarizations, so that by excluding the transmission of one by geometric means, one can produce a polarized wave. This is the principle of the *Nicol prism*.

Biaxial crystals have lower symmetry than uniaxial crystals; they are characterized by three independent permittivity values.

Propagation in Inhomogeneous and Composite Media; Diffraction If the medium is inhomogeneous, propagation of electromagnetic waves through it is more complicated, since the parameters ϵ, μ, and σ are no longer independent of position. Consider, for example, a medium in which $\sigma = 0$, $\mu = \mu_0$, and ϵ is a function of position. Assuming an exp $(-j\omega t)$ time dependence, and eliminating H between Eqs. (1) and (2), we obtain

$$\nabla^2\mathbf{E} - \nabla(\nabla \cdot \mathbf{E}) + \mu_0\omega^2\epsilon\mathbf{E} = 0. \qquad (27)$$

Elimination of E gives

$$\nabla^2\mathbf{H} + \mu_0\epsilon\omega^2\mathbf{H} + \epsilon^{-1}\nabla\epsilon \times (\nabla \times \mathbf{H}) = 0. \qquad (28)$$

Equations (27) and (28) can be solved in a general form for the case where propagation conditions approximate those corresponding to geometrical optics. For this approximation to be valid the effective "wavelength" λ must be much smaller than some characteristic dimension of the medium and should not change rapidly throughout space (i.e., $|\nabla\lambda| \ll 1$). This type of approximation is called *ray theory*; a one-dimensional version is equivalent to the W.K.B. approximation used extensively in the semiclassical solution of *wave mechanical* problems. If, e.g., propagation occurs in the x-z plane, and ϵ varies in one dimension only (so that $\epsilon = \epsilon(z)$), then the k dependence for the x-direction is a constant, k_1. Defining

$$f(z) = \epsilon(z)\,\mu_0\omega^2 - k_1{}^2, \qquad (29)$$

we find two independent solutions to Eq. (27) of the form:

$$(\text{constant}/f^{1/4})\exp\left(\pm j\int f^{1/2}\,dz\right). \qquad (30)$$

A composite medium can be viewed either as a structured, inhomogeneous medium, or as a combination of individual (single-medium) elements. The most interesting composites are those showing a regular or uniform modulation, such as, e.g., a medium made up of layers with differing physical properties and which alternate in a regular way, or an array of equally spaced spherical or cylindrical elements imbedded in a dielectric matrix. Wave propagation through such composite structures gives rise to the phenomenon of *diffraction*; for certain directions in the transmitted wave all of the individual rays making up the wave are in phase and a diffracted beam develops, for other directions the rays are out of phase and tend to interfere destructively with each other.

A plane diffraction grating can be made from a thin film of metal (on a transparent substrate) by cutting out parallel stripes of the metal at a uniform spacing d. If the grating is illuminated from behind by a plane electromagnetic wave, each stripe or transparent element of the grating acts as a source for the transmitted wave. The diffracted beam has a maximum when the various transmitted wavelets are in phase, i.e., when

$$n\lambda = d\sin\theta, \qquad (31)$$

where n (an integer) is the diffraction order, λ is the wavelength, and θ is the angle which the diffracted beam makes with a plane normal to the grating and containing one of the stripes. Diffraction effects are most pronounced when the stripe spacing d is of the same order as the wavelength λ. The angle θ of the diffracted beam depends upon λ; if the incident electromagnetic wave contains components with different wavelengths, these will be separated into component wavelengths (or colors) by the grating.

A crystal acts like a three-dimensional diffraction grating for short-wavelength electromagnetic waves; the regularly spaced atoms making up the crystal can be viewed as sources for the wavelets contributing to the diffracted wave. Crystals are most effective in diffracting waves with wavelengths comparable to the interatomic spacing; for this reason they are used to diffract x-rays. The early experiments of Friedrich, Knipping, and von Laue (1912), in which they passed an x-ray beam through a crystal, established that both (1) x-rays are electromagnetic waves with relatively short wavelengths, and (2) the atoms of a crystal are arranged in a regular three-dimensional order.

PROTON*

Protons in Atoms The proton is the atomic nucleus of the element hydrogen, the second most abundant element on earth. Positively charged hydrogen atoms or "protons" were identified by J. J. Thomson in a series of experiments initiated in 1906. Although the structure of the hydrogen atom was not correctly understood at that time, several properties of the proton were determined. The electric charge on the proton was found to be equal but opposite in sign to that of an electron, and the measured value for the mass was much greater than that of the electron. The currently accepted proton mass is 1836 times the electron rest mass, or 1.672×10^{-24} grams.

A correct estimate of the size of the proton and an understanding of the structure of the hydrogen atom resulted from two major developments in atomic physics: the Rutherford scattering experiment (1911) and the Bohr model of the atom (1913). Rutherford showed that the nucleus is vanishingly small compared to the size of an atom. The radius of a proton is on the order of 10^{-13} cm as compared with atomic radii of 10^{-8} cm. Thus, the size of a hydrogen atom is determined by the radius of the electron orbits, but the mass is essentially that of the proton.

In the Bohr model of the hydrogen atom, the proton is a massive positive point charge about which the electron moves. By placing quantum mechanical conditions upon an otherwise classical planetary motion of the electron, Bohr explained the lines observed in optical spectra as transitions between discrete quantum mechanical energy states. Except for hyperfine splitting, which is a minute decomposition of spectrum lines into a group of closely spaced lines, the proton plays a passive role in the mechanics of the hydrogen atom. It simply provides the attractive central force field for the electron.

The proton is the lightest nucleus with atomic number one. Other singly charged nuclei are the deuteron and the triton which are nearly two and three times heavier than the proton, respectively, and are the nuclei of the hydrogen isotopes deuterium (stable) and tritium (radioactive). The difference in the nuclear masses of the isotopes accounts for a part of the hyperfine structure called the "isotope shift."

In 1924, difficulties in explaining certain hyperfine structures prompted Pauli to suggest that a nucleus possesses an intrinsic angular momentum or "spin" and an associated magnetic moment. The proton spin quantum number (I) is 1/2, and the angular momentum is given by $[I(I+1)h^2/(2\pi)^2]^{1/2}$ where h is Planck's constant. The intrinsic magnetic moment is 2.793 in units of nuclear magnetons (0.50504×10^{-23} erg/gauss) which is about a factor of 660 less than the magnetic moment of the electron.

Two types of hydrogen molecule result from the two possible couplings of the proton spins. At room temperature, hydrogen gas is made up of 75 per cent orthohydrogen (proton spins parallel) and 25 per cent parahydrogen (proton spins antiparallel). Several gross properties, such as specific heat, strongly depend on the ortho or para character of the gas.

Protons in Nuclei Protons and neutrons are regarded as "nucleons" or fundamental constituents of nuclei in most theories of nuclear structure and reactions. The nuclear forces operating between them are much stronger than the electrostatic forces which govern atomic and molecular systems but operate over very short ranges, the order of several times 10^{-13} cm. Of particular significance in the structure of nuclei is the apparent charge independence of the forces. That is, the nuclear force between two nucleons may be considered separately from the electrostatic forces due to electric charges the nucleons may carry. In addition to mass and charge, other properties such as spin and parity play important roles in determining the mechanics of nuclei.

The mass of a nucleus is the sum of the masses of the nucleons contained, plus a correction due to the total binding energy of the nucleons. This correction is an application of the Einstein mass-energy equivalence ($E = mc^2$). The atomic number or positive charge of a nucleus is given by the number of protons.

A detailed description of the motion of a proton in a nucleus is complicated by the many-body, quantum mechanical nature of the problem, but several simplified theories or models have been very successful in predicting many of the properties of nuclei. One of the best known nuclear structure models is the shell model in which a nucleon is assumed to move in a central force field. This field represents the average interaction of the proton (or neutron) with all other nucleons. An essential additional assumption is a coupling of the orbital angular momentum of the independent nucleon with its spin.

The success of a theory in which a nucleon moves among its close-packed neighbors as if they were not present is due in part to quantum mechanical restrictions, in particular to the Pauli exclusion principle.

The optical model for the scattering of protons by nuclei also rests on the assumption that the interaction with many nucleons may be repre-

*Supported in part by The U.S. Air Force Office of Scientific Research.

sented by an average potential well. An imaginary potential term is included which accounts for reactions other than elastic scattering.

Much of nuclear physics may be understood with a picture in which the proton exists as an independent particle in the nucleus. Refinements of an independent particle model to include collective effects and deformation involve a consideration of the residual interaction between nucleons and the details of the individual nucleon interaction with the average potential well.

Certain aspects of the very strong nuclear forces are understood. These forces involve π mesons in somewhat the same way that electrostatic forces responsible for atomic structure involve photons. Yukawa introduced the π meson as the field quantum for nuclear forces in 1935, and the interaction potential derived from this early theory is commonly used in nuclear physics.

Structure of the Proton A major objective of physics is to identify elementary particles and determine their properties. The proton is important in these investigations in several connections. It is itself an elementary particle. It is used as a projectile in the production and study of other elementary particles. It has been used as a target in the study of nucleon structure.

One view is to consider all fundamental particles as states of excitation of a limited number of particles. The resulting simplification correlates a large body of experimental data.

The internal structure of the proton is still being studied. In one of the experiments, the proton is a target which is probed by very short-wavelength electrons. Electrons produced by a high-energy linear accelerator are scattered from protons to study the electric charge distribution in a proton.

Questions concerning the structure of the proton or the neutron are difficult due to the ambiguity of experimental results. One cause of uncertainty is that the probe is not defined in sufficient detail. It appears desirable to use a strong interaction probe, that is, another nucleon or meson, but the structure of the probe may be no better understood than the structure of the target.

A mantel of mesons has been found about the proton. A current question is whether or not there is an internal or intrinsic core of a proton.

PULSARS

In November 1967 a group of radioastronomers at Cambridge, England, discovered a new type of star in our galaxy. The star emitted radio waves at frequencies ranging from 100 to 10,000 MHz and the radiation was confined to short pulses a few hundredths of a second in duration which repeated at very regular intervals of about one second. Systematic searches soon led to the discovery of further pulsars, and 300 had been located at the end of 1980. Attempts to detect visible light from pulsars have been unsuccessful except in two cases. Both the well known Crab Nebula, and a nebula in the southern sky called Vela, contain pulsars emitting synchronized flashes of light and γ-rays as well as radio pulses. These are rapid pulsars, having periodicities of 33 msec and 89 msec respectively.

Pulsar distances can be estimated from the different arrival times of a given pulse when recorded at different radio frequencies. This pulse dispersion is caused by ionized gas in interstellar space, and the gas density must be known to calculate the distance. Estimates, accurate within a factor of 2 or 3, place the pulsars at distances typically between 0.1 and 5 kiloparsec; since the total extent of our galaxy is about 30 kiloparsec it follows that only a small fraction of the pulsars which it contains have so far been detected.

No satisfactory explanation of pulsar radiation yet exists but it is generally believed that they are rapidly spinning neutron stars that emit a beam of radiation in some preferred direction so that a "lighthouse" effect accounts for the pulses. Only the intense gravitational force in neutron stars, which are predicted to have radii of about 10 km, would be sufficient to prevent stars' disrupting when they spin rapidly enough to explain the pulsars of shortest period. Pulsars therefore provide evidence for the existence of neutron stars. About five years after the discovery of pulsars, X-ray telescopes carried on spacecraft recorded periodic flashes of radiation from neutron stars in orbit about companion stars. These X-ray binaries emit thermal X-rays caused by gas dragged gravitationally from the companion star to the surface of the neutron star.

Neutron stars represent the end-point ot stellar evolution and contain matter in which thermonuclear processes have been completed. Sufficiently low-mass stars are stable, in this condition, as white dwarfs, but electron pressure in degenerate matter cannot balance gravity in stars heavier than 1.4 solar masses. Heavy stars must therefore collapse, when nuclear energy generation within them ceases, and such a catastrophic collapse has been suggested as the origin of stellar explosions visible as supernovae.

The fact that the Crab Nebula (perhaps the most famous supernova of all; the explosion was documented by Chinese astronomers in the year 1054) contains a pulsar provides strong circumstantial evidence of the correctness of the neutron star theory. Certainly the estimated occurrence rate of supernovae in the galaxy accounts reasonably well for the total number of pulsars which are found. Moreover the observation that pulsars lie close to the galactic plane is in agreement with the distribution of massive OB stars that are likely to develop into supernovae.

Extended timing measurements on many pulsars have revealed, without exception, a systematic increase of period entirely in accordance with the rotating-star theory. Typical pulsars, which have periods in the range 0.5 to 1.5 sec, are slowing down at such a rate that 10^6 to 10^7 years must elapse before the pulse interval is doubled. For the Crab pulsar, however, this time is only 2200 years. If a neutron star model is assumed, it is simple to compute, from the observed lengthening of the period, the rate at which the spinning star is losing energy. Rotational energy, and a small amount of residual heat, comprise the principal energy reserves of a neutron star. Hence the spin-down energy loss should be directly related to the energy radiated. Applying this argument to the Crab pulsar shows that the rotational energy loss is sufficient to explain not only the pulsar radiation, but also all the visible light from the remainder of the nebula. It has been known for many years that some source that provided a large output of high-speed electrons was necessary to maintain the luminosity of the nebula, but its origin was a mystery. The fact that a central neutron star can provide this source gives further evidence favoring the neutron star theory.

The mechanism by which a neutron star converts rotational energy into pulsed electromagnetic radiation is a topic of speculation at present. Little is known about physical conditions at the surface, and in the environment, of a neutron star. It is probable that a neutron star is encased in a rigid shell of crystalline ^{56}Fe nuclei permeated by a Fermi sea of degenerate electrons. Somewhere beneath the surface, where the density rises above 10^{13} g/cm^3, the nuclei become unstable and matter is largely in the form of a neutron fluid. It is likely that magnetic flux is conserved during gravitational collapse, which leads to immense magnetic field strengths of 10^{12} to 10^{15}G, and that conservation of angular momentum gives initial rotation speeds up to 10^3 rotations per second. Solid state physicists have been very interested in the fact that careful timing observations reveal some irregularities in the spin rate. These effects can be understood by the exchange of angular momentum between the superfluid interior of a neutron star, and its rigid outer crust, and they provide a means of checking some of the physical properties of neutron matter.

The rapid motion of the collapsed star, in the presence of its large magnetic field, generates an intense electric field which causes electrons and protons to be torn off the surface and distributed in space about the star. The resulting atmosphere must rotate with the star, and at a critical distance—the velocity of light cylinder—its tangential speed will approach the velocity of light. Beyond this region the atmosphere must stream outwards as a stellar wind, and it is likely that the flow-lines connect with the star's surface near the magnetic poles. In addition to these processes other phenomena arise if the magnetic axis of the star is not aligned with the rotation axis. A misaligned magnetic axis causes the star to radiate electromagnetic waves at the rotation frequency since it then acts as a giant oscillating magnetic dipole. Such outgoing fields can accelerate charged particles to relativistic energies in a manner analogous to linear accelerators in the laboratory and this may, for example, account for the injection of energetic electrons into the Crab Nebula which subsequently emit visible light by synchrotron radiation.

An important feature of the radiation mechanism is that it must produce a directed beam to yield the lighthouse effect. The duration of the observed pulses is almost independent of the radio wavelength and one idea common to several theories is that the beaming is a phenomenon of relativity. One well-known consequence of Special Relativity concerns a moving source of radiation; if the source radiates equally in all directions when it is stationary, the emitted waves must be cast into a narrow beam along the line of motion when the velocity is near that of light. Applying this to pulsars, it has been suggested that radiation emitted by charged particles moving outwards from the (misaligned) magnetic poles might be relativistically beamed along the magnetic axis, or alternatively, that the large tangential speed of the stellar atmosphere near the velocity of light cylinder could produce beaming in directions perpendicular to the rotation axis. Another feature of the radiation is that it must be coherent, involving the collective motion of groups of similarly charged particles, since otherwise, ridiculously high temperatures would be involved. Various possibilities such as wave amplification induced by plasma instabilities, or "antenna" mechanisms in which radiation is generated by the acceleration of bunched charges, have been suggested. One intriguing theory is that electron-positron pairs are generated by γ-radiation in a vacuum-gap zone above the magnetic poles. In the presence of electric fields caused by unipolar induction an initial "seed" pair can induce a cascade of further pairs, giving rise to an electron-positron "spark" discharge. Such discharges could be the seat of particle streams which ultimately bunch, due to plasma instabilities, and thereby generate the required conditions for coherent radio emission.

Unfortunately, no theory has yet been worked out in sufficient detail to allow comparison with the wealth of observational evidence now available. The radiated pulses have complex shapes, which differ from one source to the next, and may change rapidly with time. Usually the radiation is found to be highly polarized and the sense of polarization may vary systematically through the pulse; this shows that the radiation is emitted in a region containing a highly organized magnetic field, although different zones may be active from one instant to the next. In effect, during each pulse a "window" is opened through which complex time-dependent phenomena in the neutron star may be scrutinized. An extremely puzzling phenomenon is that of drifting subpulses, in which distinctive features in the envelope of individual pulses move steadily across the pulse window from pulse to pulse. It appears that some kind of differential rotation may be involved. Occasionally, pulsars showing this effect cease to radiate completely for a short time, and when they start again the drifting pattern reappears in the same position as where it was last seen. Some kind of memory is needed to explain this behavior, and heating of the stellar surface at the foot of an electron-positron spark may be involved.

Pulsars pose a challenge in many fields of physics including solid-state theory, relativistic plasma physics, and electrodynamics. They also provide astronomers with a new means of probing the galaxy and determining quantities such as the interstellar magnetic field strength and gas density. One pulsar has been of outstanding physical interest because it has an unseen binary companion which is almost certainly another neutron star. The system provides a unique test of theories of General Relativity, and timing observations have revealed a slight decrease in the binary orbital period which has been explained as a loss of energy in the form of gravitational waves.

PULSE GENERATION

Pulse waveforms are distinguished by abrupt, often almost discontinuous features. These features favor pulses for two broad categories of uses: (1) information processing, and (2) supplying very large momentary bursts of power to devices whose average rating is relatively low.

The fundamental element in pulse generation is the *switch*. Opening or closing a switch generates an abrupt change of circuit conditions, resulting in the formation of an approximate step-function pulse. One or more such steps, together with suitable wave-shaping, may yield the desired pulse waveform.

Information can be coded in pulse form either in the time domain (event counting, synchronization in process controllers, time-coded analogs, sequencing in computers) or in the domain of pulse amplitude (voltage or current). The power level is usually low or moderate, and the circuit elements used as switches are most commonly bipolar junction transistors (BJTs) or field-effect transistors (FETs) employed in an overdriven mode. Such elements are incorporated into popular families of "logic"-processing integrated circuits. The relevant performance aspects are the *transition times* of the switching action and the rated voltage or current levels. The best established logic families and their typical performances are presently CMOS[1] (insulated-gate FETs; ~50 ns; 5–15 V) and TTL[2] (BJTs; ~3–50 ns, depending on family; 5 V). Some building blocks suitable for pulse generation are shown in Fig. 1 (the code numbers are designations widely shared among manufacturers). The *astable* (free running) multivibrator (a) serves as primary pulse source, either directly or by further processing of the steps contained in its rectangular output. The *monostable* (b) produces a single output pulse in response to an input trigger signal, which therefore dictates the time of occurrence. These circuits define their own pulse durations (t_0, t_1, t) by reference to exponential transients in the attached RC networks. The *comparator* (c) produces an output step when a variable input signal V_{in} crosses an adjustable threshold level V_{ref}; the step thus marks the time when $V_{in} = V_{ref}$.

Steps and rectangles can be shaped into other forms by many techniques.[3,4] Three classes, linear, nonlinear, and delay-line shaping, are typified by the examples in Fig. 2. The first

FIG. 2. Examples of shaping circuits to produce short pulses from a step.

two classes produce "tail pulses" with a sharp transition only at their leading edge. The delay line produces a narrow rectangle from a step; the trailing edge is formed by the reflection of the leading edge in the unmatched line, and the pulse falltime is thus as short as its risetime (within the limitations of the delay line's response).

For applications requiring *high peak power*, switching and shaping are carried out directly at the output power level wherever possible.[5] An ideal switch dissipates no power, since voltage and current are not present simultaneously in it. The energy of the delivered pulse may come from energy *stored* in the pulse-forming network, the power supply recharging the network slowly between pulses (cf. Fig. 3). For some pulse shapes the forming process would be too inefficient to be carried out at high level; a linear output amplifier fed by the low-level shape is then required. Vacuum-tube amplifiers are common at the highest levels (up to 50 kV and several tens of A). FETs, especially such high-current types as VMOS, serve in lower-voltage ranges (up to 150 V), and BJTs may be preferred when very short transition times (below 100 ns) are needed. BJTs have restricted ratings in switching service because of "second breakdown."[6]

Some other types of switching element are listed below with their special performance aspects:

(a) *Mechanical switches.* Beyond their use in moving spark gaps in extreme-high-voltage service,[5] mechanically operated switches can excel with very short transition times, e.g., in relays with mercury-wetted contacts. Times ~100 ps are readily achieved, limited mostly by the transmission-line properties of the switch enclosure. The electromechanical drive limits the repetition rate to ~1 kHz.

(b) *Spark gaps.* Externally initiated or spontaneous flashover between electrodes in a gas near atmospheric pressure has a very short transition time (~1 ns) and can form pulses at extremely high voltages and currents. In some applications the *jitter* (irregular delay between initiating signal and flashover) can pose a problem.

(c) *Thyratrons.* These are hot-cathode gas or vapor filled tubes in which a discharge is initiated by a trigger signal applied to a grid. The discharge extinguishes only when the switch current is brought to zero by the external circuit; deionization time of the gas (~50 μs or more) limits the minimum pulse spacing. Average power limitation may also play a part; however, peak power levels can be extremely high (e.g., 50 kV and 5 kA). Risetimes as short as a few ns are common in hydrogen-filled thyratrons.

(d) *Controlled rectifiers (SCRs and TRIACs).*[7] These have regenerative switching action and

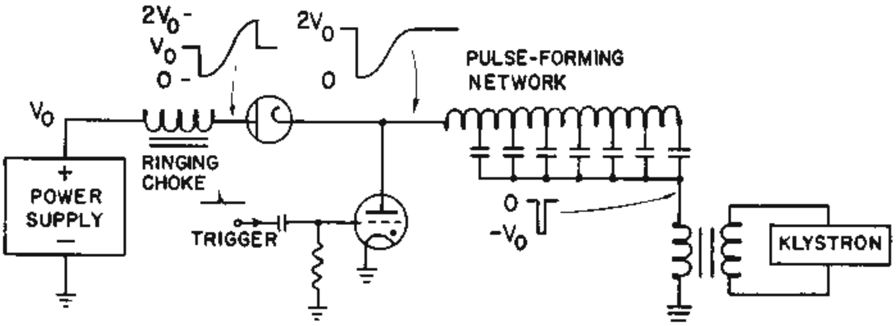

FIG. 3. High-power pulser using hydrogen thyratron.

thus require only small trigger signals for high output power. Transition times < 1 μs are typical; output levels range up to several kA and a little over 1 kV. In all but low-power devices the switch current must be brought to zero externally to restore the nonconducting state.

(e) *Avalanche transistors.*[8] Regenerative breakdown in a BPT can occur with sub-ns transition time; it may be initiated by simply overvolting the collector, or by a trigger signal applied to the base. Fast, relatively large (~30 V) pulses can be generated at high repetition rates (~5 MHz).

(f) *Unijunction transistors.* These use conductivity enhancement by injected carriers for regenerative switching. Moderate performance (~1 μs, ~10 V) is balanced by attractively simple circuit configurations, especially in the generation of trigger pulses for SCRs working at power-line frequency.

(g) *Tunnel diodes.*[9] Quantum-mechanical tunneling through an extremely thin depletion layer has a short transition time because it involves no semiconductor charge storage. The tunneling occurs over a narrow forward voltage range (~0.1 V); at higher voltages, after a sharp drop of tunnel current, ordinary injection current sets in (~0.5 V). Switching from the low to the higher voltage occurs in sub-ns times. Choice of external circuitry results in astable, monostable, or bistable operation. Transitions are provoked by suitable current signals. The voltage level of the pulses is evidently very low.

(h) *Four-layer diodes (DIACs).* These are similar to SCRs, but switching occurs spontaneously at a given voltage threshold. Their chief use lies in trigger generation for SCRs.

(i) *Step-recovery (snap) diodes.*[10] Stored charge resulting from a period of forward conduction causes a diode to conduct freely when reverse bias is first applied. In specially graded junctions this reverse current ceases abruptly, with transition times <50 ps. The resulting opening of the switch can generate fast pulses with high repetition rates (>100 MHz) at relatively high level (tens of V).

PYROMETRY, OPTICAL

Optical pyrometry is that branch of thermometry in which the temperature of a solid or liquid is determined by measuring the radiation emitted in a relatively narrow spectral region. The International Practical Temperature Scale of 1968 (IPTS) above the melting point of gold (1337.58 K or 1064.43°C)is defined in terms of such radiation, and an optical pyrometer is usually used to realize the IPTS above this temperature.

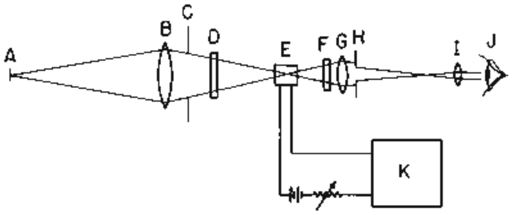

FIG. 1. Schematic diagram of a disappearing filament optical pyrometer. A. Source; B. Objective lens; C. Objective aperature; D. Absorption filter (used for temp. above 1300 C); E. Pyrometer lamp; F. Red filter; G. Microscope objective lens; H. Microscope aperture stop; I. Microscope ocular; J. Eye; K. Current measuring instrument.

Figure 1 is a schematic diagram of a common type of optical pyrometer. The objective lens (B) images that part of the source (A) for which the temperature is to be determined in the plane of the filament of the pyrometer lamp (E). The microscope (G, H, I) magnifies the source image and the small pyrometer lamp filament by a factor of about fifteen. The red filter (F) and the spectral response of the eye limit the spectral band pass of the instrument to wavelengths from about 6200 to 7100Å with the effective value about 6500Å. The absorption filter (D) is inserted at source brightness temperatures above about 1300°C so that the pyrometer lamp need not be operated at higher temperatures where its stability is poor.

The optical pyrometer shown in Fig. 1 is operated by adjusting the current in the pyrometer lamp filament until the brightness of the filament equals the brightness of the image of the source. From this current and a previous calibration of the pyrometer, the brightness temperature of that part of the source or object sighted upon can be determined. The brightness temperature of an object is defined as the temperature of a blackbody which emits the same spectral radiance as the object. Spectral radiance is defined as the limit of the quotient of the radiant power emitted in a particular wavelength interval and in a particular direction by the product of the wavelength interval, the solid angle and the emitting area projected perpendicular to the direction of sighting as the latter three quantities tend to zero. If the object is a blackbody, the brightness temperature of the blackbody is its temperature. If the object is not a blackbody, the temperature of the object can be obtained from its brightness temperature and the equation

$$\epsilon_\lambda = \frac{e^{c_2/\lambda T} - 1}{e^{c_2/\lambda T_\mathrm{B}} - 1} \qquad (1)$$

where ϵ_λ is the spectral emissivity (also called spectral emittance), λ is the wavelength, in centimeters, at which the pyrometer is effectively operating (usually about 0.65×10^{-4} cm), c_2 is the second radiation constant (1.4388 centimeter degrees on the IPTS), T_B is the brightness temperature and T is the temperature, both in Kelvins. The spectral emissivity of a surface is the fraction of blackbody spectral radiance emitted by the surface when it has the same temperature as the blackbody. Spectral emissivities for a wavelength of 0.65×10^{-4} cm have been determined for a large number of materials. When $C_2/\lambda T$ is greater than about 5, Eq. (1) can be replaced, with negligible error, by the simpler equation

$$\frac{1}{T} = \frac{1}{T_B} + \frac{\lambda}{C_2} \ln \epsilon_\lambda \qquad (2)$$

where ln is the symbol for the natural logarithm.

The calibration of an optical pyrometer from basic principles is called a primary calibration and is usually performed in national standard laboratories such as the National Bureau of Standards. The first step of a primary calibration of an optical pyrometer is making a brightness match while sighting on a blackbody surrounded by freezing gold. The temperature of freezing gold is defined to be 1337.58 K or 1064.43°C on the International Practical Temperature Scale of 1968. Higher brightness temperature points are obtained by using the defining equation of the IPTS,

$$R = \frac{e^{c_2/\lambda T_\mathrm{B}} - 1}{e^{c_2/\lambda T_\mathrm{Au}} - 1} \qquad (3)$$

Experimentally, the brightness temperature of a stable source is adjusted until the source, as seen through a rotating sectored disk with transmittance R, has the same brightness as a gold blackbody. Independent measurement of R and λ then permit, from Eq. (3), a calculation of T_B. The pyrometer lamp current required for making a brightness match while sighting on the source without the sectored disk completes the calibration at this higher temperature. This process is repeated with a sufficient number of sectored disks and temperatures so that a smooth curve can be drawn relating current in the pyrometer lamp to the brightness temperature of the source.

With a well-designed optical pyrometer of the type in Fig. 1, it is possible to realize the IPTS in a primary calibration with an estimated uncertainty of ±0.4 deg at 1337 K, ±2.0 deg at 2300 K and ±10.0 deg at 4300 K. The National Bureau of Standards also calibrates commercial pyrometers of the type in Fig. 1 by comparison to a primary calibrated pyrometer. The uncertainty of this comparison calibration is estimated to be ±3 deg, ±6 deg, and ±40 deg respectively at the temperatures given above. These figures apply to brightness or blackbody temperatures. The accuracy with which an optical pyrometer can determine the temperature of a non-blackbody depends not only on the pyrometer calibration in terms of brightness temperature, but also on the uncertainty of the spectral emissivity required. This often produces an error greater than the calibration uncertainties given above.

Many of the national standards laboratories throughout the world have developed photoelectric pyrometers to replace the visual instrument shown in Fig. 1. These modern, high-precision pyrometers use a photomultiplier tube rather than the eye as detector and an interference filter or monochromator to limit the spectral band pass. With the resulting increased sensitivity and smaller band pass, these instruments can realize (1982) the IPTS above the melting point of gold with about one tenth the uncertainty possible with the best visual instruments. They have been used in the national standards laboratories primarily in their calibration services and in determining thermodynamic temperature differences between various thermometric fixed points (melting point of gold, silver, and copper). The latter has been possible with an uncertainty of only a few one hundredths of a degree. Portable photoelectric pyrometers are available commercially, but their calibration uncertainty is much greater than that of the instruments developed by the national standards laboratories. This is due largely to the instability of the pyrometer lamp used as a reference standard in the portable instruments. The national laboratory instruments avoid this problem either by conducting frequent primary calibrations or by using a gold-point blackbody as the reference standard.

In addition to optical pyrometers, total radiation pyrometers and two color pyrometers are sometimes used for measuring temperatures. Usually, however, these instruments are less accurate than optical pyrometers and are primarily intended for controlling temperature rather than for measuring it.

Q

QUANTUM CHROMODYNAMICS

Quantum chromodynamics is a theory of the strong interactions of elementary particles, including most notably the interaction that binds protons and neutrons to form nuclei. It is widely believed to be the correct theory of the strong interactions, and has survived some experimental tests at high energy accelerator laboratories.

The theory can be developed by examining the spectrum of elementary particle states discovered experimentally in the last thirty years. One finds that this spectrum can be largely explained by supposing that the strongly interacting particles are made of smaller, spin $\frac{1}{2}$ particles called *quarks*. (See QUARKS for a more detailed discussion.) For instance, a proton is made up of two quarks of a type, or "*flavor*," called *up* and one quark of a flavor called *down*. The neutron consists of two *down* quarks and one *up* quark. Since protons and neutrons are fermions and consist of an odd number of quarks, the quarks must be fermions.

A most important feature of the quark model can be understood by considering a charge +2, spin $\frac{3}{2}$ cousin of the proton called the Δ^{++}, which consists of the three *up* quarks in the model. The most natural ground state wave function of the three quarks in the Δ^{++} is symmetric under interchange of any two quark position and spin variables. Since the quarks are fermions, a contradiction appears unless the three *up* quarks in a Δ^{++} are *not* identical. One supposes instead that the quarks are distinguished by a property called "color:" one quark is *red*, one is *yellow*, one is *blue*.

A useful mathematical description of this model is obtained by treating quarks as identical particles that carry a color quantum number I which may take the three values R, Y, and B. Then the color wave function of the Δ^{++} is the completely antisymmetric combination

$$|RYB\rangle + |BRY\rangle + |YBR\rangle - |BYR\rangle - |RBY\rangle - |YRB\rangle. \qquad (1)$$

It is attractive to suppose that the strong force is blind to color. To be more precise, one considers an arbitrary rotation of all quarks in color space. A *red* quark is rotated into a new *red'* state, etc., with

$$|I\rangle' = \sum_J U_{IJ}|J\rangle, \qquad I = R, Y, B. \qquad (2)$$

Here U_{IJ} is an arbitrary 3×3 unitary matrix with determinant equal to 1. (Notice that the completely antisymmetric color state of these quarks given in Eq. (1) is unchanged under such a rotation. Such states may be called *colorless*.) The attractive hypothesis mentioned above is that the strong interaction Hamiltonian is invariant under rotations U_{IJ} in color space.

In quantum chromodynamics, the idea of symmetry under color rotations U_{IJ} is carried much further. One supposes that the Hamiltonian is invariant under color rotations $U_{IJ}(x)$ that depend on the space-time coordinate $x = (t, x, y, z)$ in an arbitrary way. This invariance is called $SU(3)$ *gauge invariance*. The requirement of gauge invariance is so stringent that there is essentially only one relativistic quantum field theory that has this invariance. The theoretical development of the theory is described in the article on GAUGE THEORY. In the context of quarks and color gauge symmetry, the $SU(3)$ gauge theory is called *quantum chromodynamics*. The electroweak interactions of elementary particles are thought to be described by another gauge theory, which is described in the article on ELECTROWEAK THEORY.

The content of quantum chromodynamics can be described on an elementary level quite simply. The color gauge symmetry implies the existence of a spin 1 particle, which is called a *gluon* because of its role in binding quarks together. The gluon comes in eight color states: $|R\bar{Y}\rangle$, $|R\bar{B}\rangle$, $|Y\bar{B}\rangle$, $|Y\bar{R}\rangle$, $|B\bar{R}\rangle$, $|B\bar{Y}\rangle$, $|R\bar{R}\rangle - |Y\bar{Y}\rangle$, $|R\bar{R}\rangle + |Y\bar{Y}\rangle - 2|B\bar{B}\rangle$. Here $\bar{R}$ denotes the color *anti-red*, which is the color carried by the antiparticles to a red quark. An R quark can change into a Y quark by emitting an $R\bar{Y}$ gluon, as depicted in Fig. 1(a), or by absorbing a $Y\bar{R}$ gluon. This process is mathematically very similar to the emission of a photon by an electron in quantum electrodynamics. The similarity arises from the fact that quantum electrodynamics is also a gauge theory. In quantum chromodynamics, the gluons can also interact with each other. For instance, a $R\bar{Y}$ gluon can change into an $R\bar{B}$ gluon by emitting a $B\bar{Y}$ gluon,

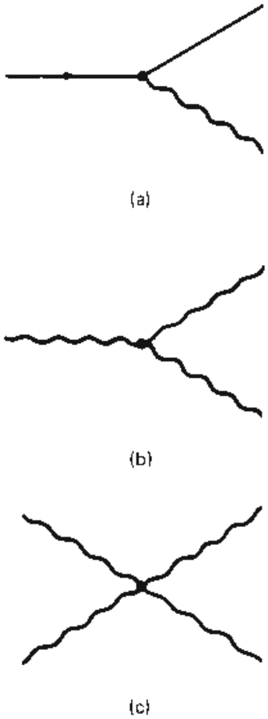

FIG. 1. Elementary processes in quantum chromodynamics. Straight lines are quarks, wavy lines are gluons.

as depicted in Fig. 1(b). There is also a four-gluon interaction, which is depicted in Fig. 1(c).

The theory gives a simple formula for calculating the probability amplitude for each of the elementary interactions shown in Fig. 1 to occur. As in all quantum field theories, physical probability amplitudes are built up from the amplitudes for the elementary interactions. For example, the scattering of two quarks can proceed by the exchange of two gluons, as shown in Fig. (2). This interaction involves four elementary interactions.

The probablity amplitude for an elementary interaction is proportional to a coupling $g(\lambda)$, in the case of Fig. 1(a) and (b), or to $g(\lambda)^2$ in the case of Fig. 1(c). The numerical value of g depends on a length λ that is taken to be a typical wavelength of the interacting particles. (There is a certain ambiguity in the choice of the value of λ to use in a calculation, but the effects of this ambiguity vanish when one sums over all possible combinations of elementary amplitudes that can contribute to the desired physical amplitude.) The coupling g is analogous to the elementary charge e in quantum electrodynamics. In quantum electrodynamics, e is small and approximately independent of λ: $e(\lambda)^2/4\pi\hbar c \cong \alpha \cong 1/137$.

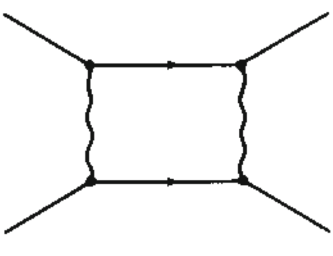

FIG. 2. Quark-quark scattering via two gluon exchange.

The fact that e is small in quantum electrodynamics implies that only a few elementary interactions are likely to occur in a scattering process, so that calculation of the scattering probability is relatively simple. In quantum chromodynamics, $g(\lambda)$ is *not* small when λ is roughly equal to the distance between nucleons in a nucleus. This is the reason that the nuclear force is so much stronger than the electromagnetic force. The fact that $g(\lambda)$ is not small when $\lambda \gtrsim 1$ fm makes calculation difficult in many important cases. For instance, in quantum chromodynamics, the force that binds the quarks in a proton arises from the exchange of gluons among the quarks, in much the same way that the exchange of photons between an electron and a proton holds a hydrogen atom together. However, it has not so far been possible to reliably calculate this force from the theory.

The color force is strong. It is widely believed, although not definitely proven, that in quantum chromodynamics the force between quarks becomes so strong at large distances that when, say, two protons collide, the quarks involved in the collision can never escape as isolated particles. Instead, the only particles that can escape from a collision are colorless combinations of quarks and gluons. This phenomenon is called *quark confinement.* It explains why isolated quarks and gluons have not been seen in accelerator experiments.

Quantum chromodynamics has an important property that makes the theory simple under special circumstances: the coupling $g(\lambda)$ decreases as the length scale decreases. The decrease is slow, with $g^2(\lambda) \propto [\ln(\lambda_0/\lambda)]^{-1}$ when $\lambda \ll \lambda_0 \approx 1$ fm. Nevertheless, by the time λ equals the wavelength of a particle with 30 GeV of momentum, $g^2(\lambda)/4\pi\hbar c$ has decreased to a value of about 0.2. Thus when quarks and gluons have high momenta, the probability that they will interact is low: they behave almost as free particles. This property is called *asymptotic freedom.*

Asymptotic freedom allows one to make predictions from quantum chromodynamics that are testable in high energy experiments. We will mention only one such experiment. The theory leads one to the conclusion that the three quarks in a proton are really assemblages of elementary quarks and gluons; when probed on a sufficiently small distance scale λ, these elementary quarks and gluons should appear to be nearly free and noninteracting. Such a short distance probe can be implemented by scattering high energy electrons from protons, breaking the protons apart in the process. One counts the electrons that scatter through a wide angle from their initial direction. Each of these electrons can scatter from an elementary quark by exchanging a photon with the quark. When the electron energy is high, the photon wavelength λ is small. This experiment was performed at the Stanford Linear Accelerator Center in 1979, before the development of quantum chromodynamics. Surprisingly, the measured cross section agreed with what would be expected if the proton consisted of noninteracting pointlike particles. The fact that the quarks appeared to be nearly noninteracting when λ was small led to the idea of asymptotic freedom and the theory of quantum chromodynamics.

QUANTUM ELECTRODYNAMICS*

Introduction Quantum electrodynamics is the fundamental theory of electromagnetic interactions. As far as we know, its equations provide a mathematically exact description of the interactions of electrons, muons, and photons (the quanta of the electromagnetic field). By extension, quantum electrodynamics (QED) is the underlying theory of all electromagnetic phenomena including atomic and chemical forces.

QED is without question the most successful dynamical theory in all of physics. Because of the pioneering theoretical efforts of Dirac, Feynman, Schwinger, and Tomonaga, and heroic labors by many others, QED possesses a systematic calculational scheme which has met with brilliant quantitative successes when faced with all experimental challenges. Its range of application has over the years been extended from atomic ($\sim 10^{-8}$ cm) to electron ($\sim 10^{-11}$ cm) to nuclear ($\sim 10^{-14}$ to 10^{-16} cm) dimensions. Adding in the classical aspects of electrodynamics, the total range of verification actually covers more than 25 decades out to 10^9 cm, where satellite measurements have verified the predicted cubic power law fall-off of the earth's magnetic field. In several cases the predictions of the theory have been confirmed at the level of parts per million or better.

In spite of this phenomenal success, there is growing evidence that electromagnetic and weak interactions are intricately related to each other and are just different manifestations of a unified electroweak interaction. It is plausible that even the strong interaction is involved in such a unification (grand unification). Experiments are in progress to verify these possibilities.

All this means is that QED, which deals with the electromagnetic force only, must be regarded as part of a more comprehensive theory unifying diverse forces. In practice, however, the modifications of the QED predictions due to weak and strong forces are generally very small until one explores the region smaller than $\sim 10^{-16}$ cm. To the extent that these small effects can be understood, either by calculations based on a (unified) theory or determined by appropriate measurements, it is possible to push the test of the validity of QED to even higher precision

Basic Features and Early History Quantum electrodynamics, the quantum theory of photons and electrons, has a simple conceptual basis. Shortly after the birth of quantum mechanics in 1925–26, P. A. M. Dirac, W. Heisenberg, and W. Pauli noted that the energy in the electromagnetic field amplitudes $\vec{E}(\vec{x}, t)$ and $\vec{B}(\vec{x}, t)$ described by Maxwell's equation must be quantized—as required by quantum mechanics for the energy of any physical system. The quanta of the radiation field could be identified exactly with Planck's photon, the fundamental carrier of light and electromagnetic radiation. The quantized form of Maxwell's equations require that the photon be a particle of zero mass, with velocity c and one unit of angular momentum $\hbar$ (Planck's constant divided by 2π)—directed either along or against its direction of motion. Upon quantization, the classical field amplitudes $\vec{E}$ and $\vec{B}$ (and the four-vector potential $A^\mu(x)$) become quantum-mechanical operators which have nonzero matrix elements only between states which differ by exactly one photon. This was the foundation stone of quantum electrodynamics, which as developed by Dirac, successfully described the emission and absorption of radiation in atomic systems.

*Supported in part by the U.S. Department of Energy and the U.S. National Science Foundation.

During this exciting period in which developments in quantum theory came at an incredible rate, Dirac also presented his famous equation

$$[i\gamma_\mu(\partial^\mu - eA^\mu) - m]\,\psi(x) = 0,$$

which described the motion and spin (internal angular momentum) of an electron or positron in an electromagnetic potential. The application of this equation to an electron bound in a Coulomb field led to a successful prediction of the fine structure of the energy-level separations in the hydrogen atom. Soon afterwards P. Jordan and E. Wigner applied the quantization procedure to the energy contained in the ψ amplitude just as had been done for Maxwell's equation. The quanta of the ψ field can, in fact, be exactly identified with the physical electrons and positrons—particles (and antiparticles) which have charge $\pm e$, mass m, and angular momentum $\frac{1}{2}h$ directed along or against their motion, which must obey the Pauli principle. The Dirac ψ field thus became a quantum-mechanical operator which connects states that differ by one electron or one positron.

The Dirac theory also determines the basic interaction of electrons, positrons and photons and thus provides the fundamental dynamical assumptions of quantum electrodynamics. The form of the interaction density is

$$e\overline{\psi}(x)\gamma_\mu\,\psi(x)A^\mu(x)$$

which, in fact, is the simplest form consistent with the principles of quantum mechanics and relativity. Because of quantization of ψ and A, the interaction only has nonzero matrix elements for the basic electron-positron-photon vertex shown in Fig. 1. The vertex conserves charge and is "local," i.e., it describes the creation or absorption of a photon at the same point $x = (\vec{x}, t)$ in space and time where an electron (or positron) scatters or where an electron-positron pair is created or destroyed. The amplitude for more complicated physical processes in QED can then be obtained from the iteration of the basic three-point interaction (i.e., a perturbation expansion in powers of e). The absolute square of the sum of all the possible amplitudes for the process gives the quantum mechanical probability, or in the case of a collision process, the cross section.

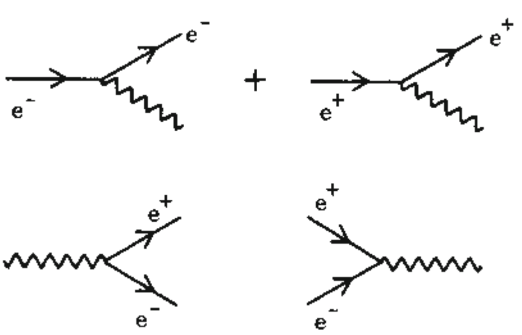

FIG. 1. The basic interaction vertex of quantum electrodynamics. The photon (denoted by a wavy line) is emitted or absorbed by a scattered electron or positron, or by the creation or annihilation of an electron-positron pair. The interaction conserves energy, momentum, and charge. The coupling strength is proportional to the electron charge e.

Rules for calculating the contributing amplitudes have been given in a very elegant and simple form by R. P. Feynman. The rules are explicitly covariant (i.e., independent of the choice of reference frame). For example, the contributing amplitudes (through order e^4) for electron-positron collisions are computed from the "Feynman diagrams" shown in Fig. 2. The lowest order contributing diagrams are of order e^2 since only the iteration of two basic three-point interactions is required. The amplitude for the first diagram in Fig. 2(a) is of the form

$$e^2 J_\mu(e^-)J^\mu(e^+)\,\frac{1}{q^2}$$

which contains factors from Dirac current of the electron $J_\mu(e^-) = \overline{u}(p')\gamma^\mu u(p)$, the Dirac current of the positron, and a factor $(q^2)^{-1} = [(E - E')^2 - (\vec{p} - \vec{p}')^2]^{-1}$ for the propagation of the photon carrying momentum $\vec{q} = \vec{p} - \vec{p}'$ and energy $E - E'$ from the electron to the positron. The last factor for the photon (the "Feynman propagator") automatically accounts for the process in which the photon is emitted by the positron and then absorbed by the electron as well. A similar propagator $(\gamma_\mu q^\mu - m)^{-1}$ occurs in diagrams such as Fig. 2(b) for the propagation of the internal electron or positron. The diagrams in Fig. 2(b) are of order e^4, and give contributions to the collision cross section which are smaller by a factor of

$$\alpha = e^2/4\pi\hbar c = 1/137.035963\ (15),$$

which is the fundamental dimensionless constant of QED. (The quantity enclosed in parentheses represents the uncertainty in the final digits of numerical value.) Because of the smallness of the fine-structure constant α (so named since its square determines the ratio of the fine structure separation to the Rydberg in the Dirac theory for the hydrogen atom energy spectrum), it is seldom necessary to retain terms in perturbation theory beyond the first few orders in order to compare with high-energy scattering experiments.

Recently, very high energy (short-distance) tests of the predictions of quantum electrodynamics for electron-positron scattering have been performed at colliding electron-positron beam facilities at Stanford, Orsay, Novosibirsk, Frascati, and Hamburg. The cross section is predicted to fall inversely with the square of the center of mass energy. The measurements have directly confirmed this prediction at cen-

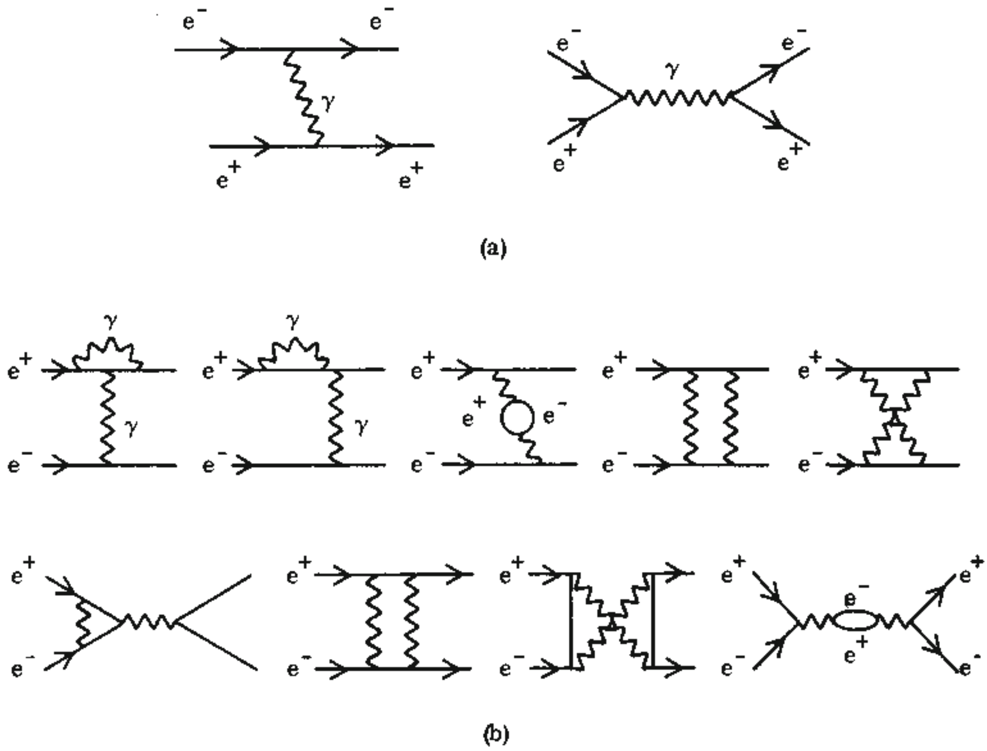

FIG. 2. Feynman diagrams for electron-positron scattering. Figure 2(a) represents the amplitudes of order e^2 obtained from the application of the basic interaction vertex of Fig. 1 to second order in perturbation theory. Figure 2(b) shows representative amplitude in order e^4 for electron-positron scattering.

ter of mass energies as high as 37 billion electron volts. The measurements rule out any modification or breakdown of QED unless it occurs at distances smaller than 10^{-16} cm where the weak boson Z^0 predicted by the theory of electroweak interaction due to Glashow, Weinberg, and Salam will modify the prediction of QED. Colliding-beam experiments in which a muon pair is produced from the annihilation of an electron pair (see Fig. 3) have provided dramatic verification of the correctness of the application of QED to the electromagnetic interactions of the muon as well.

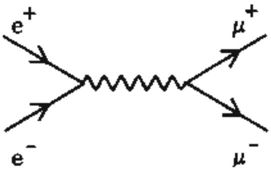

FIG. 3. The lowest-order Feynman diagram for the annihilation of an electron-positron pair into a muon pair. This process can now be studied experimentally at electron-positron colliding-beam facilities with beam energies up to nineteen billion electron volts. In these experiments, the electron and positron collide with equal and opposite momenta, producing an intermediate photon at rest in the laboratory, which then decays to the final muon pair. At higher energies this diagram interferes with one in which the photon is replaced by a weak boson Z^0.

Other high-energy collision measurements including electron or muon pair production and other inelastic processes have shown complete agreement with theory and no sign of any fundamental length at small distances, or additional heavy leptons or photons.

Complementary to these high-energy tests are the precision atomic physics and magnetic moment measurements, which have confirmed the validity of quantum electrodynamics at the level of billionths of an electron volt. For these tests, which are performed at the ppm level, an expansion through high orders in e is required, and the precise value of the fine-structure constant α is essential. The numerical value of α can be obtained independently of QED from a combination of measurements from very diverse fields, expressed via the relation

$$\alpha^{-2} = \frac{1}{4\mathrm{Ry}_\infty}\,\frac{1}{\gamma_{p'}}\,\frac{\mu_{p'}}{\mu_{\mathrm{B}}}\,\frac{2e}{h}\,\frac{c\Omega_{\mathrm{abs}}}{\Omega_{\mathrm{NBS}}}$$

The Rydberg Ry_∞, the proton gyromagnetic ratio in water $\gamma_{p'}$, the magnetic moment

$\mu_{p'}/\mu_B$ of the proton (in a water sample) in units of the electron Bohr magnetron, and $c\Omega_{abs}/\Omega_{NBS}$, the ratio of absolute to NBS ohm (required for standard voltage measurements), are known to 0.2 parts per million, or better, and the ratio $2e/h$ has been determined recently to better than 0.03 ppm via the alternating current Josephson effect in superconductors by E. R. Williams and P. T. Olsen. Very recently a completely different way of determining α has been discovered by K. von Klitzing et al. This is based on the quantized Hall effect in a semiconductor which measures e^2/h directly. It has already provided an α value almost as accurate as that described above, and further improvement is expected shortly.

The Self-Energy Problem and the Lamb Shift Despite the apparent correctness of the basic structure of the interaction between the photon and the electron, and the elegance of its equations, there is a central problem in quantum electrodynamics, which reflects on its fundamental validity. This problem involves the "self-energy" corrections of the theory. For example, the calculation of the energy shift of a free electron due to its emission and subsequent reabsorption of a single photon, gives an infinite result! This divergence is a consequence of the point-like (local) nature of the basic three-point vertex of QED.

Progress on this problem came only because of an extraordinary experiment performed by W. Lamb and his co-workers in 1947. The Dirac equation for an electron bound in a Coulomb field predicted that the energy levels with the same quantum number n and total angular momentum j should be degenerate; in particular, negligible energy separation between the $2P_{1/2}$ and $2S_{1/2}$ excited levels in atomic hydrogen was predicted. The Lamb experiment, however, conclusively demonstrated that the levels were in fact separated by ~ 1000 MHz, a full tenth of the fine-structure separation of the $n = 2$ levels (the Lamb shift). Then, in a historic paper, H. Bethe was able to show that not only could quantum electrodynamics explain the Lamb shift, but also that the divergence problem in the self-energy calculation could be circumvented.

In his 1947 paper, Bethe pointed out that when one calculates the self-energy correction to a bound electron from the emission and absorption of a photon, part of the energy shift—in fact, the divergent part—should be identified with the energy or "self-mass" of the electron itself. When the self-mass term is identified and canceled out, or alternately if the difference of energy shifts for two bound state levels is calculated, the result is a finite energy shift. Bethe's calculations showed that the net energy shift due to the electron in the hydrogen atom emitting and absorbing one photon causes the $2S_{1/2}$ level to be displaced above the $2P_{1/2}$ level by about 1080 MHz. This can be understood physically by the fact that the emission and subsequent reabsorption of the photon causes the position of the electron charge to fluctuate over a distance of the Compton wavelength of the electron ($\hbar/m_ec$) a percentage α of the time. The degeneracy predicted by the Dirac equation is a strict consequence of the inverse r dependence of the electron-nucleus Coulomb potential, and this is destroyed by the orbital dependence of the effective spreading of the electron's position. Another important effect is "vacuum polarization," which increases the binding of the electron and reduces the $2S_{1/2}$ - $2P_{1/2}$ separation by 27 MHz. This quantum-electrodynamical effect, which was discussed by R. Serber and E. A. Uehling in 1935, is caused by the modification of the Coulomb potential due to the virtual electron-positron pairs. In fact, because two charged particles always see each other through a cloud of virtual particle-antiparticle pairs, the charge e_0 that appears as a parameter in the equations of quantum electrodynamics is not precisely the physical charge e of the electron (as defined classically for an electron scattering at large distances from a test electric field).

Over the years both the theory and measurements of the Lamb shift have been developed to extraordinary precision. The theory accounts for higher-order photon processes and the relativistic effects of a two-particle bound state system (relativistic recoil corrections) using a covariant equation developed by H. Bethe and E. Salpeter. The latest theoretical prediction (by J. Sapirstein) is

$$\Delta E(2S_{1/2} - 2P_{1/2}) = 1057.860(9)\ \text{MHz}.$$

The most recent measurement (by S. R. Lundeen and F. M. Pipkin) is

$$\Delta E(2S_{1/2} - 2P_{1/2}) = 1057.845(9)\ \text{MHz}.$$

Other precision atomic physics tests of QED are described below.

Renormalization Theory Within a few years after Bethe's work, R. Feynman, J. Schwinger, S. Tomonaga, and F. Dyson demonstrated that all the divergences in quantum-electrodynamic calculations could be circumvented order by order in perturbation theory. This procedure, which is called the renormalization program, was shown to be covariant (independent of Lorentz frame), and despite the presence of infinite quantities in intermediate expressions, the calculations were shown always to lead to unambiguous finite results.

Briefly, one notes that the "bare charge" e_0 and "bare mass" m_0 which appear as parameters in the equations of quantum electrodynamics are not the physical charge and mass of the electron, but must be chosen correctly. Thus (to any given order in perturbation theory) one must adjust the values of m_0 and e_0 so that after calculation of all the contributing diagrams, electron-electron scattering at large distances will agree with classical Coulomb scattering for two particles of charge e, and that Compton scattering (elastic electron-photon scattering) at zero frequency will agree with the Thomson limit which defines the ratio e^2/m. After this adjustment is made, calculations of all *physical* quantities are finite, although the values in perturbation theory for the quantities e_0 and m_0 are mathematically divergent. In recent years, much theoretical work has been done in order to remove this last mathematical problem —either by attempts to demonstrate that e_0 and m_0 are actually finite and calculable when all orders in perturbation theory are taken into account, or by modifications of quantum electrodynamics at very small distances where unification with other interactions may occur.

Other Precision Tests of QED The classic and most basic test of quantum electrodynamics is the measurement of the anomalous magnetic moment of the electron. Thus far it has been one of the most stunning triumphs of experimental and theoretical analysis. The measurements are based on the following facts: An electron in a uniform magnetic field moves in a helical orbit with a rotational frequency $\omega_L = eB/mc$. If the electron's magnetic interactions conformed to the simple Dirac equation, the direction of its internal spin would precess with exactly the same frequency. The first experimental determination of a deviation of the electron moment from the Dirac value was made by H. M. Foley and P. Kusch in 1947; their results for the electron's "anomalous moment" were confirmed by J. Schwinger's calculation of the quantum-electrodynamic effect on the electron's spin precession frequency due to the emission and absorption of a single photon. Small corrections to the normal Dirac value can in fact be measured to tremendous precision since the net angle between the momentum and spin vectors of the electron can be determined to a few parts per million, as was demonstrated by D. T. Wilkinson and H. R. Crane in 1963. The most recent result by A. Rich and J. C. Wesley (1971) is

$$a_e{}^{\text{exp}} = 0.001\ 159\ 656\ 7\ (35).$$

Recently, based on an entirely different technique which utilizes *rf* resonance transitions between quantized levels of electrons in a magnetic field, H. G. Dehmelt and his collaborators have improved the value of a_e by two orders of magnitude. Their latest results for the electron and positron are

$$a_{e^-}{}^{\text{exp}} = 0.001\ 159\ 652\ 200(40)$$

and

$$a_{e^+}{}^{\text{exp}} = 0.001\ 159\ 652\ 222(50),$$

respectively, which are in good agreement with the theoretical value of Kinoshita and Lindquist:

$$\begin{aligned} a_e{}^{\text{th}} &= \frac{\alpha}{2\pi} - 0.328\ 478\ 966\left(\frac{\alpha}{\pi}\right)^2 \\ &\quad + 1.176\ 5(13)\left(\frac{\alpha}{\pi}\right)^3 - 0.8\ (2.5)\left(\frac{\alpha}{\pi}\right)^4 \\ &\quad + 4.4 \times 10^{-12} \\ &= 0.001\ 159\ 652\ 460\ (150), \end{aligned}$$

where the contribution 4.4×10^{-12} is due to the muon loop, hadronic, and weak interaction effects.

The gyromagnetic ratio of the electron $g = 2(1 + a)$, the ratio of the spin and rotation frequencies, which is a fundamental constant of nature, is thus correctly predicted by QED to 12 significant figures!

The theoretical result for the anomalous moment includes contributions due to emission and absorption of up to four photons by the electron. The calculations are carried out eight orders in perturbation theory beyond the lowest order and are the most complex of any in theoretical physics. The application of computerized algebraic and numerical computation techniques has been required.

Measurements of the muon anomalous magnetic moment by F. J. M. Farley and his coworkers are also in agreement with quantum electrodynamics if corrections due to the photon-hadron interaction are included. In this and in other precision measurements, the muon has been found to have symmetrical properties to the electron but for its heavier mass:

$$m_\mu/m_e = 206.768\ 60\ (47).$$

Other precision tests of quantum electrodynamics which have confirmed the correctness of the theory, including the renormalization procedure, involve the hyperfine separation of the ground state of fundamental atoms such as hydrogen, muonium, and positronium. The hyperfine separation results because of the difference in energy which occurs when the electron and nuclear magnetic moments are parallel and antiparallel. Measurements (based on the properties of the hydrogen maser) by H. Helvig et al. and L. Essen et al. have determined this separation to 13 significant figures in atomic hydrogen. The results agree with the theoretical predictions to six significant figures. Measurements of hyperfine splittings in positronium (the positron-electron atom) by V. Hughes et al. are in good agreement with the quantum electrodynamics predictions at nearly the same precision. Very accurate measurements of hyperfine splitting in muonium (the positive muon-electron atom) by V. W. Hughes et al. and V. Telegdi, et al., and recent theoretical efforts by D. R. Yennie, G. P. Lepage, et al. are pushing the test of QED to a precision approaching 0.1 ppm.

Other applications of quantum electrodynamics include high Z muonic atoms, coherent and incoherent electromagnetic processes, and general electromagnetic phenomena. Quantum electrodynamics has also served as a prototype for the development of various non-Abelian local gauge theories. There is now considerable evidence that these renormalizable gauge theories can account for the properties of the strong and weak interactions in elementary particle physics.

Conclusions As far as we know, quantum electrodynamics provides a mathematically exact description of the electromagnetic properties of the electron and muon. To the extent that the electromagnetic properties of the nucleus are known, the theory provides the fundamental dynamical theory of the relativistic atom, including its external electromagnetic interactions. At present there is no outstanding discrepancy with any of its predictions provided that the experimental data are corrected for effects due to weak and hadronic interactions, and despite our pursuing the limits of the theory to very high accuracy and very small distances.

Breakdown of the theory could still occur at short distances or at high precision if any of the following existed: (a) intrinsic lepton size or nonlocal currents, (b) heavy leptons, (c) heavy photons, (d) magnetic charge, (e) breakdown of perturbation theory or anomalous subtraction constants not given by the renormalization procedure. All of these modifications are ruled out to some extent by the various tests discussed in this article. In addition, the basic space-time symmetries of QED, conservation laws, the constancy in time of α, c, etc. have all been checked to various degrees.

All of the suggested modifications would mar the essential simplicity of Maxwell's equations and the Dirac form of the vertex interaction. Despite this simplicity, however, and despite its phenomenal success, the fundamental problems of renormalization in local field theory and the nature of the exact solutions of quantum electrodynamics are still to be resolved.

QUANTUM THEORY

1. Early History The theory of quantum mechanics has progressed by a series of discontinuous jumps from rather elementary beginnings through increasingly complex levels of abstraction. In this article we review this evolution and discuss the conceptual difficulties that have arisen, been resolved, or which have been ignored and remain to flaw the theory.

The break with classical mechanics came rapidly with two major observational discoveries. First, the spectral distribution in black-body radiation was found to be inexplicable in terms of classical models; this led Planck (1900) to postulate the particulate nature of energy propagation in electromagnetic waves. Second, Davisson and Germer (1927) and G. P. Thomson (1928) discovered that electron beams passing through crystals were diffracted in the same way as X-ray electromagnetic (e.m.) waves. Both these observations were "explained" by the simple formulae

$$\begin{gathered} E = \hbar w, \qquad p = \hbar k \\ (w = 2\pi\nu, \qquad k = 2\pi/\lambda, \qquad \hbar = h/2\pi) \end{gathered} \tag{1.1}$$

together with the statement that electromagnetic waves of frequency w can have only energies $n\hbar w$ where n is any positive integer, and electrons having momentum p interact with crystalline matter like waves having wavelength λ equal to h/p. The value of Planck's constant $\hbar$ is the same for both phenomena.

The wave-particle paradox was the major conceptual problem for quantum mechanics for many years—and still is treated as such in many semipopular discussions of the theory.

It is worth going through the calculations leading to the Planck black-body radiation formula, using the classical Gibbs expression for the mean energy of a gas (of photons) in thermodynamic equilibrium.[1] Because the photons are indistinguishable particles, the spectrum of energies of distinguishable states of the radiation having frequency w is $n\hbar w$, $n = 1, 2, \ldots$ so the mean energy of the radiation is given by the classical formula

$$\langle E(w)\rangle = \sum_n n\hbar w e^{-n\hbar w/kT} \Big/ \sum_n e^{-n\hbar w/kT} \tag{1.2}$$

$$= \hbar w/(e^{\hbar w/kT} - 1). \tag{1.3}$$

If instead of taking the discrete spectrum of energy states, we allow n to be a continuous variable, the sums of Eq. (1.2) are replaced by integrals and we find instead of Eq. (1.3) the result

$$\langle E(w)\rangle = kT \quad \text{independent of } \hbar. \tag{1.4}$$

If the radiation field is expressed as a superposition of standing modes in a cubical box of side L, the number of modes having frequency between w and $w + dw$ is

$$N(w)\,dw = 2(L/c)^3 w^2\, dw, \tag{1.5}$$

so the total energy in the field within this frequency range is on Planck's model, the product of (1.3) and (1.5):

$$2(L/c)^3 \hbar w^3\, dw/(e^{\hbar w/kT} - 1), \tag{1.6}$$

and on the continuous model, the product of (1.4) and (1.5):

$$2(L/c)^3 w^2 kT\, dw. \tag{1.7}$$

Planck's model agrees with the observed distribution, while the continuous model suffers from the "ultraviolet catastrophe"—the energy density becomes infinite at very high frequencies.

In Planck's model we picture the photons as relativistic particles with zero rest mass and energy $E = pc$, so that $E = \hbar w$ is equivalent to $p = hk$. Just how the photons are moving under the guidance of the standing waves is an essentially unanswerable question at this stage of the theory. It must be borne in mind that Eq. (1.2) derives from the statistical theory (J. W. Gibbs, 1893–1903) of the distribution having maximum probability in an ensemble of systems (gases), and identified with thermodynamic equilibrium in any one of the members of the ensemble. The mechanism for establishing equilibrium—the "approach to equilibrium"—is left very much an open question here. In the present case the normal modes of electromagnetic radiation have no direct interaction with each other, and the process of absorption and of emission of energy between the walls of the enclosure and the radiation must be invoked to cause adjustments in the energy distribution of the radiation field. The "blackness" of the walls ensures a continuous frequency spectrum for these processes, and the structure (normal modes) of the radiation field gives rise to the spectral distribution, and only if the exchanges of energy between the walls and the radiation are effected in discrete photons does one obtain the correct Planck distribution. The photons essentially only need to exist at the energy exchanges between matter and radiation field, and one has no need to try to visualize the photons as a gas of particles in space guided by the electromagnetic waves. Clearly there are serious conceptual difficulties here which are still subject to philosophical controversy.

In sharp contrast to this picture, the fact that electron beams can be diffracted supported de Broglie's idea (1926) that all material particles may be guided by wave fields. Matter waves were to be regarded as just as "real" as electromagnetic waves. Schrödinger (1887–1961) discovered a successful formula to express this concept. Starting with the classical Hamiltonian function $H(p, q)$ in phase space, and adopting the transcription formulae

$$\mathbf{p} \to -i\hbar\nabla, \qquad E \to i\hbar\partial/\partial t \tag{1.8}$$

from the classical variables p and E to differential operators, and writing $\Psi(x, y, z, t)$ for a wave amplitude, the classical relation

$$H = p^2/2m + V(x, y, z) = E \tag{1.9}$$

becomes an operator which operating on the function Ψ yields the Schrödinger wave equation

$$i\hbar\partial\Psi/\partial t = -(\hbar^2/2m)\nabla^2\Psi + V\Psi. \tag{1.10}$$

This differential equation seems to describe the matter waves of the de Broglie picture. Indeed when solved for the case $V = 0$ everywhere—the free particle in empty space—one finds plane wave solutions:

$$\Psi_k = C \exp(-iE_k t/\hbar + i\mathbf{k}\cdot\mathbf{r}) \tag{1.11}$$

where $\mathbf{r}$ means the vector (x, y, z), $\mathbf{k}$ is an arbitrary wave number vector, $E_k = \hbar^2 k^2/2m$ has the dimensions of energy, and C is an arbitrary amplitude. Ψ_k is what is called the *eigenfunction* of the operators p and E with eigenvalues $\hbar k$ and E_k because using (1.11) we find

$$E\Psi_k \equiv i\hbar\partial\Psi_k/\partial t = E_k\Psi_k \tag{1.12}$$

and

$$P\Psi_k \equiv -i\hbar\nabla\Psi_k = \hbar\mathbf{k}\Psi_k. \tag{1.13}$$

Note that the wavelength in Eq. (1.11) is $\lambda = 2\pi/k$ and the particle momentum is $\hbar\mathbf{k}$, so that the de Broglie relation $p = h/\lambda$ is satisfied. However the speed of propagation of the Ψ-wave is $E_k/\hbar k = \hbar k/2m = p/2m$, which is only half the particle speed. Instead, the "group" velocity of a wave packet with a Gaussian distribution of frequencies does agree with the particle speed, so a rather clear picture emerged for the association between wave and particle aspects of the phenomenon, which we may call the *tentative probability interpretation* of the Ψ wave, discussed in Section 2.

Using the appropriate Hamiltonian for the motion of an electron in the Bohr-Sommerfeld model of the hydrogen atom, and noting that the Schrödinger transcription yields an operator also for orbital angular momentum, one can derive the familiar H-atom eigenfunctions and the fact that the angular momentum of an orbit is quantized in integral numbers of $\hbar$. But to obtain the correct Zeeman effect, Pauli, Uhlenbeck, and Goudsmit discovered (1925–1927) that it was necessary to postulate angular momentum to the electron itself, equal in magnitude to one half the quantum $\hbar$, and Pauli invented the *spin operator* with the eigenvalues plus and minus $\frac{1}{2}\hbar$, an operator with no classical analog—not derived from any classical variable by any transcription formula like Eq. (1.8). The result was to split every atomic state into two states of opposite spin; the wave functions became "spin degenerate" in the absence of a magnetic field.[2] The spin operator was represented by three two-by-two matrices, and seemed completely alien in nature to the differential operators for energy and linear momentum.

Generally ignoring the conceptual difficulties of reconciling the Schrödinger transcription formulae with common sense, theoretical physicists proceeded to apply the rules with widespread spectacular success. The entire chaotic field of spectroscopy was brought into a beautiful orderly pattern, the periodicity of the table of the elements was rationalized, the basic elastic properties of the solid state were explained.[3] Such a vast array of agreements between new and old experimental data on the one hand and the predictions of quantum mechanics on the other was established that the essential truth of the theory could not be denied.

2. Tentative Statistical Interpretation Conceptual difficulties meanwhile continued to accumulate.[4] Success of the theory was possible only after abandoning the naive interpretation of Schrödinger's wave function as the "real" de Broglie matter wave. The classical Hamiltonian of a many-particle system, like a crystalline solid or a complex molecule, involves an abstract phase space with at least $6N$ dimensions, where N is the number of particles. To carry through the Schrödinger transcription in such a phase space is possible only if one takes the overall wave function to be a product of functions, each factor a function of the phase coordinates of one of the particles. This is quite incompatible with the de Broglie picture of each particle being accompanied by a wave packet, all packets being defined on the same physical space. Even a system as elementary as a single pair of indistinguishable particles must be represented by a wave function of 12 variables, a function that cannot be visualized as two wave packets in the same three-dimensional space. Abstract interpretation of Ψ as a complex probability amplitude was first adopted, tentatively, leading to the following basic rule: When a system is in a state represented by the wave function Ψ, then measurements of any observable attribute of the system, represented by the operator A, produce on average the result

$$\langle A\rangle = \int \Psi^* A \Psi \, d\tau \tag{2.1}$$

asserting that the function Ψ is a probability density amplitude. The arbitrary amplitude C in Eq. (1.11) has to be chosen so that the probability is normalized:

$$\int \Psi^* \Psi \, d\tau = 1. \tag{2.2}$$

Note the essential distinction between the "superposition" of different functions Ψ involved in the wave packets mentioned in Section 1 above and the product of different Ψ functions in different spaces required to describe different particles. The wave packets result in a dispersion of measurement probabilities on a single-particle system; the wave products result in a single function describing a state of many particles, and may well be an eigenstate with well defined measurement probabilities.

One labels this interpretation as "tentative" advisedly, because many of the more creative thinkers in the field—Einstein,[5] de Broglie, and E. Wigner, to name a few—felt with good reason that a true quantum mechanics should have a deeper than purely statistical meaning. Louis de Broglie in fact established an active school of thought that sought escape from statistics by postulating the existence of "hidden variables"[6] and the use of nonlinear equations of motion. Einstein was never convinced that statistical quantum mechanics could be a complete theory, but failed to discover any alternative. Wigner, contemplating the meaning of Heisenberg's uncertainty principle has been interested in the essential part played by the consciousness of the physical observer during the process of measurement, in part because the concept of "probability" is itself difficult to divorce from purely subjective considerations.

The *Heisenberg uncertainty principle* arises directly from the wave-packet picture of the single particle: The more precisely one locates the particle by sharpening the spatial dimensions of the packet, the wider the spread of the wave numbers of the component waves, and hence the less precisely can one determine the momentum. Crudely written the principle states:

$$\Delta x \Delta p \geqslant \hbar/2 \tag{2.3}$$

and identical statements pertaining to many other "conjugate pairs" of classical variables. Innumerable "Gedankenexperiments" were described to test the principle, and much discussion was concerned with whether the particle really "possessed" the quantities that could not be measured precisely in one and the same procedure ("simultaneously"). Perhaps physical observables should be thought of as attributes belonging rather to the measurement procedures than to the object measured. The mathematical content of the principle was quite definite,[7] whatever the philosophical implications. Let A and B be any two operators. Schwartz's inequality can be applied to two functions u and v defined in terms of some wave function Ψ and operators A and B as follows. Let

$$u \equiv (A - \langle A \rangle), \qquad v \equiv i(B - \langle B \rangle), \tag{2.4}$$

where $\langle A \rangle$ and $\langle B \rangle$ are defined as in Eq. (2.1). The result is the following form of Schwartz's inequality:

$$\begin{aligned} \langle (A - \langle A \rangle^2) \rangle - \langle (B - \langle B \rangle^2) \rangle \\ \geqslant - \tfrac{1}{4} \langle (AB - BA)^2 \rangle. \end{aligned} \tag{2.5}$$

Then if $A = P$ and $B = Q$, the momentum and position operators, respectively, this inequality reads

$$\Delta p^2 \Delta q^2 \geqslant - \tfrac{1}{4} \langle (PQ - QP)^2 \rangle. \tag{2.6}$$

The commutator $PQ - QP$ is to be evaluated directly from the definitions of the two operators, $P\Psi = -i\hbar\partial\Psi/\partial q$, $Q\Psi = q\Psi$, when $PQ\Psi - QP\Psi = -i\hbar\Psi$ and therefore, as operators

$$PQ - QP = -i\hbar \tag{2.7}$$

and Eq. (2.6) becomes

$$\Delta p^2 \Delta q^2 \geqslant \tfrac{1}{4} \hbar^2 \tag{2.8}$$

equivalent to Eq. (2.3). The meaning is taken to be that the dispersion in measurements of momentum and the dispersion in measurements of position of a particle in any "state" are necessarily related in such a way that the product of two dispersions cannot be less than $\frac{1}{4}\hbar^2$. This result cannot be understood in terms of classical mechanics.

3. Hilbert Space Concepts Without going into all the technical mathematical details, we may state the following abbreviated definition of a Hilbert space:[8] A set of elements, for example a set of complex functions χ defined on the Cartesian space of real numbers (x, y, z), is said to form a Hilbert space $\mathcal{H}$ if:

(a) A finite scalar product of every pair of members of the set can be defined, writing for the scalar product of the nth and mth member

$$(\chi_n, \chi_m) \; \Bigg(\text{for example} \quad (\chi_n, \chi_m) \equiv \left(\int \chi_n{}^* \chi_m \, d\tau \right)\Bigg); \tag{3.1}$$

(b) A distance between any two members, written $d(n, m)$, can be defined with the metric properties

$$\begin{gathered} d(n, m) \geqslant 0, \qquad d(n, m) = 0 \\ \text{if and only if} \quad n = m \\ d(n, m) \leqslant d(n, k) + d(k, m) \end{gathered} \tag{3.2}$$

(for example

$$d(n, m) \equiv \sup_{\text{all } x} \{ |\chi_n(x) - \chi_m(x)| \}).$$

There are other prerequisites which need not concern us here.

To be of physical interest, function spaces must be "separable," meaning that they can be "spanned" by a complete set of mutually orthogonal functions chosen from among the functions forming the space. Separable Hilbert spaces embrace almost all functions of physical interest. If we write $\{|n\rangle\}$ for the set of functions in $\mathcal{H}$ that span the space, we have $(|n\rangle, |m\rangle)$ for the scalar product, and writing $\langle m|$ for the complex conjugate of $|m\rangle$ we can match the definition (3.1) by writing the scalar product in the form $(\langle n|m\rangle)$ and require

$$(\langle n|m\rangle) = \delta_{mn}, \quad 0 \text{ or } 1. \tag{3.3}$$

The basis vectors $|m\rangle$ and $|n\rangle$ are mutually orthogonal and normalized to unity.

Simply stated, the spanning concept means that any member of $\mathcal{H}$, for example χ, can be expressed as a linear combination (or superposition) of the members of the basis set spanning the space:

$$\chi = \sum_n a_n |n\rangle. \tag{3.4}$$

It also means that any operator, say A, which maps any member of the space into some other member of the same space, can be represented by a matrix: thus let A map χ into ϕ:

$$A\chi = \phi \tag{3.5}$$

and expand both χ and ϕ in terms of the basis $\{|n\rangle\}$

$$\chi = \sum_n a_n |n\rangle \quad \text{and} \quad \phi = \sum_n b_n |n\rangle. \tag{3.6}$$

Then Eq. (3.5) becomes

$$\sum_n a_n A |n\rangle = \sum_m b_m |m\rangle. \tag{3.7}$$

Taking the scalar product from the left with the basis element $|k\rangle$ Eq. (3.7) yields

$$\sum_n a_n \langle k|A|n\rangle = \sum_m b_m \langle k|m\rangle = b_k \tag{3.8}$$

because of Eq. (3.3). This permits one to determine the function ϕ in Eq. (3.6) when we know the operator A and operand χ. The quantities $\langle k|A|n\rangle$ in Eq. (3.8) are collectively called the matrix of A on the "$\{|n\rangle\}$ representation." An abbreviated notation is often used:

$$\langle k|A|n\rangle = A_{kn}, \qquad (3.9)$$

and explicitly we could write out the matrix in the form

$$\{A_{kn}\} = \begin{pmatrix} \langle 1|A|1\rangle & \langle 1|A|2\rangle & \langle 1|A|3\rangle & \cdots \\ \langle 2|A|1\rangle & \langle 2|A|2\rangle & \langle 2|A|3\rangle & \cdots \\ \langle 3|A|1\rangle & \langle 3|A|2\rangle & \langle 3|A|3\rangle & \cdots \\ \cdots & \cdots & \cdots & \cdots \end{pmatrix} \qquad (3.10)$$

with as many rows, or columns, as there are members in the basis set, which in some cases may be infinite. Using the scalar product as defined in Eq. (3.1), the matrix elements displayed in Eq. (3.10) are

$$\langle k|A|n\rangle = \int f_k{}^* A f_n \, d\tau \qquad (3.11)$$

where f_n is written in place of $|n\rangle$ to emphasize the familiar form of integrals.†

There is one other general theorem we shall quote here: The complete set of eigenvectors of any operator with a discrete point spectrum of eigenvalues, forms an acceptable basis of a separable Hilbert space.

We saw in Eqs. (1.11) and (1.13) that Ψ_k of Eq. (1.11) was an eigenfunction of the momentum operator with eigenvalue $\hbar k$. In free space this is a continuous variable and therefore the functions Ψ_k cannot form the discrete basis of a Hilbert space. But if the problem is restricted to a finite volume the values of k do become discrete, and the set of functions Ψ_k reduce to the discrete set of trigonometric functions which vanish at the boundaries of the volume of interest. If this is a line of length $2L$, the functions are $\sin \pi nx/L$ when n is even and $\cos \pi nk/L$ when n is odd, and the expansion of Eq. (3.4) is the familiar Fourier expansion of any function of x which vanishes outside the domain $-L \leqslant x \leqslant L$.

A similar difficulty occurs with the eigenvectors of the position operator Q which presents the eigenvector equation

$$Qf(x) = xf(x). \qquad (3.12)$$

This operator maps any function $f(x)$ on to the function $xf(x)$, and x is clearly the eigenvalue; any function whatever is an eigenfunction, and the eigenvalue x can have any value in the space, so is continuous, and there is no acceptable basis for the Hilbert space on these terms.[8]

4. Simple Harmonic Oscillator Representation[9] The classical Hamiltonian for a one-dimensional simple harmonic oscillator (S.H.O.) is

$$H = (1/2m)\,(p^2 + m^2w^2x^2). \qquad (4.1)$$

Schrödinger's wave equation derived from this by the transcription of Eq. (1.8) reads

$$i\hbar\partial\Psi/\partial t = (1/2m)\,(m^2w^2x^2\Psi - \hbar^2\partial^2\Psi/\partial x^2). \qquad (4.2)$$

If we write

$$\Psi = u(x)\,e^{-iEt/\hbar} \qquad (4.3)$$

Eq. (4.2) reads

$$(1/2m)\,(m^2w^2x^2 - \hbar^2\partial^2/\partial x^2)\,u(x) = Eu(x) \qquad (4.4)$$

which one recognizes as an eigenvalue relation for the Hamiltonian operator

$$H = (1/2m)\,(m^2w^2x^2 - \hbar^2\partial^2/\partial x^2). \qquad (4.5)$$

Eq. (4.4) is a differential equation with well-known solutions if and only if E is chosen as one of the spectrum of values

$$E = E_n = (n + \tfrac{1}{2})\hbar w, \qquad n = 1, 2, \ldots \qquad (4.6)$$

The solutions are Hermite functions

$$u_n(x) = (2^n n!\sqrt{\pi})^{-1/2} e^{x^2/2} H_n(x), \qquad (4.7)$$

$H_n(x)$ being the nth Hermite polynomial defined by

$$H_n(x) = (-1)^n e^{x^2} \partial^n (e^{-x^2})/\partial x^n. \qquad (4.8)$$

From the point of view of Hilbert space concepts, one can say that the functions $u_n(x)$ form a closed orthonormal basis set for the whole space of Lebesgue square integrable functions of x. Any such function can therefore be written in the form

$$f(x) = \sum_n f_n u_n(x) \qquad (4.9)$$

where f_n are complex constants. For convenience we can write

$$u_n(x) = |n, x\rangle, \qquad (4.10)$$

and any operator or mapping in the space onto itself can be written as a matrix as in Eqs. (3.9) and (3.10):

$$A \to A_{mn} = \int \langle n, x|A|m, x\rangle \, dx. \qquad (4.11)$$

In particular the matrix for the Hamiltonian operator is diagonal:

$$\begin{aligned} \langle m, x|H|n, x\rangle &= (n + \tfrac{1}{2})\hbar w \langle m, x|n, x\rangle \\ &= (n + \tfrac{1}{2})\hbar w\,\delta(m, n) \qquad (4.12) \end{aligned}$$

† An excellent elementary treatment of matrix algebra, as needed for quantum mechanics, can be found in Ref. 7.

which has the diagonal (eigen)values $(n+\frac{1}{2})\hbar w$ and zeroes elsewhere. In general those operators which have real eignevalues—like the Hamiltonian—are called *Hermitian*. All physical observables are presumed to be represented by Hermitian operators. A Hermitian operator need not be diagonal on any given representation, but will have real mean values—the diagonal elements are real. The momentum and position operators discussed above have interesting matrices on the S.H.O. basis. They are zero everywhere except on two parallel rows once removed from the diagonal.

(1) Momentum operator P: the only non zero elements are, omitting the x-indicator as superfluous,

$$\langle n|P|n-1\rangle = -\langle n-1|P|n\rangle = i\sqrt{\tfrac{1}{2}n\hbar mw}, \qquad n = 1, 2, \ldots . \tag{4.13}$$

(2) Position Q: the only non zero elements are

$$\langle n|Q|n-1\rangle = \langle n-1|Q|n\rangle = \sqrt{\tfrac{1}{2}n\hbar mw}, \qquad n = 1, 2, \ldots . \tag{4.14}$$

The diagonal elements—mean values—are all zero. Using elementary matrix algebra it is not difficult to derive the theorem that the product of the matrices for P and Q satisfy the relation

$$PQ - QP = -i\hbar\mathbf{I} \tag{4.15}$$

where $\mathbf{I}$ is the identity matrix (unity on every diagonal element and zero elsewhere), matching Eq. (2.7) derived from the differential form of the operator P.

So far we have discussed motion only in one dimension. If we wish to discuss functions of position in three-dimensional space we may write out the classical Hamiltonian for the isotropic three-dimensional oscillator and transcribe it into the Schrödinger equation:

$$-(\hbar^2/2m)\nabla^2 u + \tfrac{1}{2}mw^2(x^2+y^2+z^2)u = Eu(x,y,z) \tag{4.16}$$

and note that the variables separate, giving three equations each identical in form with Eq. (4.4), independent of one another except for the fact that the sum of the three energies has to equal E. Since the individual energies must each have one of the values $(n+\frac{1}{2})\hbar w$, the total energy must be

$$E = (n_x + n_y + n_z + \tfrac{3}{2})\hbar w \tag{4.17}$$

where the set of integers n_x, n_y, n_z is an arbitrary vector $\mathbf{n}$. Writing the eigenstates

$$u_{n_x}(x) = |n, x\rangle, \quad \text{etc.} \tag{4.18}$$

the general solution of Eq. (4.16) can be written

$$\Psi = \sum_{\mathbf{n}} C_{\mathbf{n}} \prod_{j} |n, j\rangle, \qquad j = x, y, z. \tag{4.19}$$

Operating on this with the Hamiltonian

$$\begin{aligned} H &= -(\hbar^2/2m)(\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2) \\ &\quad + \tfrac{1}{2}mw^2(x^2+y^2+z^2) \\ &= \sum_k H_k, \qquad k = x, y, z, \end{aligned} \tag{4.20}$$

we have

$$\sum_k H_k \Psi = \sum_{\mathbf{n}} C_{\mathbf{n}} \sum_k H_k \prod_j |n, j\rangle. \tag{4.21}$$

Where H_k operates on a product like $\Pi_j|n,j\rangle$, it is to be understood that it "sees" only the kth factor:

$$H_k \prod_j |n, j\rangle = E_k \prod_j |n, j\rangle, \qquad k = x, y, \text{or } z. \tag{4.22}$$

Thus we have

$$H\Psi = \sum_{\mathbf{n}} C_{\mathbf{n}} \sum_k E_{n_k} \prod_j |n, j\rangle. \tag{4.24}$$

The mean energy in the state—see Eq. (2.1)—is

$$\begin{aligned} \langle H\rangle &= \langle \Psi^*|H|\Psi\rangle \\ &= \sum_{\mathbf{m}} C_{\mathbf{m}}^* \sum_{\mathbf{n}} C_{\mathbf{n}} \sum_k E_{n_k} \prod_j \langle m, j| \prod_i |n, j\rangle; \end{aligned} \tag{4.25}$$

and because of the orthonormality of eigenvectors this reduces to

$$\langle H\rangle = \sum_{\mathbf{n}} C_{\mathbf{n}}^* C_{\mathbf{n}} \sum_k E_{n_k}. \tag{4.26}$$

The square modulus $C_{\mathbf{n}}^*C_{\mathbf{n}}$ is then interpreted as the probability that, in the state Ψ, the energy "has" the set of energy eigenvalues determined by Eq. (4.17) and the set n. In the back of one's mind in making this interpretation is the idea—sometimes enunciated as a principle—that any measurement of the energy must result in some eigenvalue of the energy. We must return to the quantum theory of measurement later (Section 9).

5. Spherical Harmonic Representation A very different and frequently employed representation of the same Hilbert space of Lebesgue square integrable functions on three-dimensional space—the variable being r, θ, and ϕ instead of x, y, and z—is that based on the eigenstates of the classical Hamiltonian of the Bohr-Sommerfeld model of the hydrogen atom. Thus, the Hamiltonian of the relative motion of the electron and proton in the H atom leads to the Schrödinger equation[9]

$$\begin{aligned} &[-(\hbar^2/2\mu)\nabla^2 - Ze^2/r]\,u(r,\theta,\phi) \\ &\quad = Eu(r,\theta,\phi). \end{aligned} \tag{5.1}$$

The variables separate, and solutions exist of the form

$$u(r, \theta, \phi) = R(r)\, Y(\theta, \phi). \qquad (5.2)$$

The factor $Y(\theta, \phi)$ may be any one of the set of spherical harmonic functions, normalized to unity under integration over a unit sphere:

$$Y_{lm}(\theta, \phi) = \left[\frac{2l+1}{4\pi}\;\frac{(l-m)!}{(l+m)!}\right]^{1/2} \cdot P_l^m(\cos\theta)\, e^{im\phi}. \qquad (5.3)$$

Here $P_l^m(\cos\theta)$ are the associated Legendre functions described in many texts on differential equations, l is any integer, and m is an integer between $+l$ and $-l$.

The factor $R(r)$ is some member of a set of functions defined in terms of the associated Laguerre polynomials; which member it is depends in part on the choice of which spherical harmonic is chosen—explicitly on the integer l. It also depends on another quantum number, n, indexing which energy eigenvalue is chosen. The solution of Eq. (5.1) exists only when the energy E has one of the eigenvalues

$$E_n = -Z^2 e^4 / 2\hbar^2 n^2, \qquad n = 1, 2, \ldots. \qquad (5.4)$$

The general solution of Eq. (5.1) is then

$$u(r, \theta, \phi) = \sum_{n,l,m} C_{nlm} R_{nl}(r) Y_{lm}(\theta, \phi)$$

$$n, l \text{ arbitrary integers}, \quad -l \leqslant m < l. \qquad (5.5)$$

The constants C_{nlm} are chosen to normalize $\int u^* u \, d\tau$ to unity over an infinite sphere.

The set of eigenvectors $R_{nl}Y_{lm} \equiv |nlm\rangle$ determine the spherical representation matrix of the Hermitian operator corresponding to any physical observable, being particularly useful when axial symmetry exists in the situation. For example, this is the case for the Schrödinger operators corresponding to orbital angular momentum, derived from the classical expressions

$$M_x = yp_z - zp_y \to -i\hbar(y\partial/\partial z - z\partial/\partial y),$$
$$= i\hbar\,[\sin\phi\,\partial/\partial\theta + \cot\theta\,\cos\phi\,\partial/\partial\phi],$$
$$M_y = -i\hbar\,[\cos\phi\,\partial/\partial\theta - \cot\theta\,\sin\phi\,\partial/\partial\phi],$$
$$M_z = -i\hbar\,\partial/\partial\phi, \qquad (5.6)$$

and

$$M^2 = M_x{}^2 + M_y{}^2 + M_z{}^2 \to$$
$$-\hbar^2[(1/\sin\theta)(\partial/\partial\theta)(\sin\theta\,\partial/\partial\theta)$$
$$+ (1/\sin^2\theta)\partial^2/\partial\phi^2].$$

The matrices as defined in Eq. (4.11) are given by the integrals

$$(M_j)_{nlm,n'm'l'} = \iiint \langle nlm|M_j|n'l'm'\rangle \cdot \sin\theta\, d\theta\, d\phi\, r\, dr. \qquad (5.7)$$

The radial factor integrates to $\delta(n, n')$, integration over θ yields $\delta(l, l')$ and the final integration over ϕ results in a matrix the number of whose elements depends on l. For any given l value, the number of eigenvectors, i.e., the number of rows or columns in the matrix is the number of values of m, namely $2l + 1$. This for $l = 1$ we find the matrices:

$$M_x = (\hbar/\sqrt{2})\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$

$$M_y = (i\hbar/\sqrt{2})\begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}$$

$$M_z = \hbar\begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}$$

$$M^2 = 2\hbar^2\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \qquad (5.8)$$

For $l = 2$ there are five rows or columns, etc. In general, for all values of l the matrices for M_z and M^2 are diagonal, meaning that the basis vectors are eigenvectors of the operators, the eigenvalues being displayed on the diagonal terms. The same basis vectors are not eigenvectors of either M_x or M_y, and the three operators M_x, M_y, and M_z do not commute with one another under the rules of matrix multiplication. Indeed, it is easy to verify the following:

$$M_xM_y - M_yM_x = [M_x, M_y] = i\hbar M_z,$$
$$[M_y, M_z] = i\hbar M_x, \quad \text{and} \quad [M_z, M_x] = i\hbar M_y. \qquad (5.9)$$

These commutation relations can also be derived independently of any matrix representation directly from the definitions of M_x, etc., namely $M_x = yp_z - zp_y$, etc., and the known commutation relations between P and Q, as in Eq. (2.7):

$$[x, p_x] = [y, p_y] = [z, p_z] = i\hbar. \qquad (5.10)$$

The existence of the Pauli spin, or intrinsic angular momentum can be incorporated into this formalism when it is noticed that the set of matrices typified by Eq. (5.8) for all integral values of l is not the only set that satisfies the commutation relations Eq. (5.9). A set of matrices having even numbers of rows or columns also satisfy Eq. (5.9), in particular, corresponding to $l = \frac{1}{2}$ we have

$$M_x = \tfrac{1}{2}\hbar \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad M_y = i\,\tfrac{1}{2}\hbar \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$
$$M_z = \tfrac{1}{2}\hbar \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad M^2 = \tfrac{3}{4}\hbar^2 \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \tag{5.11}$$

which are recognized at once as the Pauli spin matrices. When a system such as the electron in an H-atom possesses both orbital and intrinsic angular momentum a technical problem presents itself: how to add operators which receive matrix representations having different numbers of rows or columns. This leads to a fascinating and highly abstract field of mathematics usually known as the *theory of irreducible tensors*, which is far beyond the scope of this article, but which is an essential chapter in the application of quantum mechanics to all atomic problems. Some valuable references to the theory of angular momentum generally are given at the the end of this article.[10]

6. Dirac's Relativistic Wave Equation The classical relativistic Hamiltonian for a free particle is

$$H = \sqrt{c^2p^2 + m^2c^4} \tag{6.1}$$

where c is the velocity of light and m the mass of the particle, but when $\mathbf{p}$ is transcribed into the operator $-i\hbar\nabla$, there is trouble assigning a meaning to the square root. To avoid this one may take the square of Eq. (6.1) and then use the transcription of Eq. (1.8) to derive a relativistic invariant second-order differential equation known as the Klein-Gordon equation (1926):

$$\left(\nabla^2 - \frac{1}{c^2}\frac{\partial^2}{\partial t} - \frac{m^2c^2}{\hbar^2}\right)\Psi = 0. \tag{6.2}$$

However it was found that this equation is incapable of describing the behavior of a particle with spin, and so will be of no use in electron theory. Dirac (1928) discovered that the only way to achieve a linear differential equation—equivalent to the "square root" of Eq. (6.2)—in the form

$$i\hbar\,\partial\Psi/\partial t = H\Psi \tag{6.3}$$

is to write H as a 4×4 matrix having the form

$$H_{\mu\nu} = c\sum_k (\alpha_k)_{\mu\nu}p_k + \beta_{\mu\nu}mc^2, \tag{6.3}$$

where $k = 1, 2, 3, \mu, \nu = 1, 2, 3, 4$, and β, α_k are four 4×4 dimensionless constant matrices which have to satisfy several algebraic conditions in order to agree with Eq. (6.1), in the sense that matrix multiplication yields

$$H^2 = c^2p^2 + m^2c^4. \tag{6.4}$$

The conditions on the four matrices are stated as matrix products:

$$\begin{gathered} \alpha_j\alpha_k + \alpha_k\alpha_j = 2\delta_{jk} \\ \alpha_j\beta + \beta\alpha_j = 0 \\ \beta^2 = \mathrm{I}. \end{gathered} \tag{6.5}$$

A set of four matrices in which β is diagonal was found to be

$$\alpha_j = \begin{pmatrix} \mathbf{0} & \sigma_j \\ \sigma_j & \mathbf{0} \end{pmatrix}, \quad \beta = \begin{pmatrix} \mathrm{I}_2 & \mathbf{0} \\ \mathbf{0} & \mathrm{I}_2 \end{pmatrix} \tag{6.6}$$

where each element in the brackets is itself a 2×2 matrix:

$$\mathbf{0} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}, \quad \mathrm{I}_2 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

and $\frac{1}{2}i\hbar\sigma_j$ is the jth Pauli spin matrix of Eq. (5.11). To give Eq. (6.3) a meaning with this kind of Hamiltonian, it is clearly necessary to write Ψ as a column of four separate functions, and the equation becomes in effect four equations for four different wave functions. Taking the time factor $e^{-iEt/\hbar}$ to be the same on each function, and seeking four-particle solutions analogous to Eq. (1.11), one finds

$$\begin{gathered} \Psi_\mu(r, t) = C_\mu(E, k)\, e^{i\mathbf{k}\cdot\mathbf{r}}\, e^{-iEt/\hbar}, \\ \mu = 1, 2, 3, 4, \end{gathered} \tag{6.7}$$

where $\hbar k$ is the eigenvalue of $\mathbf{p}$, and C_μ are constants. Because of the "square root" nature of the equation, for each value of E there is another set of solutions with $-E$ for the energy—the negative energy states. This was eventually understood in terms of the existence of a positive electron and its interaction with electric fields.

There is another important "degeneracy" in the solutions. For each value of E, and correspondingly also for each negative energy state, there are two sets of four wave functions. This was quickly identified with the "spin degeneracy" postulated in the Pauli theory of the electron. When one applies the time-evolution law with the relativistic Hamiltonian (see Eq. (7.8) in the next section) the orbital angular momentum has to be augmented with spin angular momentum before one obtains a "constant of the motion." Thus Dirac's equation was the first theory of the electron that actually required the spin logically, rather than simply including it as an ad hoc hypothesis. The fundamental significance of Dirac's discoveries for the subsequent development of quantum mechanics can hardly be exaggerated, but to go further in that direction would take us beyond the scope of this article. The serious student is referred to Ref. 11.

7. Time-Dependent Wave Functions Up to this point we have been ignoring the time dependence of the Schrödinger wave function implied by Eq. (1.10), and included explicitly in Eq. (1.11) and Eq. (4.3). We shall now rewrite Eq. (4.3), in view of Eq. (4.6) and (4.10), in the form

$$|n, x, t\rangle = e^{-iE_nt/\hbar}|n, x\rangle, \qquad E_n = (n + \tfrac{1}{2})\hbar. \tag{7.1}$$

The general time-dependent wave function is

$$\Psi(x, t) = \sum_n C_n(t)|n, x\rangle$$

where

$$C_n(t) = C_n(0)e^{-iE_nt/\hbar}. \tag{7.2}$$

On the other hand, because $H|n,x\rangle = E_n|n,x\rangle$, we have

$$|n, x, t\rangle = e^{-iHt/\hbar}|n, x\rangle, \tag{7.3}$$

which is the fundamental dynamical law on what is traditionally known as "the Schrödinger picture." On this same picture, any observable A, defined as a time-independent mapping on $\mathcal{H}$, has matrix elements formed on the time-dependent Schrödinger eigenstates, using Eq. (7.3):

$$A_{mn}(t) = \langle m|e^{iHt/\hbar}Ae^{-iHt/\hbar}|n\rangle. \tag{7.4}$$

We may define a time-dependent operator

$$A(t) \equiv e^{iHt/\hbar}Ae^{-iHt/\hbar}, \tag{7.5}$$

called the Heisenberg operator, corresponding to the Schrödinger operator A. The matrix elements of $A(t)$ formed on the time-independent eigenstates $|n, x\rangle$ are the same as Eq. (7.4). The time derivative of $A(t)$ is clearly

$$\partial A(t)/\partial t = (i/\hbar)\,[H, A(t)], \tag{7.6}$$

and this equation is the fundamental dynamical law on the Heisenberg picture.

In both pictures, time evolution is seen to correspond to a unitary transformation in $\mathcal{H}$ with the Hamiltonian H acting as the generator. In the Schrödinger picture it is the wave function or the state of the system that is evolving in time, while in the Heisenberg picture it is the observables that are evolving in time—two alternative pictures of the same essential situation.

Note that if A commutes with H, the product,

$$e^{iHt/\hbar}Ae^{-iHt/\hbar} = A, \tag{7.7}$$

so the Schrödinger matrix elements of Eq. (7.4) are time independent even when formed on the time dependent wave functions, while the time-dependent Heisenberg operator of Eq. (7.5) is identical with the Schrödinger operator.

There is one other important implication of these considerations. If we take the average (expectation) value of any observable A when the system is in a state represented by some wave function Ψ, then, using Eq. (2.1) we have from Eq. (7.5)

$$\langle \partial A/\partial t\rangle = (i/\hbar)\,[\langle\Psi|HA|\Psi\rangle - \langle\Psi|AH|\Psi\rangle]. \tag{7.8}$$

If Ψ happens to be an eigenfunction of H,

$$\Psi = \Psi_E, \qquad H\Psi_E = E\Psi_E, \tag{7.9}$$

then

$$\begin{aligned}\langle \partial A/\partial t\rangle &= (i/\hbar)\,[E\langle\Psi_E|A|\Psi_E\rangle \\ &\quad - \langle\Psi_E|A|\Psi_E\rangle E]. \\ &= 0.\end{aligned} \tag{7.10}$$

We conclude that any eigenstate of the Hamiltonian is an equilibrium state of the system, such that the average time derivative of any observable A, whether it commutes with H or not, averages zero when measured in that state.

For lack of space, we refrain from discussing either perturbation theory or collision theory,[8, 12] both of which have very wide uses in practical applications, and proceed instead with subjects that have more impact on the theoretical concepts of quantum theory.

8. Many-Body Problems In dealing with a single particle system we have seen in Section 3, Eqs. (3.4) and (3.6), that the wave function can be expressed as a linear "superposition" of eigenstates of any Hermitian operator—in particular the energy eigenstates of a harmonic oscillator, Eqs. (4.19) and (4.26)—when the square moduli of the superposition coefficients are interpreted in some sense as the "probabilities" that measurement of the observable results in the corresponding eigenvalue. In dealing with a more complex system—two or more particles—we have already stated (Section 2) that the sum of the individual wave functions does not result in a suitable wave function of the pair, but that a product is required, and that this fact forces a further increase in the level of abstraction needed to interpret the symbolism physically.

Consider two "classical" particles, i.e., particles that are the "same" in the normal sense, like two billiard balls, but may be distinguished from one another by otherwise neutral indicators, like "color" or some simple numbered label. The wave function for such a pair is a function of at least the six center-of-mass coordinates of the two particles, and the simplest such function would be the product

$$\Psi(x_A, x_B) = f(x_A)g(x_B) \qquad (8.1)$$

where $f(x_A)$ is the wave function for particle A alone, and $g(x_B)$ that for particle B alone, and x_A, x_B are the center-of-mass positions of the two particles. Plotted on a hyperspace spanned by x_A and x_B, this function $\Psi(x_A, x_B)$ is different from the function

$$\tilde{\Psi}(x_A, x_B) = g(x_A)f(x_B) \qquad (8.2)$$

formed from Ψ by interchanging the two particles.

In Section 1, in developing Eq. (1.2) for blackbody radiation, we noted that photons were treated as indistinguishable particles. It is not possible to attach distinguishing labels to them as individuals, and it is reasonable to make the same assumption regarding all the fundamental particles—in particular electrons, protons, etc. For the compelling observational evidence for this assumption see BOSE-EINSTEIN STATISTICS AND BOSONS and FERMI-DIRAC STATISTICS AND FERMIONS in this Encyclopedia. To embody this assumption in the appropriate wave function one must form a linear superposition of products such that no exchange among the particles can make any difference that could be detected experimentally. For a pair, the only possible such wave functions are

$$\Psi_\pm(x_A, x_B) = (1/\sqrt{2})\,[f(x_A)g(x_B) \pm g(x_A)f(x_B)]. \qquad (8.3)$$

With the + sign the function is symmetrical; with the - it is antisymmetrical, but its square modulus—its only experimentally significant feature at this stage of the theory—is unchanged by the exchange of particles.

To generalize this to N particles, we may replace f and g by the set of eigenstates written $|m, x_j\rangle$ to show the mth energy eigenstate and the jth particle, $j = 1, 2, \ldots, N$. Then the normalized symmetrical product is a function of the set of coordinates $\{x\}$ and the set of eigenvalues $\{m\}$:

$$\Psi_S(\{m\}, \{x\}) = (1/\sqrt{N!}) \sum_P \prod_{j=1}^{N} |m_j, x_{Pj}\rangle \qquad (8.4)$$

where the state $|m_j, x_{Pj}\rangle$ assigns the quantum number m_j to the particle $j' = Pj$ obtained by a permutation P among the N particles. The product is over all N particles, the sum is over all $N!$ permutations among them. Clearly this wave function is unchanged by any further permutation among the particles; all the permutations are already included with equal weight.

Similarly for the normalized antisymmetrical product we write

$$\Psi_A(\{m\}, \{x\}) = (1/\sqrt{N!}) \sum_P (-1)^P \cdot \prod_{j=1}^{N} |m_j, x_{Pj}\rangle, \qquad (8.5)$$

where the sum alternates in sign, positive for even permutations, negative for odd permutations—it is in fact an $N \times N$ determinant. The interchange of any two particles means interchanging two rows in the determinant, which simply changes its sign without changing the modulus of the wave function. The most important feature of this is that if any two particles are assigned the same eigenstate, their two rows are identical and the determinant vanishes. In this case no more than one particle can be assigned to any one-particle state. This is the feature of the antisymmetrical wave function that leads to the Fermi-Dirac statistics. The symmetrical wave function leads to the Bose-Einstein statistics where there is no upper limit to the population of any one-particle state—except of course N.

If the number of m-values available in the one-particle energy spectrum is greater than N, some of the m-values cannot be assigned any occupants, but every particle must be assigned to some m-value. In the antisymmetrical case these occupation numbers are either 1 or 0. In the symmetrical case the only restriction is that their sum be N. Each assignment of all N particles to the spectrum characterized by the set of occupation numbers determines the overall symmetrical or antisymmetrical wave function. Writing n_m for the number of particles assigned to the mth eigenvalue, the occupation numbers n_m determine the state, and in place of Eq. (8.4) or (8.5) we could equally well write

$$\Psi(S, A) = |n_1, n_2, \ldots, n_m, \ldots\rangle_{(S, A)} \qquad (8.7)$$

with the understanding that the one-particle Hamiltonian is used as the initial basis. These "vectors," identified by the set of n-values, are clearly energy eigenvectors for the whole system, and can be used as the basis spanning the Hilbert space having the "dimensionality" equal to the total number of such sets of occupational numbers. If the one-particle spectrum has a countable infinity of states, aleph-zero in number, the number of dimensions in this Hilbert space is aleph-zero to the power N. This huge multitude does not alter the theorem that any member of the space can be expressed as a linear superposition of the basis vectors written out in Eq. (8.7). This means that the general state of an N-particle system can be expressed in the form

$$\Psi(\{x\}, t) = \sum_{\{n\}} C(\{n\}, t)|n_1, n_2, \ldots, n_m, \ldots\rangle \qquad (8.8)$$

where $C(\{n\}, t)$ is the time-dependent amplitude of the probability that the system be in the state specified by the set $\{n\}$ and have therefore, the energy

$$E = E\{n\} = \sum_m n_m (m + \tfrac{1}{2})\hbar w, \qquad (8.9)$$

assuming here that the Hamiltonian used for the initial one-particle basis was that of the simple harmonic oscillator as in Section 4. In the antisymmetrical case $n_m = 0$ or 1. In the symmetrical case the only restriction on n_m is that the sum

$$\sum_m n_m = N. \tag{8.10}$$

The scheme here outlined is usually known as the "N-representation," and was historically derived in the process known as "second quantization," which gets its name from the following: First quantization yields Schrödinger's wave equation; then, regarding Schrödinger's function Ψ as a field, the classical Hamiltonian theory of fields is quantized and applied to Ψ, which then has to be taken as an operator whose domain is the Hilbert space spanned by the basis set we have written in Eq. (8.7). Having already produced this Hilbert space, which we may call $\mathcal{H}_N$, from the obvious N-particle wave function based on the "first" quantization of the single particle, we do not need to go through that painfully obscure reasoning. The second quantization operators can now be defined directly from the form of the basis vectors, Eq. (8.7).

The "destruction," or "lowering" operators a_j are defined by*

$$\begin{aligned} a_j |n_1, n_2, \ldots, n_j, \ldots, n_m, \ldots\rangle \\ = \sqrt{n_j}\, |n_1, n_2, \ldots, n_j - 1, \ldots, n_m, \ldots\rangle, \end{aligned} \tag{8.11}$$

and the "creation" or "raising" operator $a_j\dagger$ are defined by*

$$\begin{aligned} a_j\dagger\, |n_1, n_2, \ldots, n_j, \ldots, n_m, \ldots\rangle \\ = \sqrt{n_j + 1}\, |n_1, n_2, \ldots, n_j + 1, \ldots, n_m, \ldots\rangle. \end{aligned} \tag{8.12}$$

In each case $j = 1, 2, \ldots$ over the whole spectrum. There is a creation and a destruction operator associated with each one-particle state. The ordered product of operations, first a_j then $a_j\dagger$, results in

$$\begin{aligned} a_j\dagger a_j\, |n_1, n_2, \ldots, n_j, \ldots\rangle \\ = n_j\, |n_1, n_2, \ldots, n_j, \ldots\rangle. \end{aligned} \tag{8.13}$$

The basis states Eq. (8.7) are eigenstates of this operator with eigenvalue equal to the occupation number. We may write

$$N_j = a_j\dagger a_j \tag{8.14}$$

for the number operator for the jth state.

This number operator is Hermitian, and so is a good observable. The creation and destruction operators are not Hermitian, but the following linear combinations of them are:

$$\kappa_j \equiv a_j + a_j\dagger, \qquad \pi_j \equiv i(a_j\dagger - a_j), \tag{8.15}$$

and could be identified with observables. To check for Hermiticity one can write down the matrix elements by the rule of Eq. (3.9), omitting the unaffected occupation numbers, and dropping the then redundant subscript, thus:

$$\begin{aligned} \langle n'|N|n\rangle &= n\delta(n', n), \quad \text{purely diagonal,} \\ \langle n'|(a + a\dagger)|n\rangle &= \langle n|(a + a\dagger)|n'\rangle \\ &= \sqrt{n}\,\delta(n', n - 1) \\ &\quad + \sqrt{n + 1}\,\delta(n', n + 1) \\ i\,|\langle n'|(a\dagger - a)|n\rangle &= -i\langle n|(a\dagger - a)|n'\rangle \\ &= -i[\sqrt{n}\,\delta(n', n - 1) \\ &\quad - \sqrt{n + 1}\,\delta(n', n + 1)]. \end{aligned} \tag{8.16}$$

We must emphasize that this formalism is the moment purely mathematical. One is not obliged to think of the particles as harmonic oscillators. Any wave function in the space $\mathcal{H}_N$ can be expressed in the form Eq. (8.8), and we could have chosen spherical representation for the basic one particle states just as effectively. Even box normalized plane wave states are also available, provided we are satisfied with functions existing only inside the "box."

Quantum field theory, or for that matter, many-body problems in solid state physics, depends on a systematic application of this formalism to a wide variety of different Hamiltonians. The serious student should refer to the texts listed in Ref. 13.

9. The Quantum State In classical mechanics the state of a system is defined by the generalized coordinates of the system in its phase space—e.g., the position and momentum of every particle in the system. If this is known, the state is completely specified and both the future and the past of the path of the system in its phase space is determined. Ever since the earliest form of quantum theory it has been recognized that the quantum state must be less specific, and it is still traditional to identify the wave function with the quantum state, its time evolution being determined by the Hamiltonian operator, Eq. (1.10), and by Eq. (6.3). The statistical interpretation of the wave function signifies that the present quantum state can determine at most the probabilities of future measurement results, no matter how precisely one determines the present wave function.

This tradition has one serious flaw that is generally overlooked—there has so far in the theory been no clear prescription for observationally determining the wave function representing the quantum state. Almost all problems posed traditionally have been of the form: given Ψ, find the behavior of the system. In this section we address the reverse problem: given

*These definitions are appropriate only for the symmetrical, Bose-Einstein case.

some system, what, if any, measurements can we make to determine the quantum state it happens to find itself in? The question is not nearly as trivial as it may sound.

Some tentative work in this direction was done during the very early development of the theory, but the only attempt to include the idea in the structure of the theory was Von Neumann's[14] "measurement of the first kind."* This was a proposition that a measurement of any observable A that results in an eigenvalue a of A leaves the system in the eigenstate of A following the measurement. This was, from a mathematical point of view, a very neat axiom, and undoubtedly because Von Neumann's other contributions to the theory were tremendously important, it still carries weight in the literature. But from a physicist's point of view it is utter nonsense. The typical measurement performed on any fundamental particle, e.g., the energy of a photon, or the momentum of an electron, results either in the complete destruction of the particle or at least a violent disturbance in its state: the best any real measurement can do is to ascertain the properties of the particle just before the measurement; what happens afterwards is practically impossible to predict. This is known as a "measurement of the second kind."

To make sense of the "first kind," the axiom must be rephrased as follows: It is postulated that there exist procedures that can leave a system in an eigenstate of any observable of interest—a strategically designed preparation procedure which will produce the desired quantum state. This is not a measurement. To give the postulate a meaning, one must still make measurements on the emerging system, and repeat the process a large enough number of times with the identical preparation procedure to convince ourselves that the scheme "works." In simpler words we must set up a mechanism for determining the quantum state; otherwise any proposition concerning such states is empty.

As an example, consider a nonideal gas of N particles weakly interacting, given some total energy at time $t = 0$, and then allowed to remain undisturbed and isolated for a sufficient time to reach what physicists call "thermodynamic equilibrium." It is a familiar experience in the laboratory, and the thermodynamic state is well known. How shall we describe this state quantum mechanically? Clearly it must be an equilibrium quantum state, and therefore an eigenstate of the system's Hamiltonian. We can express these eigenstates in the form of Eq. (8.8). In a large system there is a great deal of "accidental degeneracy," numerous sets $\{n\}$ which correspond to the same total energy, Eq. (8.9). The "vectors," Eq. (8.8), all corresponding to the given total energy may be written $\Psi_s(C_s\{n\}, E)$, and for each value of s, the degeneracy index, there exists a set of coefficients $C_s\{n\}$, a different set for each index. Among these different wave functions there seems to be no way, on the basis of thermodynamic information, to decide which is the "true" state of the gas. Traditionally, this problem has been resolved by assigning a "reasonable" (on the basis of information theory[15]) probability to every member of the set of possible states, and combining them to form what has been termed a "mixed state."

The distinction between the mixed state and the superposition state where the coefficients are probability *amplitudes* was emphasized by writing it as a diagonal matrix

$$\Psi_{\text{mixed}} = \sum_s \Psi_s(C_s\{n\}, E)\rangle\, W_s \langle \Psi_s{}^*(C_s\{n\}, E) \tag{9.1}$$

which has rows and columns equal in number to the "degeneracy" number S:

$$s = 1, 2, 3, \ldots, S; \qquad W_s = \text{real probability.}$$

To accommodate this generalization, some of the basic rules of quantum theory have to be modified. In particular Eq. (2.1) must be replaced as follows: The expectation value of an operator A on the state Ψ (mixed) is

$$\langle A \rangle = \text{Trace}(\Psi_{\text{mixed}} A). \tag{9.2}$$

The Trace operation involves the following sum:

$$\langle A \rangle = \sum_{s'} \sum_{s} \langle \Psi_{s'} | \Psi_s \rangle\, W_s \langle \Psi_s | A | \Psi_{s'} \rangle \tag{9.3}$$

where we have omitted the detailed arguments of the functions $\Psi_{s'}$ and Ψ_s. Then because the functions Ψ_s can in principle be made an orthonormal set this reduces to

$$\langle A \rangle = \sum_s W_s \langle \Psi_s | A | \Psi_s \rangle \tag{9.4}$$

which is the weighted average of the expectation values of A on the individual members of the degenerate set of eigenvectors of H, as given by the traditional formula (2.1) on the "pure states" Ψ_s.

The procedure just outlined has been widely adopted and has been remarkably useful in applying quantum mechanics to practical problems. For advocates of the application of information theory to explain the laws of thermodynamics the situation is completely satisfactory. However, other physicists do not accept the implication that the quantum state of any system—in particular the "mixed" state—depends essentially on a "gentleman's agreement" to avoid seeking technological advances which could provide more precise information than is currently available regarding the "likelihood"

*The names "measurement of the first kind" and "measurement of the second kind" were coined by W. Pauli.

of the various members of the degenerate set of eigenstates in the state of the system.

The more "realistic" school of thought has adopted a straightforward postulate which denies that the wave function by itself is an adequate quantum state except under the most unusual conditions. The new postulate reads:[16]

I. To every reproducible empirical scheme for the preparation of the physical system, there corresponds an Hermitian operator ρ with unit Trace and only nonnegative eigenvalues, such that, given any observable A on the domain $\mathcal{H}$ of the operator, the arithmetic mean value of a statistical collective of A-measurements obtained from an ensemble of systems all prepared identically in the manner characterized by ρ is equal to

$$\langle A \rangle = \mathrm{Trace}(\rho A). \tag{9.5}$$

The "mixed state" of Eq. (9.1) is an example of ρ, which is already in diagonal form and displays its nonzero positive eigenvalues W_s, with unit Trace equal to

$$\sum_s W_s = 1. \tag{9.6}$$

Any "pure" state Ψ_m of the Schrödinger theory is also equivalent to the density matrix $|\Psi_m\rangle\langle\Psi_m|$—it is a matrix with only one eigenvalue (equal to unity). The rule (9.5) in this case states

$$\begin{aligned}\langle A \rangle &= \mathrm{Trace}\,|\Psi_m\rangle\langle\Psi_m|A \\ &= \sum_n \langle\Psi_n|\Psi_m\rangle\langle\Psi_m|A|\Psi_n\rangle\end{aligned} \tag{9.7}$$

where the set $\{\Psi_n\}$ is an orthonormal set including Ψ_m. Thus

$$\langle A \rangle = \langle\Psi_m|A|\Psi_m\rangle \tag{9.8}$$

which is identical with Eq. (2.1).

It must be emphasized that the quantum state operator ρ is a feature not of any single system, but of the procedures employed to produce the ensemble of systems. It does not depend on the amount of information available to the observer, but can in principle be determined by a sufficient number of measurements of observables in the ensemble. We discuss this in detail in the next section.

The more "realistic" statistical interpretation of the quantum state based on postulate I has important implications for scientific epistemology. The proposition itself is simply an extension of the purely classical statement that the accepted result of a series of measurements has to be obtained as an average over an ensemble of results obtained from a system prepared in the same way before each measurement. There are two differences between the quantum and classical theories: (a) The quantum system is usually so small that measurement itself disturbs it, and the preparation must be fully repeated before each measurement; whereas the classical system is usually so bulky that the repreparation can be quite perfunctory. (b) In classical physics one accepts the hypothesis that every system "possesses" observables with unique and precise numerical values that measurements are designed to discover; the classical laws of motion refer only to these ideal values; whereas in quantum theory no such hypothesis is entertained, and the quantum laws refer only to the statistics of the measurement results.

It was essentially this difference that caused Einstein[5] to proclaim that quantum theory was an incomplete theory; like most classical physicists Einstein hoped for a deeper meaning behind observed data which quantum theory explicitly denies being able to produce.

10. The Quorum Concept To postulate I of Section 9 we now append another postulate:[11]

II. There exists a "quorum" of observables, Q_m, $m = 1, 2, 3, \ldots$, such that, from the collective of mean values of the Q_m-measurements

$$\langle Q_m \rangle = \mathrm{Trace}\,\rho Q_m \tag{10.1}$$

it is possible to calculate a matrix representation of ρ which is thereby uniquely determined.

The simplest example of this is to be found in the "spin $\frac{1}{2}$" system. This is a traditionally standard example of a nonclassical system, and is essentially a "disembodied electron," i.e., one ignores all other physical parameters such as position, orbital momentum, and electric charge, and treats the Hamiltonian as a two-eigenvalue operator describing the interaction of the spin with a uniform magnetic field in the z-direction. The Hilbert space for this system is a two-dimensional continuum, and the "wave functions" are two-element "spinors"—compare the remarks in Section 6 about the Dirac electron. The familiar observables are the Pauli spin matrices, Eq. (5.11). The Hamiltonian is the diagonal

$$H = E\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}$$

where E is the product of spin and magnetic field.

The matrix representation of the operator ρ has to be of the form

$$\rho = \begin{pmatrix}\rho_{11} & \rho_{11}\\ \rho_{12} & 1-\rho_{11}\end{pmatrix}, \qquad \rho_{12} = \rho_{21}{}^*, \;\; \rho_{11} \leqslant 1. \tag{10.3}$$

Clearly only three real numbers are needed to determine ρ. After some elementary algebra we find,[18]

$$\begin{aligned}\rho_{11} &= \tfrac{1}{2} + \langle\sigma_z\rangle, & \rho_{22} &= \tfrac{1}{2} - \langle\sigma_z\rangle\\ \rho_{12} &= \langle\sigma_x\rangle - i\langle\sigma_y\rangle, & \rho_{21} &= \langle\sigma_x\rangle + i\langle\sigma_y\rangle\end{aligned} \tag{10.4}$$

where $\langle\sigma_x\rangle$, $\langle\sigma_y\rangle$ and $\langle\sigma_z\rangle$ are the mean values of the spin component measurements. There is no question here about "simultaneous" measurements of noncommuting observables. Each individual measurement is preceded by a new (identical) preparation, the process being repeated on each observable often enough to ensure statistical validity of the results. The three spin-component observables therefore constitute a quorum. From the measurements one can decide exactly what the density matrix is corresponding to any prescribed preparation procedure. The algebra shows, in fact, that

$$\langle\sigma_x\rangle^2 + \langle\sigma_y\rangle^2 + \langle\sigma_z\rangle^2 \leqslant \tfrac{1}{4}. \qquad (10.5)$$

Only if the equality sign agrees with the data is the density matrix "pure;" otherwise it is "mixed." There is nothing in this "mixed" case that asks for a confession of ignorance on the part of the observer.

Another example that has been worked out in detail—this one a "classical problem"—is the motion of a free particle in one dimension, where the wave functions are box-normalized plane waves. The density matrix must have a countably infinite number of rows or columns, and a countably infinite sequence of time derivatives d^nQ^m/dt^n to all orders n of powers m of the position operator form a quorum that could in principle determine the density matrix.[19]

Other examples have been worked out in detail, but no general proof of postulate II has been found. However, while it is obvious that the practical determination of the quantum state ρ of a complicated system may be even more difficult than in classical mechanics, the theoretical existence of an unambiguous result is at least plausible.

11. Quantum Dynamics Having taken the quantum state to be a Hermitian statistical operator ρ in $\mathcal{H}$, we are obliged to regard it as in some sense an observable, although it is not to be assumed that its time evolution be subject to the same laws as are conventional physical observables. To settle this question we recall first that from Eq. (7.3) we have the time evolution of the "state vector"

$$\Psi(t) = e^{-iHt/\hbar}\,\psi(0), \qquad (11.1)$$

and that the diagonal form of ρ is essentially the same as Eq. (9.1):

$$\rho = \sum_s \Psi_s W_s \Psi_s{}^* \qquad (11.2)$$

which now implies

$$\rho(t) = e^{-iHt/\hbar}\rho(0)e^{iHt/\hbar}, \qquad (11.3)$$

and from this we derive

$$\partial\rho/\partial t = -(i/\hbar)\,[H, \rho(t)]. \qquad (11.4)$$

This is adopted as the dynamical law of evolution on the Schrödinger picture. It has the opposite sign compared with Eq. (7.6), which is the dynamical law on the Heisenberg picture.

The time dependence of an observable A on the Heisenberg picture can actually be derived from Eq. (11.4). Applying Eq. (11.4) to Eq. (9.5) we have

$$\begin{aligned}\partial\langle A\rangle/\partial t &= \text{Trace}\,(A\,\partial\rho/\partial t)\\ &= -(i/\hbar)\,\text{Trace}\,(A\,[H, \rho(t)]),\end{aligned} \qquad (11.5)$$

and because the Trace of a product is unchanged by cyclic permutation among the factors this becomes

$$\partial\langle A\rangle/\partial t = (i/\hbar)\,\text{Trace}\,(\rho(t)\,[H, A]), \qquad (11.6)$$

which is not inconsistent with Eq. (7.6) of the Heisenberg picture if we accept the equivalence of $\partial\langle A\rangle/\partial t$ with $\langle\partial A/\partial t\rangle$.

From Eq. (11.3) it is clear that the dynamical evolution of ρ is equivalent to a unitary transformation generated by H and parametrized by the time t. The changes created by a unitary transformation are very limited. First, consider equilibrium states under which no observable measurement results can change with time. Evidently all this would require is that $\partial\rho/\partial t$ be zero, which in turn requires from Eq. (11.4) that ρ commutes with the Hamiltonian at any one time—when it would continue to commute for all time. Therefore the equilibrium state ρ may be taken as some function of the Hamiltonian, and for compelling reasons—chiefly by comparison with well established classical thermodynamics—the equilibrium ρ is assumed to be

$$\rho_{\text{eq}} = e^{-\beta H}/\text{Trace}\,e^{-\beta H}, \quad \beta = 1/kT. \qquad (11.7)$$

Using this equilibrium ρ in Eq. (9.5) we have the equilibrium "value" of the observable A:

$$\langle A\rangle_{\text{eq}} = \text{Trace}\,Ae^{-\beta H}/Z \qquad (11.8)$$

where $Z = \text{Trace}\,e^{-\beta H}$ is the "partition function." If Eq. (11.7) is used for ρ in Eq. (11.5) we see that

$$\partial\langle A\rangle_{\text{eq}}/\partial t = 0 \quad \text{for all } A. \qquad (11.9)$$

If on the other hand ρ does not commute with H we shall have a nonequilibrium situation; we would then expect physically that the dynamical laws would propel the system toward equilibrium, but this result does not emerge from the theory. According to traditionally accepted axioms, the time evolution of ρ would still be governed by Eq. (11.3) whether ρ is an equilibrium state or not, and we can prove that this unitary transformation will not produce the desired approach towards equilibrium. The proof is outlined below.

The equlibrium state Eq. (11.7) is derived by maximizing the quantity

$$S = -k \text{ Trace } (\rho \ln \rho). \qquad (11.10)$$

For any state differing from ρ_{eq} the quantity S is less than the maximum. (For this reason S is identified with the thermodynamic entropy.) But Trace ($\rho \ln \rho$) is invariant under any unitary transformation of ρ, so the dynamical law cannot change the entropy of the system, whatever its initial state. Quantum mechanics is no more successful than classical mechanics in "explaining the second law of thermodynamics."

Over the past twenty years a number of mathematical physicists have made sporadic attempts to generalize quantum dynamics in some way that would escape this dilemma.[20] Ths most recent attempts have made use of the theorem that the set of all Hermitian operators on a Hilbert space $\mathcal{H}$ themselves form a super Hilbert space, $\mathcal{H}_S$. The statistical operators ρ form a special subset of the elements of $\mathcal{H}_S$, and a "super operator" is sought, acting on the elements of $\mathcal{H}_S$, parametrized by t, which would carry $\rho(0)$ to $\rho(t)$ in a more general way than that given by the standard unitary transformation. There are so many possibilities here that it becomes a matter of taste what particular hypothesis to espouse.

The majority of specialists[21] in this field have been convinced that the unitary transformation is correct, and they have sought alternative ways of escape from the dilemma. The most recent consensus among these workers seems to be to blame the second law of thermodynamics on the long-range interactions of any apparently isolated system with the rest of the universe: gravitational fields, the pervasive background of electromagnetic radiation, beams of neutrinos, and so on. The mathematical decoration of these ideas runs something like this: Let $\mathcal{H}_{SL}$ be the super Hilbert space accommodating all the observables in the lab system, supposed isolated. The unitary evolution law then causes the state "point" ρ in $\mathcal{H}_{SL}$ to wander all over the place but never to cross its own path. If two paths start from two different points they can never meet, so the approach to equilibrium is forbidden. But if we admit the existence of long-range interactions, no matter how weak, we must enlarge the super Hilbert space to accommodate more observables. Call the enlarged space $\mathcal{H}_{SO} \supset \mathcal{H}_{SL}$. Then the true unitary evolution in $\mathcal{H}_{SO}$ will again be a path which cannot intersect itself in $\mathcal{H}_{SO}$, but the projection of the path onto the lab space $\mathcal{H}_{SL}$ could intersect itself, and so a state of equilibrium be approached from different starting points. Also the existence of the difference space $\mathcal{H}_{SO} - \mathcal{H}_{SL}$ provides an escape for the entropy balance—what is gained in the lab is taken from the rest of the universe. Probably the most fanciful of these speculations is the hypothesis that there is an entropy path connecting the universe with a mirror image anti-matter universe, and when entropy increases in the universe, negative entropy increases in the anti-universe, so that the overall unitary evolution causes the second law to hold both in the universe and in the anti-universe.

QUARKS

Introduction It seems that protons and neutrons (in fact, the various hadrons) are not the fundamental constituents of nuclear matter. These particles, themselves, have a detailed, and possibly complicated, structure. Several theoretical physicists have suggested that they may be composed of various combinations of a few much more "fundamental" objects. These objects have been called "quarks" by Gell-Mann (1964); "aces" by Zweig (1964). In both these schemes the new "fundamental" particles have electric charges less than the charge on the electron. In other schemes, developed later, the charges are normal.

Chemical experiments in the late eighteenth and early nineteenth centuries led Dalton to revive the atomic hypothesis. Atoms, at first, were thought of as small impenetrable spheres. By the end of the nineteenth century it had become obvious that the atoms themselves had a detailed structure. Research, particularly on radioactivity, showed that they consist of a central, small ($\sim 10^{-12}$ cm diameter), massive, positively charged nucleus surrounded by a light, negative, and comparatively large ($\sim 10^{-8}$ cm diameter) electron cloud. The structure of the nucleus itself then came under investigation. By 1932 it was known that nuclei are made of comparatively small numbers of neutrons and protons. A new force was discovered (in addition to the electromagnetic and gravitational forces) that held the positive protons and electrically uncharged neutrons together in the nucleus. This nuclear force was very strong but of limited range. Its "quantum," the particle analogous to the photon in the electromagnetic field, was of nonzero rest mass. This particle, now called the π-meson, or pion, was predicted by Yukawa in 1936 and discovered in *Cosmic Radiation* by Lattes, Occhialini, and Powell in 1947. For a short time in that year it seemed that physicists had achieved a clear, simple, and correct theory of the fundamental constitution of matter. However, later in the same year two new and unpredicted particles were reported, again in *Cosmic Radiation*, by Rochester and Butler. The first of these was another meson, somewhat like the pion but more massive. The second was probably a hyperon, i.e., a strongly interacting particle heavier than the neutron. Since then many more examples of both classes have been found.

To describe these particles one gives the values of various parameters, or quantum numbers. Some of these are familiar. For instance, the particles have different masses, and some relationships between these masses are now quite well understood. They have various electric charges which are integral multiples of the electronic charge. They possess intrinsic angular momentum or spin (sometimes this is zero). They have an analogous property called isotopic spin (or isospin). The mesons are distinguished from particles like the proton, neutron, and various hyperons (which are collectively called baryons) by a quantity, baryon number, which is an extension of the old atomic weight. The parity of the wave function describing the particle is an important property. There is also a quantum number called "strangeness." This has zero value for the "familiar" particles such as the proton, neutron, and pion, ±1 for the early strange particles discovered by Rochester and Butler, and as high as ±3 for some fairly recently discovered particles.

There are about one hundred of these "fundamental" particles now known. They interact with each other via various fields. Two of these have been known for some time, the gravitational and electromagnetic fields. Two others, the weak nuclear field and the strong nuclear field, were discovered in the 1930s. It seems likely from the results of experiments in high-energy cosmic radiation that there is at least one more, the superstrong field.

The large number of these particles has made physicists suspect that they are not "fundamental" but must themselves have structure, just as in the nineteenth century the large number of different types of atoms discovered suggested that atoms had structure. Also, many of the properties of these particles point to an internal structure. For instance, the neutron has a total electric charge which is indistinguishable from zero down to very fine limits, yet the neutron has a sizeable magnetic moment.

The Quark Hypothesis In 1964 M. Gell-Mann and G. Zweig independently pointed out that all the known hadrons (i.e., particles that interact via the strong nuclear force) could be constructed out of simple combinations of three particles (and their three antiparticles). These hypothetical particles had to have slightly peculiar properties (the most peculiar being a fractional electric charge). Gell-Mann called them quarks (referring to a sentence in James

TABLE 1. SOME OF THE SUGGESTED CHARACTERISTICS OF THE THREE QUARKS. M_p IS NOT DEFINED BY THE THEORY OTHER THAN THAT IT SHOULD BE CONSIDERABLE; THE UNITS OF MASS ARE MeV/c^2.

Particle	Charge	Spin	Baryon No.	Strangeness	Mass	Isospin	Iz
u	$\frac{2}{3}e$	$\frac{1}{2}$	$\frac{1}{3}$	0	M_u	$\frac{1}{2}$	$-\frac{1}{2}$
d	$-\frac{1}{3}e$	$\frac{1}{2}$	$\frac{1}{3}$	0	$\sim M_u$	$\frac{1}{2}$	$\frac{1}{2}$
s	$-\frac{1}{3}e$	$\frac{1}{2}$	$\frac{1}{3}$	-1	$M_u + 146$	0	0

Joyce's work *Finnegan's Wake*, "Three quarks for Muster Mark"). The three quarks are designated u, d, and s because they somewhat resemble the proton, neutron, and Λ° hyperon. Some of their quantum numbers are given in Table 1.

The theory supposes that three quarks bind together to form a baryon, while a quark and an antiquark bind together to form a meson. If one supposes that the binding is such that the internal motion of the quarks is nonrelativistic (which requires that the quarks be massive and sit in a broad potential well), then many quite detailed properties of the hadrons can be explained.

Predictions and Verification of the Nonrelativistic Quark Theory (1) *The Predicted and Observed Particles*. The particles which can interact via the strong nuclear force are called hadrons. Hadrons can be divided into two main classes, the mesons (with baryon number zero) and the baryons (with nonzero baryon number). Within each of the classes there are small subclasses. The subclass of baryons which has been known longest consists of those particles with spin $\frac{1}{2}$ and even parity. The members of this class are the proton, the neutron, the Λ° hyperon, the three Σ hyperons and the two Ξ hyperons. There are no other baryons with spin $\frac{1}{2}$ and even parity (or, to use the usual notation, $J^P = \frac{1}{2}^+$). The next "family" of baryons has ten members, each with $J^P = \frac{3}{2}^+$. The mesons can be grouped into similar families. One of the first successes of the quark model was to explain just why there should be eight baryons with $J^P = \frac{1}{2}^+$, 10 with $\frac{3}{2}^+$, and so on and why the various members of these families have the particular quantum numbers observed. The explanation is most easily understood if we start with the $\frac{3}{2}^+$ baryon family.

On the left-hand side of Fig. 1 the members of the family are arranged on a plot on which the ordinate is the value of their strangeness and the abscissa that of their electric charge. Most of the particles have rather short lifetimes but otherwise are not very different from "ordinary" baryons like the neutron. On the right-hand side of the diagram we see the way in which quark theory suggests that the particles arise. For instance, the Ω^- hyperon is supposed to consist of three s quarks. The spin of all these baryons is $\frac{3}{2}$, so all three quark spins must be aligned. One then has ten, and only ten, possible combinations of three quarks and all these combinations exist. Moreover the quark model gives just the right quantum numbers for all particles. If we assume, in addition, that s is 146 MeV/c^2 more massive than u and d (which we take to be about equally massive) then we have at once an explanation of the mass differences. The "apex" particle, the Ω^-, had its existence and detailed properties predicted before its discovery.

The $J^P = \frac{1}{2}^+$ baryon family is similarly treated in Fig. 2. In this case, to get spin $\frac{1}{2}$ we must always have one quark with its spin antiparallel. This explains the absence of "corner" particles like sss and also the occurrence of two different particles in the center position. For, if we consider both groups, we must obviously have

a particle with spin $\frac{3}{2}$ and spin projection on the z asix (s_z) equal to $\frac{3}{2}$. For the u quark, for instance, this is the particle $\Delta^{++} = u \uparrow u \uparrow u \uparrow$. This particle with $s = \frac{3}{2}$ must equally obviously have a state with spin projection $\frac{1}{2}$ (i.e., $s = \frac{3}{2}$, $s_z = \frac{1}{2}$). This is the case $u \uparrow u \downarrow u \uparrow$. But that is the only possibility, because $u \uparrow u \downarrow u \uparrow = u \downarrow u \uparrow u \uparrow = u \uparrow u \uparrow u \downarrow$, since the u's are indistinguishable. So no $s = \frac{1}{2}$ state is possible from three u's (or 3 d's or 3 s's). However, for the combination of u, d, and s we can have either an $s = \frac{3}{2}$ state or an $s = \frac{1}{2}$ state with either the d and s spins parallel, or u and s parallel. So two different $s = \frac{1}{2}$, $s_z = \frac{1}{2}$ combinations of these three can occur, and indeed, are found (the Σ^0 and the singlet Λ^0 hyperons.)

The various mesons are constructed from pairs of quarks and antiquarks. The scheme for the pseudoscalar, $J^P = 0^-$, mesons is shown in Fig. 3. These include the pions and kaons.

The theory predicts all the known particles. Extensive searches have been made for particles *not* predicted by the theory (the so called "exotic" particles), so far without success.

(2) *Particle Masses.* The masses of the various particles can be calculated using the nonrelativistic quark model. Some of these are given in Table 2. The model predicts the masses both of mesons and baryons with very fair accuracy. Note that this table gives the mean masses of various subfamilies. Thus proton and neutron are taken together and designated by N (for nucleon) and have a mean mass of 939 MeV/c^2.

The quark model also predicts the mass differences within these subgroups rather accurately. A few of the predicted and observed differences are given in Table 3.

(3) *The Electromagnetic Properties of Hadrons.* If the uncharged neutron were a "simple" elementary particle with no substructure, then it should not have a magnetic moment. On the other hand the quark model supposes that the neutron is composed of three charged particles (two with charge $-\frac{1}{3}e$ and the third with charge $+\frac{2}{3}e$). Thus, on this theory, we expect it to have a magnetic moment. The magnetic moments of various particles calculated using the quark model are given in Table 4 and compared with observation. The two are obviously in good agreement.

Many other aspects of electromagnetic behavior also can be calculated with good accuracy using the quark model.

(4) *Scattering of High-energy Hadrons.* The

	Observed	+2.79	−1.91	−0.73±0.16	+2.5±0.5

[a] Many other aspects of electromagnetic behavior also can be calculated with good accuracy using the quark model.

total cross sections for proton-proton and pion-proton scattering at high energies (> 20 GeV) are predicted by the quark model to be in the ratio 3:2 (crudely, because a proton is supposed to contain three quarks and a pion two quarks). The observed value is (1.58 ± 0.05):1. This result has not been predicted by any other model.

The nonrelativistic quark model has also had considerable success in explaining the scattering of positrons by negative electrons at high energies and the deep inelastic scattering of electrons by protons.

Defects and Extensions of the Simple Quark Model Quarks are fermions (i.e., they have spin $\frac{1}{2}$) so one expects them to obey the Pauli exclusion principle. But the Ω^- particle (whose prediction, as we have seen, was one of the great early triumphs of quark theory) requires three s quarks with their spins aligned. If the three quarks were identical this would be forbidden by the Pauli exclusion principle. To get out of this and other similar difficulties Greenberg suggested in 1964 that quarks have a previously unknown property which he called "color." Each "flavor" of quark (i.e., u, d, or s) comes in three different colors (and the anti-quarks in three different anti-colors). These "colors" have become known as *red*, *blue*, and *green* (and the anti-colors as magenta etc.). All hadrons are colorless, i.e., they are made of one *red*, one *blue*, and one *green* quark, or one quark and its oppositely colored anti-quark.

A further extension of the quark scheme was suggested (also in 1964) by Glashow, Bjorken, and others. This was the addition of at least one extra flavor which has since been given the symbol c (for *charm*). The clinching evidence for this extra quark (and anti-quark, also in three colors) came with the discovery of the J-ψ particle in 1970 by Ting and his co-workers at Brookhaven, and Richter and his team at Stanford. Since then, evidence for at least two other flavors, b (*bottom* or *beauty*) and t (*top* or *truth*) has accumulated.

So now the scheme requires at least 18 quarks (6 flavors each in 3 colors) and 18 anti-quarks plus a number of particles called *gluons* which serve to carry the force binding the quarks together.

Another surprise in quark physics has been the failure of many experiments to find free quarks. If these exist, their remarkable properties (including electric charges of $\frac{2}{3}e$ and $\frac{1}{3}e$ should make them easy to detect. They have been looked for at all large accelerators, in low energy and high energy cosmic radiation, and in condensed matter (water, iron, niobium, oyster shells, deep sea cores, moon dust, meteorites, etc.). No certain free quark has been seen in many experiments using accelerators or low energy cosmic radiation. Only three of the many searches in condensed matter have found apparently fractionally charged particles (though in one case, at least, the evidence is very solid). Two experiments have found lightly ionizing tracks in the cores of the air showers generated by high energy cosmic radiation (including one by the present author) and other experiments in this field give supporting evidence for the existence of free quarks. The failure of many experiments to find free quarks has led to the promulgation of "confinement" theories which assert that quarks are permanently confined in hadrons and can never get free. However, it has not been possible, so far, to prove that this is necessarily so.

The quark families seem to have some relation to the leptons. (See ELEMENTARY PARTICLES.) The quark family of lowest mass is the *u-d* family. Corresponding to it is the electron group (electron, positron, electron neutrino, and electron anti-neutrino). Next is the *s-c* quark family and the corresponding leptons (positive and negative muons and the muon neutrino and the anti-neutrino). Finally (at present) the *b-t* quark family and the τ mesons and their neutrinos. Thus, if these are the fundamental particles out of which the Universe is constructed there are a lot of them—36 quarks and anti-quarks, 12 leptons and anti-leptons, the gluons, the photon, the graviton, and some other assorted particles. The picture is reminiscent of the many different types of atom that Daltonian chemistry required, which, of course, turned out to be not fundamental, but compound particles. One is driven to consider Heisenberg's rejection of the atomic hypothesis and believe, instead, that the Universe is one, whole, and indivisible.

R

RADAR

Radar is the name given to the use of electromagnetic energy for the detection and location of reflecting objects. It operates by transmitting an electromagnetic signal and comparing the echo reflected from the target with the transmitted signal.

The first demonstration of the basic radar effects was by Heinrich Hertz in his famous experiments in the late 1880's in which he verified Maxwell's electromagnetic theory. Hertz showed that short-wave radiation could be reflected from metallic and dielectric bodies. Although the basic principle of radar was embodied in Hertz's experiments, the practical development of radar had to wait more than 50 years for radio technology to advance sufficiently. It wasn't until the late 1930's that practical models of radars appeared. The rapid advance in radar technology during World War II was aided by the many significant contributions of physicists and other scientists pressed into the practical pursuit of a new technology important to the military. In addition to its military application, radar has been applied to the peace-time needs of air and ship navigation, air traffic control, rainfall observation, tornado detection, hurricane tracking, surveying, radar astronomy, remote sensing of the environment, and the familiar speed measuring meter of the highway police.

The measurement of distance, or range, is probably the most distinctive feature of radar. Range is determined from the time taken by the transmitted signal to travel out to the target and back. The distances involved might be as short as a few feet or as long as interplanetary distances.

If the target is in motion relative to the radar, the echo signal will be shifted in frequency by the DOPPLER EFFECT and may be used as a direct measurement of the relative target velocity. A more important application of the Doppler shift is to separate moving targets from stationary targets (clutter) by means of frequency filtering. This is the basis of MTI (moving target indication) radar and pulse Doppler radar.

Radar antennas are large compared to the wavelength so as to produce narrow, directive beams. The direction of the target may be inferred from the angle of arrival of the echo. Radar antenna technology has profited greatly from the theory and practice of optics. Both the lens and the parabolic mirror have their counterpart in radar, and the analysis of antenna radiation patterns follows from diffraction theory developed for optics.

The external appearance of a radar is dominated by its ANTENNA. Most radars use some form of parabolic reflector. The radar antenna can also be a fixed array of many small radiating elements (perhaps several tens of thousands or more) operating in unison to produce the desired radiation characteristics. Array antennas have the advantage of greater flexibility and more rapid beam steering than mechanically steered reflector antennas because the beam movement can be accomplished by electrically changing the relative phase at each antenna element. High power can be radiated since a separate transmitter can be applied at each element. The flexibility and beam switching speed of an array antenna make it necessary in many instances to control its functions and analyze its output by automatic data processing equipment rather than with an operator using a grease pencil to mark the face of a cathode ray tube.

Radars are generally found within the microwave portion of the electromagnetic spectrum, typically from about 200 MHz (1.5 meters wavelength) to about 35,000 MHz (8.5 mm wavelength). These are not firm bounds. Many radars operate outside these limits. The famous British CH radar system of World War II which provided warning of air attack, operated in the high-frequency region of the spectrum in the vicinity of 25 MHz. Radars have also been demonstrated in the millimeter wavelength region where small physical apertures are capable of narrow beam widths and good angular resolution. The radar principle has also been applied at optical frequencies with LASERS for the measurement of range and detection of small motions (using the Doppler effect).

The detection performance of a radar system is specified by the *radar equation* which states

$$P_{\text{rec}} = \frac{P_t G}{4\pi R^2} \times \quad \sigma \quad \times \frac{1}{4\pi R^2} \times A$$

Received power	=	Power density at a distance R	×	Target backscatter cross section	×	Space attenuation on return path	×	Antenna collecting area

where P_t is the transmitted power, G is the transmitting antenna gain, R is the range, σ is the target backscatter cross section, and A is the effective receiving aperture of the antenna. The wavelength λ of the radar signal does not appear explicitly in this expression, but it can be introduced by the relationship between the gain and effective receiving area of an antenna which states $G = 4\pi A/\lambda^2$.

The detection capability and the measurement accuracy of a radar are ultimately limited by noise. The noise may be generated within the radar receiver itself, or it may be external and enter the receiver via the antenna along with the desired signal. External noise is generally small at microwave frequencies, but it can be a significant part of the overall noise if low-noise receiving devices are used (see MEASUREMENTS, PRINCIPLES OF).

Since the effects of noise must be considered in statistical terms, the analysis and understanding of the basic properties of radar have benefited from the application of the mathematical theory of statistics. The statistical theory of hypothesis testing has been applied to the radar detection problem where it is necessary to determine which of two hypotheses is correct: the output of a radar receiver is due to (1) noise alone or (2) signal plus noise. One of the results is the quantitative specification of the signal-to-noise ratio required at the receiver for reliable detection. The statistical theory of parameter estimation has also been applied with success to analyze the accuracy and theoretical limits of radar measurements.

Radar receivers are usually designed as *matched filters* which maximize the ratio of peak-signal power to mean-noise power at the output. The magnitude of the frequency response function of a matched filter is equal to the magnitude of the spectrum of the radar signal, and the phase is the negative of the phase of the radar signal.

Reliable detection of targets requires signal-to-noise power ratios of the order of 10 to 100 at the receiver, depending on the degree of error that can be tolerated in making the decision as to the presence or absence of a target. Even larger values are generally needed for the accurate measurement of target parameters. (These values may seem surprisingly high but, for comparison, the minimum signal-to-noise ratio of quality television signals is usually of the order of 10 000.)

The rms error δT in measuring the time delay to the target and back (the range measurement) can be expressed as

$$\delta T = \frac{1}{\beta\sqrt{2E/N_0}}$$

where β is defined as the effective signal bandwidth, E is the total energy of the received signal, and N_0 is the noise power per unit cycle of bandwidth assuming the noise has a uniform spectrum over the bandwidth of the receiver. The square of β is equal to $(2\pi)^2$ times the second central moment of the power spectrum normalized with respect to the signal energy. For a simple rectangular pulse, β is approximately equal to $\sqrt{2B/\tau}$, where B = receiver bandwidth and τ = pulse width. Also, E/N_0 is approximately equal to the signal-to-noise (power) ratio. To obtain an accurate range measurement, E/N_0 and the signal bandwidth must be large. A similar expression applies to the accuracy of the measurement of Doppler frequency if the rms time delay error is replaced by the rms frequency error and the effective bandwidth is replaced by the effective time duration of the signal. Thus, the longer the signal duration and the greater the ratio E/N_0, the more accurate is the Doppler frequency measurement. Likewise the angular measurement accuracy also depends on the ratio E/N_0 and the effective aperture size.

In addition to noise, radar can be limited by the presence of unwanted interfering echoes from large nearby objects such as the surface of the ground, trees, vegetation, sea waves, birds, insects, and weather. Although these "clutter" echoes may be troublesome in some applications, they are sometimes the echoes of interest as, for example, in ground mapping and meteorological applications.

Radar pulses can be as short in duration as a nanosecond or less, giving a range resolution of several centimeters. The shorter the pulse width the greater must be the peak power in order to maintain sufficient energy in the pulse for adequate detection sensitivity and accurate measurement in the presence of noise. Unfortunately, peak power is limited by voltage breakdown. It is possible, however, to achieve the resolution of a short pulse and the energy of a long pulse by means of *pulse compression* in which a pulse with peak power and pulse width T sufficient to give the desired energy is internally modulated in either phase or frequency to increase its bandwidth B. The product BT is called the *pulse compression ratio.* After passing through a matched filter on reception, the pulse of width T is compressed to a width $1/B$, and the peak power of the received signal is increased by a factor BT. A common form of pulse compression modulation is linear FM, also called *chirp.* Pulse compression ratios of practical radars are typically from 100 to 200, but can be as great as several hundreds of thousands.

Recent advances in digital processing technology have allowed the practical employment of automatic detection and tracking (ADT) in radars used for the surveillance of aircraft. ADT systems relieve the burden on the radar operator by automatically making the detection decision as to the presence or absence of targets and establishing target tracks (course or speed). ADT systems generally employ some form of CFAR (constant false alarm rate) receiver so as to prevent false targets due to noise or clutter echoes from overloading the tracking computer.

Radar has been used for the remote sensing of the environment. One of the oldest and most important applications of radar as a remote sensor has been for weather observation. In addition to providing rainfall rate, weather radar is able to determine wind conditions by extracting the relative velocity (measurement of the Doppler frequency shift). Remote sensing radar on aircraft or spacecraft have been employed for geological prospecting, mapping of remote regions under cloud cover, sea state measurement, measurement of the geoid, and the mapping of ice conditions. Other potential applications include crop census and measurement of soil moisture. The synthetic aperture radar (SAR) has been employed for remote sensing because of its ability to produce map-like images with high resolution at long ranges. Resolution can be as small as several meters and, unlike optical imaging, the resolution is independent of the range. In the range dimension good resolution is obtained by pulse compression, and in the cross-range dimension it is obtained by synthesizing the effect of a large antenna by storing the received signals over the time it takes for the radar to travel the length of the synthesized antenna.

The HF over-the-horizon (OTH) radar operates at frequencies (typically from about 5 MHz to perhaps 30 MHz) which are refracted by the ionosphere so as to provide illumination of regions from about 500 to 2000 nautical miles from the radar. Such radars can provide detection and tracking of aircraft and other targets at distances far greater than can be obtained with line-of-sight microwave radar. One interesting application of HF OTH radar is the determination of sea conditions and the winds generating the sea, by proper interpretation of the radar echo's Doppler spectrum induced by the motion of the sea waves.

Radar comes in many sizes and shapes. The smallest can be held in the hand and might radiate as little as a few milliwatts and be used to detect the movement of people at short range. The largest might radiate megawatts of average power and operate with antennas the size of a football field and would be used for the detection of space objects at ranges of many thousands of miles or more.

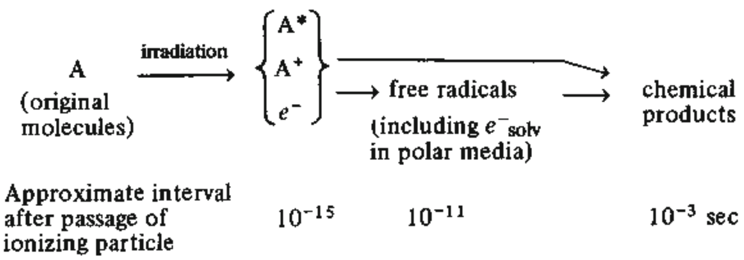
RADIATION CHEMISTRY

Radiation chemistry is the study of the chemical effects produced by the absorption of ionizing radiation. It includes chemical effects produced by the absorption of radiation from radioactive nuclei (α, β, and γ rays), of high-energy particles (electrons, protons, neutrons, recoil nuclei, etc.), and of electromagnetic radiation of short wavelength (x-rays with a wavelength less than about 100Å and an energy greater than about 100 eV, for example). Electromagnetic radiation of rather longer wavelength, in the ultraviolet and visible regions of the spectrum, may also initiate chemical reactions, though normally without producing ions as reactive intermediates; such reactions are the province of photochemistry. Reactions chemically similar to those caused by the absorption of ionizing radiation can be initiated by electric discharges; others, initiated in various ways, occur in the upper atmosphere.

Radiation chemistry originated with the observations by Röentgen (1895) and by Becquerel (1896) that led to the discovery of x-rays and of radioactivity, namely that photographic plates become fogged when placed near discharge tubes and uranium salts respectively. The subject was studied to only a limited extent until about 1942, when the advent of nuclear reactors and the increased interest in high-energy physics provided both the incentive and the means (in the form of relatively cheap artificial radioactive isotopes and of large particle accelerators) for a more intensive study. In the following two decades, earlier work was consolidated and the basic mechanisms for radiation-induced action were established in outline, making possible an extremely rapid development of the subject since about 1960.

Absorption of any form of ionizing radiation by matter (A) produces positive ions (A^+), electrons (e^-), and electronically excited atoms or molecules (A^*) distributed along the tracks of charged particles. The charged particles may be those which comprise the radiation (e.g., electrons or helium nuclei with fast electron or α-irradiation) or secondary particles produced by interactions of the primary radiation (e.g., fast secondary electrons formed by the absorption of x- or γ-rays, or fast protons produced by interaction of neutrons with hydrogenous materials). In addition, some of the electrons produced by ionization in the medium will have sufficient energy to produce further ionization and excitation, and will do so in slowing down to thermal energy (such electrons are known as δ-rays). Except in gases, where the ions and excited molecules can diffuse apart quite readily, these primary species are initially concentrated within about 10Å of the track of the ionizing particle. Heavy charged particles (protons and, particularly, helium nuclei and heavier particles) lose energy very rapidly in liquids and solids and leave a track densely populated with the primary species; radiations of this type are said to have a "high LET," where LET stands for linear energy transfer. In contrast, fast electrons and the secondary electrons produced by the absorption of x- and γ-rays lose energy relatively slowly and form the primary species (which are the same as those produced by the heavier particles) in small groups containing, on an average, two or three ion pairs and about the same number of excited molecules. These groups (called *spurs*), with an initial diameter of $\sim$ 20Å, are separated by a relatively great distance ($\sim 10^3$Å) from neighboring spurs along the same track, and the radiation responsible is said to have a "low LET." However, the spurs along an electron track become closer together as the electron loses energy, and eventually overlap each other. The initial localization of the ions and excited molecules in the track of a high-LET particle or in spurs produced by a low-LET particle causes spatial, or track, effects in radiation-induced reactions which are absent in photochemistry, where excited molecules are produced with an essentially uniform distribution in any plane at right angles to the direction of the beam of light. The excited molecules involved in radiation chemistry include excited states similar to those formed by the absorption of ultraviolet or visible light and also other states, formed by optically forbidden transitions or with more intrinsic energy, that are not produced photochemically.

Chemical changes in the irradiated material are brought about by breakdown or reaction of the ions and excited molecules and via free radicals formed by these primary species. The sequence of events in many radiation-induced (radiolysis) reactions may be represented as:



A
(original molecules)
irradiation
A*
A+
e−
free radicals
(including e−solv in polar media)
chemical products
Approximate interval after passage of ionizing particle
10−15
10−11
10−3 sec

Electronically excited molecules and ions are produced by passage of an ionizing particle. The excited molecules may return to the ground state without producing chemical change, dissociate to free radicals, or dissociate directly to stable chemical products. Positive ions also give rise to free radicals or stable products by dissociation, reaction with the substrate (in ion-molecule reactions), or upon neutralization by an electron. In polar media the neutralization may be delayed by solvation (association of the ion with a group of solvent molecules held by electrostatic forces), and the solvated ions, particularly the solvated electron, may react in a similar manner to free radicals. The events outlined above are often considered to occur in three stages: a *physical stage* lasting about 10^{-14} sec corresponding with the initial dissipation of energy in the system; a *physiochemical stage* lasting from $\sim 10^{-14}$ to $\sim 10^{-10}$sec during which thermal equilibrium is established, dissociation of excited molecules and positive ions occurs, and (in polar media) ions become solvated; and a *chemical stage* lasting about 10^{-3}sec during which radical reactions occur and give rise to chemically stable molecules. Processes occurring during the late physiochemical and the chemical stages can sometimes be observed directly by absorption spectroscopy following a brief radiation pulse. This technique, known as *pulse radiolysis*, is routinely used to investigate reactions occurring microseconds after the radiation pulse and can be extended into the nanosecond and picosecond regions.

Free radicals, which are formed when most materials except metals are irradiated, are atoms or molecules which have unpaired valence electrons; the solvated electron behaves like, and is often described as, a free radical. Free radicals are generally chemically unstable species and react rapidly in such a manner that the unpaired electrons become paired, for example by combination of two free radicals (shown below with a $\cdot$ to represent the unpaired electron)

$$2\cdot OH \longrightarrow HO{-}OH \text{ (or } H_2O_2\text{)}$$

or transfer of an atom (disproportionation)

$$CH_3CH_2\cdot + \cdot CH_2CH_3 \longrightarrow CH_3{-}CH_3 + CH_2{=}CH_2$$

or an electron

$$\cdot OH + Fe^{2+} \longrightarrow OH^- + Fe^{3+}.$$

Other common radical reactions are addition to oxygen and doubly bonded (unsaturated) compounds and abstraction of hydrogen or halogen atoms from compounds, e.g.,

$$e_{aq}^- + O_2 \longrightarrow O_2^-$$

$$\cdot CH_3 + CH_2{=}CH_2 \longrightarrow CH_3{-}CH_2{-}CH_2\cdot$$

$$H\cdot + CCl_4 \longrightarrow HCl + \cdot CCl_3.$$

The latter reactions do not result in electron pairing but instead give rise to less reactive (more stable) radicals that may react further before they are stabilized by electron pairing. Many free radicals have been identified in irradiated systems by pulse radiolysis, and in solid or frozen systems, by electron spin resonance.

Quantitative studies in radiation chemistry are based either on the number of ions (N) formed in the irradiated medium or on the energy absorbed from the radiation. Ionization measurements in irradiated gases allow N to be estimated, and radiation yields in gases are best expressed as the *ionic* (or *ion-pair*) *yield*, M/N, where M is the number of molecules of product formed by radiation which produces N ion pairs. Reliable estimates of N are, at present, only available for gaseous systems, and for condensed materials it is usual to express the radiolysis yield as a G value (the number of molecules of product formed, or of starting material changed, per 100 eV of energy absorbed). Ionic yields and G values are related by $G = M/N \times 100/W$, where W (electron volts) is the mean energy required to form an ion pair in the material being irradiated. The determination of N, or of the energy absorbed, is termed "dosimetry" and may involve ionization measurements, calorimetry, measurement of the charge carried by a beam of charged particles of known energy, or measurement of a chemical change produced by irradiation [the oxidation of ferrous iron to ferric iron in 0.4 M sulfuric acid solution is often used (Fricke dosimeter)]. However, chemical dosimeters must first be calibrated against some absolute physical measurement. The energy absorbed by an irradiated system is generally expressed in units of *rads* (1 rad is an energy absorption of 100 ergs g^{-1}) or of eV g^{-1} or eV ml^{-1}, though these units are being displaced by a new SI unit, the gray (Gy). 1 Gy = 1 J $\cdot$ kg^{-1} = 100 rad.

Radiation-induced reactions have been studied in the gas, liquid and solid phases and in inorganic, organic, and biological systems. They have also been studied over a wide range of temperatures.

Most thoroughly studied of all radiation-induced reactions is the radiolysis of water and aqueous solutions, where the following have been identified as the major products formed in the tracks or spurs: hydrogen (H_2), hydrogen peroxide (H_2O_2), hydrogen atoms ($H\cdot$), hydroxyl radicals ($\cdot OH$), and solvated, or hydrated, electrons (e_{eq}^-). These products are formed by the primary species, H_2O^+, e^-, and H_2O^*, and, in the case of hydrogen and hydrogen peroxide, by $H\cdot$, $\cdot OH$, and e_{aq}^-. Relatively more hydrogen and hydrogen peroxide are formed in the track of a high-LET α-particle [$G(H_2) \sim 1.57$, $G(H_2O_2) \sim 1.45$] than in the spurs associated with a high-energy, low-LET, electron [$G(H_2) \sim 0.40$, $G(H_2O_2) \sim 0.80$] since the concentration of the precursors is greater in the track than in the spurs. However, relatively more of the other products ($H\cdot$, $\cdot$ OH, and e_{aq}^-) escape from the spurs [G(radical) ~ 6.5] than from the α-particle track [G(radical) ~ 1.2]. These three species are free radicals and react very readily with substances present in solution, the hydroxyl radical generally producing oxidation, and the hydrogen atom and the solvated electron producing reduction, of the solute if the solution is free of air. Both the hydrogen atom and the solvated electron react rapidly with oxygen to give oxidizing species, so that oxidation reactions predominate when aerated aqueous solutions are irradiated. In acid solutions, solvated electrons are rapidly converted to hydrogen atoms ($H\cdot$) by reaction with hydrogen ions (H^+).

Many organic materials have been irradiated and, making a very rough generalization, the products are those expected if the action of the radiation is to break the organic molecules randomly into two fragments (free radicals). The fragments then react together in pairs, again in a random fashion, either combining to form larger molecules or transferring an atom from one fragment to the other to give two stable molecules. The products from a hydrocarbon, for example, include hydrogen and hydrocarbons ranging in size from methane (CH_4) to compounds containing twice as many carbon atoms as the original compound; unsaturated materials, containing relatively less hydrogen than the original compound, will also be formed. Hexane, $CH_3{-}(CH_2)_4{-}CH_3$, forms at least 16 products upon irradiation, of which the two most abundant are hydrogen ($G = 5.0$) and dimeric C_{12} hydrocarbons ($G = 2.0$); the remaining products are formed with G values of 0.5 or less. More complex compounds may break preferentially (though generally not exclusively) at a particular point in the molecule; thus the carbon-iodine bond breaks most frequently when methyl iodide CH_3I is irradiated. Some classes of compound can enter into chain reactions in which the reaction, once started, continues on its own. Typical of such substances are the unsaturated "monomers" which polymerize to produce polymers such as polymethyl methacrylate ("Lucite") and polyvinyl chloride (PVC). The chain reactions here are initiated by free radicals, and other means of producing free radicals besides irradiation bring about the same effect. G values for chain reactions may run from a few hundred to many thousands.

Aromatic compounds such as benzene are more resistant to radiation than most compounds lacking the "benzene" ring. Thus $G(H_2)$ from liquid benzene is only 0.036, and the total yield of radiolysis products does not exceed $G = 1$. In favorable instances, aromatic compounds can reduce the radiation damage in non-aromatic compounds mixed with them, energy absorbed by the second component being transferred in part to the "protecting" aromatic compound.

Apart from its intrinsic interest, the importance of radiation chemistry has rested largely upon its application to problems of reactor technology and its close relationship to radiation biology and radiation medicine. More recently several commercial applications have been realized, such as irradiation of polyethylene to produce a higher-melting polymer and the synthesis of ethyl bromide via a radiation-induced chain reaction between ethylene and hydrogen bromide. However radiation energy is relatively expensive, and the commerically viable processes have generally involved either reactions having a high G value (i.e., chain reactions) or reactions producing a high molecular weight product such as a polymer. Both G value and molecular weight are related to the mass of product formed per unit radiation energy absorbed, for example the yield of product in pounds produced per kilowatt hour radiation energy absorbed is given by $G \times M \times 8.23 \times 10^{-4}$. The ethyl bromide synthesis is an example of a reaction with a high G value ($\sim 10^4 - 10^5$), other examples being the polymerization of unsaturated monomers absorbed in wood or concrete, or present in printing inks and coatings, and the production of graft polymers. Crosslinking of bulk polymer, such as polyethylene wire and cable insulation, to increase heat resistance and toughness is an example where M is large and a relatively small degree of chemical change brings about a large change in physical properties. Other well established applications of radiation technology are the sterilization of bulk medical supplies such as sutures and disposable plastic items, and radiation treatment of foodstuffs to extend storage life (the key chemical changes in these instances presumably involve large protein or nucleic acid molecules).

RADIATION, IONIZING, BASIC INTERACTIONS

Radiations of a large class, called *ionizing*, which interact with matter in its many forms and lead to a wide variety of "observed" or expressed effects have similar basic interaction pathways. Sources of ionizing radiations are varied and include radioactive isotopes, fission and fusion reactions, particle accelerators, and cosmic rays. Regardless of the source of any given radiation (applied to a given target), the basic interaction depends only upon the fundamental properties of the radiation itself.

Ionizing Radiations The principal ionizing radiations are summarized in Table 1. Although only the gamma or x-rays are electromagnetic in character and thus "radiations" in the classical sense, the distinction between "radiations" and ionizing "particles" is often not made (x-rays are distinguished from gamma rays only with respect to their origins; gamma rays result from nuclear interactions or decays; x-rays result from transitions of atomic or free electrons, produced artificially by bombarding metallic targets with energetic electrons). It is sometimes difficult to make a clear distinction between ionizing and nonionizing electromagnetic radiations, particularly in condensed phases. The ionization potential of *gaseous* elements, i.e., the energy required for removal of the first electron, varies from 3.9 eV (Cs) to 24.6 eV (He). Comparable values are not well known for most complicated molecular systems or liquid- and solid-state systems, but a few selected additional values are included in Table 2, and others are probably in or near this general range. Although ultraviolet and even visible light can in special cases cause ionizations, the general assumption is that more energetic x- or gamma radiation is required to insure ionization, especially in substances of practical importance.

TABLE 2. IONIZATION POTENTIALS OF SOME SELECTED ELEMENTS (WEAST, 1975).

Element	Ionization Potential (Volts)
Argon	15.6
Carbon	11.3
Cesium	3.9
Hydrogen	13.6
Helium	24.5
Nitrogen	14.5
Neon	21.6
Oxygen	13.6
Phosphorus	10.5
Silicon	8.1
Sodium	5.1

Hence the name "ionizing radiation" is reserved for electromagnetic radiation at least as energetic as x-rays and for charged particles of similar energies. Neutrons also lead to ionization, but for other reasons, described below. *Ionization* is, of course, not the sole interaction of high-energy particles and radiations with matter. The *excitation* of atomic electrons into higher-energy states always accompanies ionization.

Basic Action The fundamental processes leading to ionization differ for charged particles, electromagnetic radiations, and neutrons.

Charged Particles. Fast charged particles are produced in radioactive decay processes, particle accelerators, nuclear reactions, and extraterrestrial sources. They undergo *coulombic* and *nuclear* interactions. The latter are far less probable and are discussed in other parts of this encyclopedia (see NUCLEAR REACTIONS). There are two principal means whereby charged particles can lose energy by coulomb interaction: radiative loss and direct ionization. The probability of radiative energy loss (BREMSSTRAHLUNG) is roughly proportional to

TABLE 1. PROPERTIES OF THE MOST COMMON IONIZING RADIATIONS.

Name	Symbol	Location in Atom	Relative Rest Mass	Charge

Gamma^a (photon)	γ	Emitted during decay processes	0.0	0

^{a}X-rays of equal energy are identical, but of extranuclear origin.

$$\frac{z^2 Z^2 T}{M_0^{\ 2}}$$

where z is the particle charge in units of the electron charge e, Z is the atomic number of the target material, T is the particle kinetic energy, and M_0 is the rest mass of the particle. The ratio of energy lost by bremsstrahlung to that by ionization can be approximated by

$$\left(\frac{m_0}{M_0}\right)^2 \frac{ZT}{1600\, m_0 c^2}$$

in which m_0 is the rest mass of the electron and c^2 is the speed of light squared, or 931 MeV per atomic mass unit. Electrons in the 10-MeV region lose about half of their energy by bremsstrahlung (in high-Z material), whereas heavier charged particles lose nearly all of their energy by ionization.

Loss of energy by ionization results when the particle undergoes coulomb collision with the *electrons* of the target. From the ratio of total energy lost to the number of ion pairs produced in cloud chambers (see Fig. 1), it has been estimated that approximately 100 eV are dissipated in each *primary ionization event* and that each event results in the production of, on the average, three ion pairs, each consisting of a free electron and a positive ion. If a resulting electron carries more than a certain amount (usually considered to be about 100 eV) of kinetic energy, it is called a *delta ray*, because it is capable of further ionizations. "Delta ray" and "track core" ionizations are depicted in Fig. 1. The experimentally determined energy required to produce each *observed* ion pair lies in the range of 20 to 40 eV per ion pair for gases. A figure in the neighborhood of 30 eV per ion pair is commonly assumed for condensed phases of matter, with the exception of semiconducting solids. This value is called W and is generally slightly different for electrons and low-velocity heavy particles in the same material.

For example, although $W = 26.2 \pm 0.2$ eV per ion pair for electrons in argon, and $W = 26.2 \pm 1.8$ for fast (relativistic) nitrogen ions in argon, recoiling nuclei of polonium and thorium (with very low energies) ionize argon gas with a W value exceeding 85 eV (Myers, 1968; Schimmerling et al., 1976). Theoretically, for heavy ions of low velocity W' takes the place of W and is found from

$$W' = \frac{W}{1 + (\frac{1}{2}A/WT^{1/2})}$$

where A is an empirical constant, 9500 for nitrogen ions in argon gas, for example. As T approaches the Bohr-orbit energy W' becomes large. The value of W in liquid argon is 26.0 eV per ion pair, not significantly different from that of gaseous argon, 26.3 eV per ion pair. Ionization in a few solids has been studied, and $W = 3.57 \pm 0.05$ eV per electron-hole pair in silicon, for example, and a range of about 1–10 eV per electron-hole pair has been found in about a dozen semi-conducting solids (Myers, 1968). Additional useful W values are included in Table 3 for materials often used in radiation dosimetry.

On the basis of coulomb scattering theory, it is possible to calculate the energy loss per unit path length $(-dT/dx)$ for charged particles. For electrons and positrons the theory is complicated by the quantum mechanical effects of spin, identity, and relativity. In general, the *total* expectation energy loss per unit path length (also termed *mass stopping power* when path length is expressed in grams per square centimeter) for electrons and positrons can be expressed by

$$-\frac{dT}{dx} = \frac{2\pi e^4}{m_0 V^2} NZ \left\{ \ln\left[\frac{m_0 V^2 T}{2I^2(1-\beta^2)}\right] - \beta^2 \right\}$$

in which V is the particle velocity, beta is V/c, N is the number of atoms per unit mass, and I is the geometric mean ionization and excitation energy of the atoms of the target material. Classical theory is more adequate in describing the

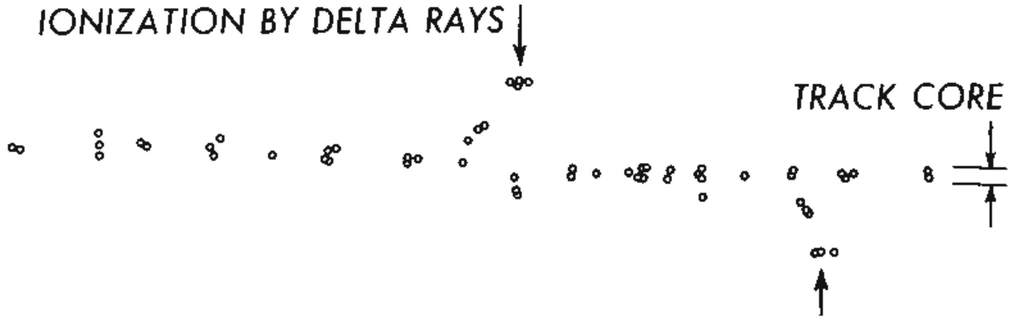

FIG. 1. Schematic drawing of a cloud-chamber photograph of the track of an ionizing particle, illustrating that ion pairs (illustrated by small circles) occur in clusters. Spurs indicated by arrows are ionizations due to *delta rays*. The arbitrary identification of the *track core* is also indicated.

TABLE 3. VALUES OF W, THE AVERAGE ENERGY LOST IN PRODUCING AN ION PAIR, FOR MATERIALS OFTEN USED IN RADIATION DOSIMETRY.

Substance (Gas)	W (eV/ion pair)

Water	30.1
Xenon	21.9

loss of energy by heavy charged particles, and the mass stopping power is determined from

$$-\frac{dT}{dx}=\frac{4\pi e^4 z^2}{m_0 V^2}\, NB$$

where B is called the *stopping number* and assumes various forms.

The complete stopping number for a positively charged particle with effective charge Z, velocity V, and mass m traversing a substance having N atoms/cm^3, atomic number Z, and mean excitation energy I is

$$B = Z\left[\ln\frac{2mV^2}{I(1-\beta^2)} - \beta^2 - \frac{C(V,Z)}{Z} - \frac{1}{2}\delta(V,Z) + z\phi(V,Z) + z^2\psi(V,Z)\right].$$

The terms within the brackets are as follows:

$C(V,Z)/Z$ is the *shell correction term* and adjusts the field of the target atom on the basis of the electric fields of outer shell electrons; there is one such term for each significant shell.

$\frac{1}{2}\delta(V,Z)$ is the *Fermi density effect* and adjusts the field of the target atom on the basis of atoms that actually lie between the projectile and the target atom when interaction distances are very large.

$Z\phi(V,Z)$ is the Z^3 term.

$Z^2\psi(V,Z)$ is the Z^4 term, and these account for higher-order electric force fields related to the shapes of the target atom and projectile.

The most important parameter in the stopping equation is the mean excitation energy I. These have been determined by theory and/or by experiment for the elements and numerous compounds. In the case of compounds the theoretical determinations may include the effects of chemical binding and the physical state of aggregation of the medium. Mean excitation energies for 50 common substances are compiled in Table 4, using the data compiled by S. M. Seltzer and M. J. Berger which lists 278 materials.

A complete account of the energy lost by fast charge particles includes energy loss events over the complete range of amount of energy transferred. Some events only result in excitation of atoms and molecules and can be characterized through optical studies of the absorbing material. The probabilities (or *cross sections*) of such events depend in a very irregular fashion on the amount of energy transferred per event, since quantum level transitions of orbital electrons absorb the energy. Their transition probabilities are called *oscillator strengths;* the interaction cross sections depend strongly on the molecular structure of the target. Bethe-Born theory provides a reliable extrapolation of emission spectra of low energy electrons from optical spectroscopic data. Thus a means of determining I from first principles is to consider *oscillator strength* df/dT and dielectric response ϵ determined from optical properties of the material:

$$\ln I = \frac{\int \ln T\,(df/dT)\,dT}{\int (df/dT)\,dT} = \frac{\int T \ln T\ \mathrm{Im}\,[-1/\epsilon(T/\hbar)]\,dT}{\int T\ \mathrm{Im}\,[-1/\epsilon(T/\hbar)]\,dT}$$

where Im refers to the imaginary part of the dielectric response, which is responsible for energy absorption.

Instead of stopping power, the term *linear energy transfer* (LET) is frequently used. The two quantities are not strictly interconvertible, according to a recent decision by the international committee on radiation units (see *National Bureau of Standards (U.S.) Handbook* **84**). Mass stopping power should be used only in the sense described above, whereas LET should be used only for energy lost by the particle within a specified distance of the track core. (Stopping

power is usually expressed in units of million electron volts per gram per square centimeter, and LET in units of kiloelectron volts per micron.) These are both measures of linear *density of ionization* in the target material.

From the above equations, it is possible to derive range-energy relationships for charged particles by simple integration. Theoretical and experimental range-energy curves are now available in the literature for nearly all charged particles.

Electromagnetic Radiation (X, gamma). For fast, charged particles interacting with matter we had, above, relations of the form

$$-\frac{dT}{dx} \propto \frac{(\text{charge})^2}{(\text{velocity})^2}$$

If it were permissible to extend this idea to electromagnetic radiation, one might expect photons with no charge (and with the velocity of light) not to ionize at all. They indeed do ionize sparsely though for different reasons. The three principal mechanisms of interaction can be summarized as follows:

(1) Photoelectric effect. Low-energy photons can give up all their energy to a bound electron, forming an ion pair and disappearing in the process. (Generally unimportant above 1 MeV.)

(2) Compton scattering. For medium-energy photons (0.5 to 5 MeV), this elastic collision process predominates, leading to ejection of a recoil electron plus the partially degraded (longer-wavelength) photon.

(3) Pair production. Photons of highest energy most often interact by forming an electron-positron pair in the field of a nucleus and disappearing in the process. The absolute energy threshold for this process is the rest mass energy of the pair: 1.02 MeV.

The net result of all three processes is the formation of (charged) ion pairs and in particular of electrons having energies ranging up to the photon energy but on the average only a fraction of this maximum. The discussion on charged particles thus applies to x- or gamma-ray action also. Each of these processes will now be considered in more detail.

In the *photoelectric process*, the photon collides directly with an atomic electron, imparting kinetic energy

$$T = h\nu - B_e$$

where B_e is the atomic binding energy of the electron and $h\nu$ is the photon energy. For a considerable range of photon energies and target material Z's, the probability of this process is approximately dependent upon the fourth power of Z and the inverse third power of the photon energy. There are, however, very specific energies at which photoelectric absorption is very probable ("absorption edges"), due to nearness of the photon energy to the binding energy of a specific electron (K, L, M, etc.). The probability per unit thickness of absorber of a photon undergoing photoelectric absorption is denoted by τ. An initial photon intensity I_0 is reduced by this process to an intensity I_x after traversing a thickness of material, x, according to the relation

$$I_x/I_0 = e^{-\tau x}$$

The *Compton process* differs from the photoelectric process in two important ways: the photon usually loses less than all of its energy to the electron with which it collides, giving rise to a lower-energy scattered photon, and the process may occur with a free or loosely bound electron. Momentum and energy are conserved according to the laws of classical mechanics, and the energetics can be described by

$$h\nu = h\nu' + (m - m_0)c^2$$

where $h\nu'$ is the energy of the secondary photon, and $(m - m_0)c^2$ is the kinetic energy of the recoil electron (expressed in terms of the relativistic mass increase). At high photon energies, the collision probabilities are governed by the laws of quantum mechanics. Photons are lost by the Compton process according to the relation

$$I_x/I_0 = e^{-\sigma x}$$

where σ is the absorption probability per unit thickness.

If the energy of the photon is greater than two electron masses (1.02 MeV), there is a finite probability that it will interact with the nuclear field giving rise to electron-positron *pair production*. In pair production, energy is conserved according to

$$h\nu - 2m_0c^2 = T_+ + T_-$$

where T_+ and T_- are the positron and electron kinetic energies, respectively. The positive electron is ultimately annihilated by a negative electron, and the masses of both are converted into photons with energies distributed about 0.51 MeV (one electron mass each). Very high-energy electron-positron pairs may, in turn, produce further photons by bremsstrahlung, initiating a sequence of photon-electron-photon, etc., interactions, known as a *cascade*. (If the photon energy is greater than four electron masses, pair production may occur in the field of an electron, under which condition the original electron is set in motion, and the process is called "triplet production.") The probability of pair production increases very rapidly with increasing photon energy above 1.02 MeV and increases as Z^2, the square of the atomic number of the target material. The absorption probability per unit thickness is denoted by κ, so that high-energy photons are absorbed according to

$$I_x/I_0 = e^{-\kappa x}$$

It is usually desirable to know the *total* photon absorption per unit thickness of a given material, so one simply states

$$I_x/I_0 = e^{-\mu x}$$

where

$$\mu = \tau + \sigma + \kappa.$$

μ is called the "total linear absorption coefficient" and is expressed in units reciprocal to those in which x is measured.

Neutrons. Because of their lack of charge, neutrons do not interact electrostatically either with orbital electrons or with nuclei. They do interact with nuclei, however, in various other ways.

Fast neutrons (up to a few MeV) lose energy primarily by elastic collisions with other nuclei. From considerations of momentum transfer, this process is most efficient for target nuclei of about the same mass (i.e., protons in hydrogenous materials), though other light nuclei are also effective. On the *average*, about half the initial neutron kinetic energy is transferred to the protons, so that fast-neutron bombardment looks (to a hydrogenous material) like bombardment with fast protons of half the neutron energy. In addition to such simple collision processes, fast neutrons also induce nuclear reactions in certain elements, leading to emission of particles or photons with their previously described interactions.

After about 20 collisions, neutrons are no longer sufficiently energetic to eject recoil protons but have become "thermalized," i.e., they act (for a short time) like a gas in thermal equilibrium with its surroundings (energies of about 1/40 eV).

When a neutron has become thermalized and wanders into a nucleus, it is quite often captured, momentarily yielding an excited isotope of the original nucleus. Nuclei usually lose their excitation by emission of particles or characteristic gamma rays. Thus, even an uncharged slow neutron gives rise to the release of ionizing radiation inside a material being irradiated. In living tissue, slow neutrons commonly are captured by H^1 nuclei with emission of an energetic gamma ray, and by N^{14} nuclei with emission of an energetic proton.

Associated or Post-ionization Events Subsequent to the primary and secondary molecular ionizations (and excitations), a number of events can occur that depend rather strongly on the form of the target material, including

(1) dissociation of molecules and formation of free radicals (species with unpaired electrons, hence great chemical reactivity, e.g., in water, H, OH, HO_2);

(2) recombination of ions and radicals, leading to no net change;

(3) dispersion of energetic ions and radicals, and reaction with other species present or with each other;

(4) nondiffusion migration of electronic excitation to energy "sinks," e.g., in macro-molecules or crystals; and

(5) eventual degradation of the excess absorbed energy to heat (insignificant from the standpoint of effects).

For many systems the basic interactions must be considered only the initiators of a complex sequence of later events.

Comparison of the Radiations Diverse electromagnetic and particulate radiations thus have in common as their basic interaction (or closely following upon it) the production of molecular ionizations (and excitations, dissociations, free radicals) inside target matter. They differ in the *geometry* of these events (especially in LET), a difference that leads to wide variations in range or penetrating ability and, thus, in the subsequent reactions leading to the final expression of the radiation effect.

The slower, more highly charged, heavy particles (such as alphas) travel in straight-line tracks ionizing densely along the track and exhibiting discrete ranges characteristic of the particle energy. Lighter, less highly charged particles such as electrons have their tracks more easily deflected and therefore have less precisely specified ranges in matter (although they have a maximum range). With a lower ionization density, however, they travel much farther than heavy charged particles of the same energy. Gamma or x-rays interact causing release of electrons in matter but at widely spaced intervals and in a random fashion; they have a still lower ionization density (LET) and much longer "range." (Since the resultant of all their absorption processes is a roughly exponential attenuation in matter, their "range" must be described in terms of a parameter such as "half thickness," $x_{1/2}$, the thickness of material that reduces incident intensity to 50 per cent. The relation $x_{1/2} = 0.693/\mu$ is seen to follow from the above equation for total photon absorption.) X-ray interaction has been likened to a "shotgun" effect in contrast to the "rifle" effect from incident heavy charged particles. Neutrons, which only interact with nuclei, may have either high or low LET. Their penetration in matter is great though difficult to specify well except in terms of specific materials. For much of their path, *fast* neutrons also are attenuated roughly exponentially.

The approximate range r or half thickness $x_{1/2}$ is given in Table 5 for several 1-MeV radiations in water.

Finally, a variety of conventional particle and wave interactions (such as reflection, transmission, and refraction) are also experienced by the above radiations. Moreover, many other more-or-less-ionizing radiations have been omitted from this discussion, including mesons, hyperons, heavy cosmic particles, large fission and spallation products, and anti-particles. Their relative interactions can be quite well predicted from their composition, charge, and velocity, and the above considerations.

RADIATION, THERMAL

The term *thermal radiation* refers to the electromagnetic energy that all substances radiate, by transformation of their thermal energy. More exactly the term implies that the radiative degrees of freedom of a system are in equilibrium with the material ones, so that a common temperature has been achieved. For a closed system the radiation spectrum is a continuum, and the intensity at any wavelength is determined solely by the temperature. Viewing the universe as a closed system, its temperature is 3 K, based on observations of the isotropic background radiation at microwave and far infrared wavelength.

Radiative cooling occurs when the energy radiated by a body is not replenished; thus it might cool to a limiting temperature of 3 K in space.

When a body's temperature is raised to approximately 500 C it appears "red-hot," due to the visible part of its thermal radiation. At lower temperatures almost all the radiation is in the infrared.

The discovery that radiation existed outside the visible spectral region was made by Sir William Herschel in 1800. He used a prism to disperse the solar spectrum onto a table in a dark room, and scanned it with a sensitive thermometer. The latter revealed the presence of infrared solar radiation beyond the red end.

Sources other than the sun were also studied. One that is of fundamental importance is an isothermal enclosure, or hohlraum, with a small hole for viewing the radiation escaping from the interior. Kirchhoff had proved, from the second law of thermodynamics, that the flux and the spectral distribution of the radiation are the same in all such enclosures at a given temperature, irrespective of the materials composing them. A related fact, known as Kirchhoff's law, is that the ratio of radiant emittance to absorptance is the same for all surfaces at the same temperature. (The radiant emittance of a surface is the integrated power radiated in all directions per unit area of surface. Definitions of other radiometric quantities, symbols and units will be found in the references.) In accordance with this law, metallic surfaces, having high reflectance and hence low absorptance, also have a low radiant emittance. Hence, the inner surfaces of the double walls of a Dewar flask are silvered, to minimize radiant heat loss.

At a given temperature, the surface having maximum absorptance will also have maximum emittance of radiant energy. Since such a surface absorbs all incident energy, it appears black, and the radiation it emits is known as "blackbody radiation." Like the pupil of the eye, an opening in the surface of a hollow body appears to be perfectly black (as long as there is no reflection back out) and the opening acts as a blackbody radiator as well as absorber. No surface can have a larger radiant emittance than a blackbody, at a given temperature.

Toward the end of the nineteenth century, quantitative studies of the magnitude and spectral distribution of blackbody radiation were made (see INFRARED RADIATION for typical curves). Stefan had found experimentally in 1879 that the radiant emittance of a blackbody, integrated over all wavelengths, is proportional to the fourth power of the absolute temperature. And, in 1884, Boltzmann gave a theoretical derivation for what is now known as the Stefan-Boltzmann law: $W = \sigma T^4$. The value of the constant σ is 5.67×10^{-12} watts cm^{-2} deg^{-4}. In 1893, Wien derived a "displacement law," one of whose implications is that $\lambda_{\max} T = 2898$, where $\lambda_{\max}$ is the wavelength (in microns) at which maximum radiance occurs for a blackbody at absolute temperature T.

In 1896, Wien derived the following distribution law for the spectral radiant emittance W_λ of a blackbody: $W_\lambda = c_1 \lambda^{-5} \exp(-c_2/\lambda T)$. This fits the experimental observations within 1 per cent, provided λT is less than 3100, i.e., $\lambda \leqq \lambda_{\max}$; but at larger values, the predicted values rapidly become too low (see Fig. 1). On the other hand, by applying the classical equipartition theorem of statistical mechanics to the radiation, Rayleigh and Jeans derived the following formula: $W_\lambda = (c_1/c_2)\lambda^{-4} T$. For $\lambda \geqq$

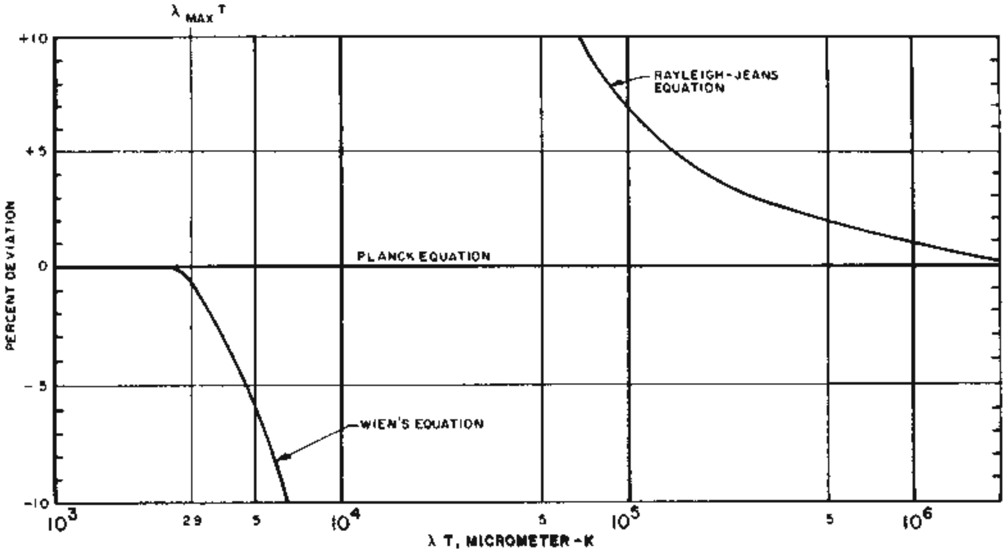

FIG. 1. Fractional deviation of classical radiation equations from the Planck equation.

$250\lambda_{max}$, the Rayleigh-Jeans equation matches the experimental data to 1 per cent, but it diverges, leading to the "ultraviolet catastrophe," as $\lambda \to 0$. It remained for Max Planck in 1900 to find an expression that is valid at all wavelengths and temperatures, namely: $W_\lambda = c_1\lambda^{-5}/[\exp(c_2/\lambda T) - 1]$. c_1 and c_2 are known as the first and second radiation constants, respectively, and have the values $c_1 = 3.74 \times 10^{-12}$ watt cm^2; $c_2 = 1.44$ cm degree. Planck's theory leads to the following expressions for the radiation constants in terms of fundamental physical quantities: $c_1 = 2\pi hc^2$; $c_2 = hc/k$, c being the velocity of light, and k Boltzmann's constant. The validity of these expressions has been experimentally justified.

Planck first developed this law empirically, and tried unsuccessfully to justify it on the basis of classical physics. He was forced to postulate that the elementary oscillators, of which a radiating body consists, did not have a continuous distribution of energy, but only quantized values. According to the "quantum hypothesis," the energy E that an oscillator may assume is given by $E = nh\nu$, where n is an integer, and the proportionality constant h (now known as Planck's constant) $= 6.63 \times 10^{-34}$ watt sec^2. Though forced to assume that the energies of the elementary oscillators, of which the radiator is composed, could take on only discrete values, Planck considered the emitted radiation to be propagated according to classical electromagnetic theory. The quantization of the radiant energy into photons was conceived by Einstein and used by him to explain the phenomena of photoelectricity. These quantum concepts were later extended by Bohr and Sommerfeld to explain atomic spectra and by Schrödinger, Heisenberg, Dirac, and others to develop quantum mechanics. Thus, they stand as one of the most important milestones in the history of theoretical physics.

Integration of Planck's equation leads to the Stefan-Boltzmann equation. Wien's laws and the Rayleigh-Jeans law may also be derived from Planck's law under appropriate conditions. For example, when dealing with photons whose energy $h\nu$ is sufficiently small compared to the thermal energy kT, the product λT is large enough so that the exponential in the denominator of Planck's law may be replaced by the first two terms of a series expansion. This leads to the Rayleigh-Jeans law.

High-speed computers have been used to compile tables of spectral radiance and related functions for a blackbody over a broad range of wavelengths and temperatures. There are also several radiation calculators, or slide rules, that are convenient for engineering use. Some of these make use of the fact that a log-log plot of blackbody radiation vs wavelength has the same shape at all temperatures. The radiance curve for a given temperature blackbody may then be obtained by sliding the universal curve in such a way that its peak falls on the line corresponding to the Wien displacement law (see Fig. 1 in INFRARED RADIATION). It is convenient to remember that the peak radiance varies as T^5; that a quarter of the total power radiated lies between $\lambda = 0$ and $\lambda = \lambda_{max}$ (see Fig. 2); and that this power, on the short-wavelength side of the peak of the radiation curve varies as $T^{6.4}$.

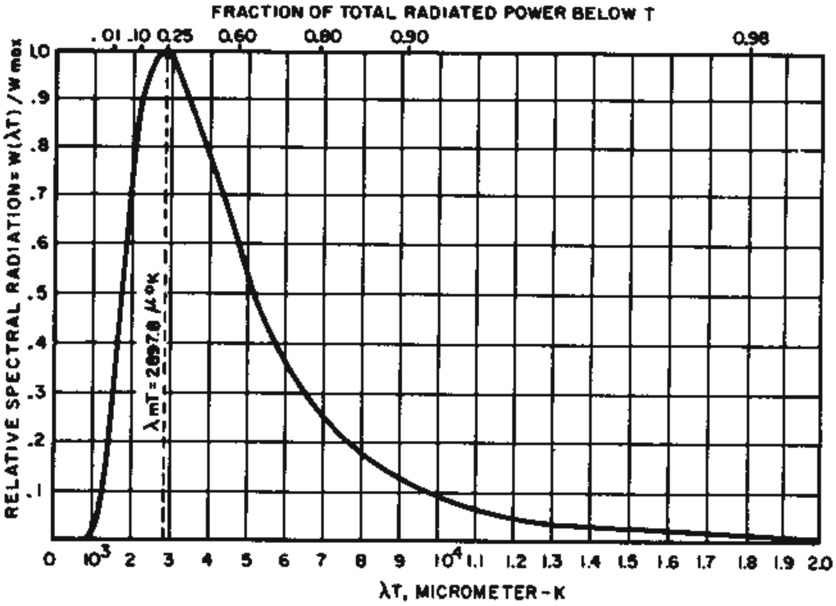

FIG. 2. General blackbody radiation curve.

At wavelengths less than λ_{max}, the monochromatic radiance changes as T^n, where $n \cong 15000/\lambda T$. For an object at 1500 K, for example, observed through an optical pyrometer with a filter transmitting at 0.6μm, $n \cong 17$. This relatively high value of n is advantageous in reducing the temperature error resulting from uncertainty in the observed radiance or the emittance of a surface.

The ratio by which the surface radiation falls short of that of an ideal blackbody, is denoted as the surface's emissivity or emittance. Some authorities prefer to use "emissivity" as a material property characterizing an ideally pure and polished surface of the material, as distinguished from the properties of engineering samples. The emittance of some substances, though less than one, is essentially the same at all wavelengths. Such radiators are referred to as gray bodies. In most real substances, however, emittance varies as a function of wavelength as well as temperature.

If one can make a reasonable estimate of the emittance of a surface, a measurement of its thermal emission will give its temperature. This is the basis of contactless, radiometric temperature measurement. Should the emittance be unknown, but assumed to be relatively constant, a temperature may be inferred from the shape of the spectral distribution curve. Other schemes have also been used to determine the temperature of surfaces of undetermined characteristics.

The *color temperature* of a body is that temperature of a blackbody which has the same ratio of radiances as the selective radiator in two spectral intervals. In general, the value of the color temperature depends on the choice of the two spectral intervals. However, if these wavelengths are in the visible region, the color temperature is relatively insensitive to the specific values chosen. The color temperature of a gray body equals its true temperature. When dealing with semitransparent materials such as glass in the near infrared, one speaks of volume emissivity, which in turn is related to the optical constants of the material.

In some solids, and especially in gases and flames, the emittance in some spectral regions is much larger than in others. Kirchhoff's law tells us that gases radiate well in the same spectral regions where they have strong absorption bands. One must bear in mind, however, that the shape of an absorption band changes and new "hot" bands may appear as the gas temperature rises, so emittance and absorptance must be equated at the same temperature. The thermal radiation from a cool, low-pressure gas, is resolvable into discrete emission lines, as explained by the quantum theory. Increased temperature and pressure cause the lines to broaden as a result of molecular interactions and perturbations of the energy levels, and new lines also appear. As the optical path length increases, the emissivity of the gas approaches unity, at first at the line centers, where the absorptance is strongest, and then extending into the line wings. Eventually, when the gas density and thickness are great enough, as on the sun, the original line spectrum assumes the appearance of a blackbody distribution. A good example of this is seen when one compares two infrared emission spectra of earth's atmosphere—first looking overhead from a mountain top, and then along the horizon at a humid seacoast. The latter spectrum's blackbody-like shape (from which, incidentally, the atmosphere's temperature may be inferred) contrasts strongly with the peaks and valleys of the former.

In strongly absorbing spectral regions, only a relatively thin layer of gas, nearest the viewer, contributes to the observed radiance, the radiation by the more distant molecules having been almost completely absorbed by the nearer molecules. For this reason, the Fraunhofer lines in the solar spectrum, occurring at strongly absorbing atomic wavelengths, originate in the cooler outer part of the sun and appear relatively dark.

In exceptional situations, it is possible to circumvent the consequences of Kirchhoff's law. The Doppler shift, due to the relative motion of the earth and Mars, prevents the narrow line radiation by planetary H_2O from being reabsorbed by terrestrial water vapor. As a result, it has been possible to estimate the water vapor concentration on Mars (see DOPPLER EFFECT and PLANETARY ATMOSPHERES).

The spectral emittance of gases is an important area of investigation, with respect to such topics as the heat budget of the earth; the composition of planetary atmospheres; and radiation by flames and rocket engines. The analysis of the gas radiation transfer in many of these applications is complicated by the fact that conditions are nonisothermal.

The Welsbach mantle (or the Coleman lantern) is an example of selective radiation in a solid; in this case, its efficiency as a source of visible light is enhanced by the high emittance in the visible, and low emittance in the near infrared, of the mixture of thoria and cerium oxide of which the source is composed. For some metals, the emittance varies as $\sqrt{T/\lambda}$, while in others it may vary in a more complicated way. In either case, the form of the spectral distribution curve differs from that of a blackbody, and the total emission will usually vary more nearly as T^5 than as T^4. The emittance of a tungsten filament is approximately 0.45 in the visible spectrum, decreasing to less than 0.2 in the infrared. Its visible efficiency increases as its operating temperature increases.

By considering the equilibrium between incoming and outgoing radiation, one can show that the sum of the radiant absorptance a, reflectance r, and transmittance t, is unity. These quantities refer to monochromatic, hemispherical radiation from the surface and do not take into account the way it is distributed geometrically. For an opaque surface, $a + r = 1$, and since by Kirchhoff's law $a = e$, the emittance, we have $e = 1 - r$. Errors may result if due account is not taken of angular and spectral factors in the application of this equation. Early studies of the angular distribution of radiation from surfaces led to the formulation of Lambert's law, i.e., $J_\theta = J_n \cos \theta$, where J_θ is the source intensity or radiant power per unit solid angle in a direction making an angle θ with the normal to the surface, and J_n is the intensity along the normal. A surface that obeys Lambert's law is said to be perfectly diffuse, like a sheet of blotting paper in the visible. Its radiance, N (intensity per unit of projected area of source), is constant and independent of θ. Integration over the hemisphere leads to the relationship $W = \pi N$. A truly black surface obeys Lambert's law exactly. Although the law is a useful approximation for many radiators and reflectors, there are numerous exceptions. The emissivity of clean, smooth surfaces of some materials has been studied from a basic theoretical viewpoint and related to their optical constants. The analysis, whose results agree generally with experimental determinations, indicates that for electrical conductors, the normal emissivity is quite low and increases with θ; whereas insulators have relatively high normal emissivity, decreasing at large values of θ. Insulators, as well as metals covered with thick oxide films, behave approximately as diffuse radiators. In the case of many practical materials, however, the surfaces are either rough or chemically complex, and it is necessary to rely upon empirically determined emittances. Many substances, such as concrete, porcelain, and paper, have a higher absorptance for long- than for short-wave radiation. Many more data are needed on the spectral emittances of various materials under different conditions. In addition to their engineering uses in radiant heat transfer calculations, emittance and reflectance data have been used to deduce the chemical composition of the moon and planets.

Space vehicles absorb energy from the sun and lose it by radiation to space. By the application of coatings with suitable radiative characteristics, the internal temperature of a vehicle may be controlled within desired limits. The quantity a/e is often used to characterize such coatings. It refers to the ratio of the absorptance of solar radiation (approximated by a 6000 K blackbody) to the emittance at the temperature of the vehicle's surface. High-temperature emittances of many materials are being studied in connection with the design of ablative nose cones, and reentry vehicles.

Although all objects are continuously emitting and absorbing thermal radiation, specially designed sources are available for particular applications. For industrial heating and drying, for example, there are numerous varieties of heaters and infrared lamps. The latter are similar to incandescent lamps used for lighting purposes, but designed for operation at lower temperatures, with reduced visible output. In recent years, high-temperature lamps with quartz envelopes have been used increasingly for both heating and illumination. The clarity of the envelope is maintained, and the filament life prolonged, by incorporating a small amount of iodine within the tube. Tungsten that has evaporated onto the tube walls combines with the iodine vapor to form tungsten iodide. This is a gas which decomposes thermally when it comes in contact with the hot filament, thus replenishing the latter and liberating the iodine for use again.

For scientific purposes, such as calibrating a radiometer or spectrometer, a reproducible source of known characteristics is essential. Sources with characteristics approaching those of an ideal blackbody, have been built for operation from cryogenic temperatures to about 3000 K. Most of the commercially available blackbodies, which come with a variety of aperture sizes and in many configurations, use a conical cavity (Fig. 3), the interior walls of which are oxidized or blackened to decrease their reflectance. Electrical heating is most often used, in conjunction with a thermostatic controller. A number of authors have discussed the considerations involved in designing a blackbody, and it is possible to calculate how closely a given design approximates an ideal blackbody. It is sometimes necessary to have a black radiating surface whose area is impractical to obtain with a cavity-type body. Flat surfaces have been coated with "blacks" whose emittances are close to unity over a broad spectral

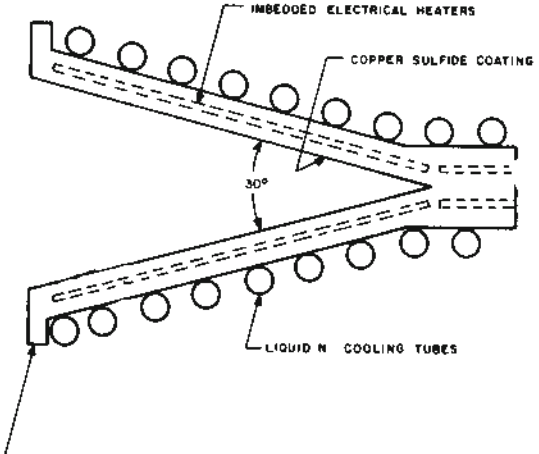

FIG. 3. Schematic representation of a conical blackbody that can be used at high or low temperature.

range. These are generally not suitable for high-temperature use, however. Other methods that have been used to obtain high-emittance surfaces include: wedges or closely stacked razor blades viewed edge on, a telescoped cone pattern similar to that of a Fresnel lens impressed on a flat surface, a vortex in a liquid or molten metal, etc. The National Bureau of Standards has calibrated some special tungsten filament lamps for use as spectral irradiance standards from about 0.3 to 2.6μm. Beyond 2.6μm, strong, but variable, atmospheric absorption becomes troublesome. When using infrared sources for quantitative thermal radiation measurements, one must make due allowance for the absorption at different infrared wavelengths by the CO_2 and water vapor in the atmosphere between the source and the instrument being calibrated.

For reasons of compactness and convenience, it is sometimes desirable to use non-blackbody sources of thermal radiation. Among the most common of these are the Nernst glower, which is a hollow rod approximately 25 mm long and 2 mm in diameter, made of a mixture of oxides of zirconium, yttrium, and thorium and the globar, a rod of bonded silicon carbide. These are most useful at the shorter infrared wavelengths. In the far infrared, mercury discharge tubes and other sources have been used. At long wavelengths, the power output of a thermal radiator increases almost linearly with temperature, as indicated by the Rayleigh-Jeans law, and inordinately high temperatures would be required for a significant increase in power. Nonthermal sources, in particular lasers, or other coherent radiators can generate much greater power. Lasers that can be tuned over a considerable spectral range are coming into increasing use.

In order to study the properties of materials at very high temperatures without contamination, it is convenient to heat them by thermal radiation rather than convection. Solar furnaces have been used for this purpose, as well as arc-imaging furnaces, in which a specially designed high-intensity carbon arc replaces the sun as the source.

Thermal radiation can be detected by eye when the source temperature is sufficiently high. Figure 4 shows the luminous efficiency of a blackbody as a function of temperature. And although its sensitivity is greatly reduced at longer wavelengths, the human eye has some sensitivity to radiation at wavelengths as long as 1.2μm. Some insects, such as moths, respond to thermal radiation at even longer wavelengths, and some snakes can detect the heat of a warm-blooded animal at an appreciable distance.

Many types of detectors have been developed for thermal radiation. In some of these, known as quantum detectors, the energy of the incident photon must exceed some lower limit, but its effects are very rapid. An example is the lead sulfide detector, which responds to wavelengths less than 3μm, or HgCdTe, which is most sensitive to radiation around 10 μm, where objects at ambient temperatures emit most copiously. In others, thermal radiation of any wavelength can be detected by virtue of its effect on some physical property of the detector. The response of the latter kind of detector is slower than that of the former. Among the thermal detectors are: metal and thermistor bolometers, in which the absorbed radiation causes a slight temperature rise and consequent change in the resistance of the detector; thermocouples and thermopiles in which the differential heating of two junctions of dissimilar materials generates an emf; pyroelectric crystals whose polarization changes with temperature; the Golay cell or pneumatic detector, where the absorbed radiation heats a gas and distorts a reflecting optical element; the evaporograph in which the incident radiation causes differences in the rate of evaporation of a thin oil film and the resulting differences in thickness give rise to interferometric patterns. Numerous other physical mechanisms have been exploited for radiation detection. (The more usual infrared de-

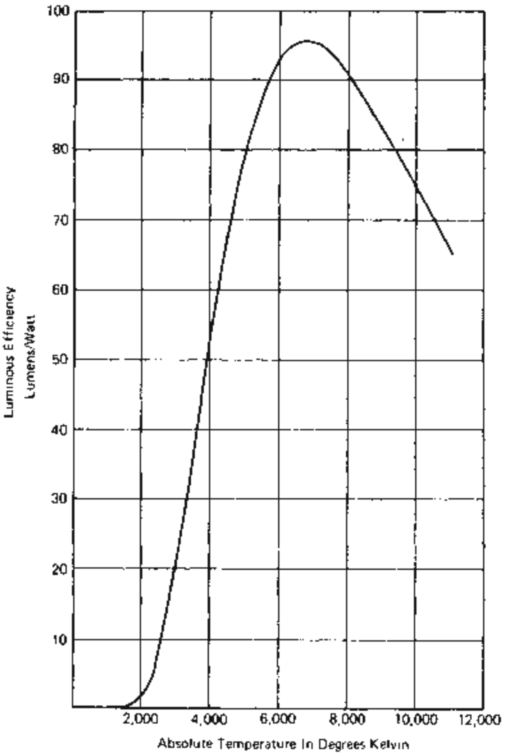

FIG. 4. Luminous efficiency of blackbody radiation (based on K_{max} = 683 lumens/watt). (This K_{max} corresponds to a choice of 2041 K for the freezing point of platinum.)

tectors are discussed under INFRARED RADIATION.)

Recent developments in detector technology include: (a) charge-coupled detectors (CCD). These are devices that arrange a relatively large number of discrete detectors in a self-scanned array, requiring only one output channel. (b) Negative-electron-affinity photoemitters, whose uses may extend the use of photomultipliers to longer wavelengths in the near IR. (c) Nonlinear heterodyne detectors for both optical and IR.

For coverage of an extended field of view, mosaics of conventional detectors have been used, as well as electronic imaging tubes such as infrared vidicons and orthicons. Whether by such detectors or by raster-like scanning of a small elemental field of view, it is possible to study the temperature pattern of an extended source of thermal radiation. Thermography is such a process, in which the temperature gradients are displayed in visible form, e.g., on photographic film, or in real time, on a cathode ray tube. When properly interpreted, the thermograph can be a valuable diagnostic aid to the physician. Thermography is also used industrially, e.g., for aerial surveys and energy audits. In Sweden, thermal scanning is required before final acceptance of a new building. Microscopic thermography is used in the design and nondestructive testing of integrated circuits. In interpreting the observed patterns, one must bear in mind that radiance variations may result from differences in either or both surface emittance and surface temperature from point to point. This fact is less troublesome in medical thermography because the emittance of the body is close to unity. In a similar way, the radiometry of lakes, rivers, and oceans by an instrument looking vertically down from an aircraft, takes advantage of the near-unity emissivity of water within the range of wavelengths to which the radiometer is sensitive. Thermal pollution can thus be detected remotely. Oil films, due to pollution, or occurring naturally in association with schools of certain fish, can also be detected; but the significant factor here is the effect of the oil on the water's emissivity. In the near infrared and visible, as well as in the microwave region, water is not quite so opaque as it is around 10 μm. Microwave radiometry, therefore, can give information about the water temperature slightly (1 or 2 mm) below the surface, rather than at the surface itself. Microwaves are less subject than infrared to atmospheric absorption and are better able to penetrate overcast and clouds.

Satellite observations of the thermal radiation of the oceans and continents are of meteorological value. For example, satellite radiometers record the radiation by atmospheric CO_2 in a series of narrow wavelength intervals centered around the strong absorption band at 15 μm. Knowledge of the varying emittances of the atmosphere at these wavelengths, together with the use of mathematical inversion techniques, permit one to compute profiles of temperature vs height on a global scale, for a variety of atmospheric conditions; these are generally in good agreement with data from radiosondes. Data from another infrared interferometric spectrometer have yielded distribution profiles for atmospheric water vapor and ozone.

Earth resources are being surveyed by radiometers in LANDSAT and orbiting SKYLAB missions, with applications to agriculture, forestry, fishing, geology, mining, and tracking sea-ice.

RADIO ASTRONOMY

Radio astronomy, the study of radio-frequency radiation from celestial objects, began in 1932 with the discovery of radio emission from the galaxy by K. G. Jansky at the Bell Telephone Laboratories. Fourteen years later, the U. S. Army Signal Corps and the Hungarian scientist Z. Bay independently succeeded in obtaining radar echoes from the moon—thus launching the field of *radar astronomy*. Since the 1960s, *space radio astronomy* has investigated the low frequency radio waves that cannot penetrate the earth's ionosphere; a major achievement was the 1968 launch of the Radio Astronomy Explorer satellite.

Radio Telescopes A radio telescope is composed of one or more aerials and associated radiometers. The design depends on the intended operating frequency range. High spatial resolution, which implies large antennae or at least large separations between antennae, has proven to be perhaps the most important design goal. At first, high resolution was required because observations at meter wavelengths were limited by confusion of adjacent radio sources. More recently, high resolution at wavelengths of a few cm has been crucial in investigating the nature of the core regions of radio galaxies where jet phenomena originate.

L. L. McCready, J. L. Pawsey, and R. Payne-Scott at Sydney introduced the technique of interferometry to radio astronomy in 1946. They used the Lloyd's mirror principle, with the ocean surface as reflector, to measure the angular diameter and position of a localized source of solar radio emission.

Two-element interferometers were employed for radio sky surveys at the Mullard Radio Astronomy Observatory; others, notably those at Jodrell Bank, Owens Valley, and Nançay, yielded basic data on the brightness distributions of individual sources by means of variable-baseline interferometry. This technique later was generalized to the case where there are two or more antennae, located any distance apart, and not connected to each other in any sense. In this very *long baseline interferometry* (VLBI) a given radio source is observed simultaneously from each antenna location, with the radiometer output being recorded on magnetic tape, along with an atomic clock signal. Then, the taped data from all antennae are combined in a computer, and a resolving power corresponding to the separation of the antennae is obtained. Thus, the earth's diameter is the limiting baseline. In some cases, the signals are combined in real time with the aid of a communications satellite that provides a link to the central computer; then the complications of synchronizing clocks and combining tape recorder playback data are avoided. For higher spatial resolution at the same operating frequency, the VLBI technique can be surpassed only if it is extended into space, where larger baselines are possible. One or more of the aerials would be mounted on orbiting satellites or even on another celestial body. Such experiments have been proposed to NASA.

Aperture synthesis, a technique introduced by M. Ryle and A. Hewish at Cambridge, involves the use of multiple aerials, at least some of them movable, to simulate a larger array. Data taken with the aerials in each of several different relative orientations are combined mathematically. This technique can sample a large range of spatial frequencies and thus provides more complete two-dimensional mapping than is usually possible by means of VLBI, although the resolution is not as great. Aperture synthesis is used in the Very Large Array (VLA), currently the most powerful existing radio telescope, near Socorro, New Mexico. The VLA is an array of 27 parabolic dish reflectors, each 25 meters in diameter. At its highest operating frequency, the VLA produces radio images about as sharp as photographs made with visible-light telescopes.

The 250-foot dish at Jodrell Bank, near Manchester, was the largest fully steerable parabolic antenna until the construction of the 100-meter antenna near Bonn in 1972. In the Southern Hemisphere, the major dish antenna is the 210-foot telescope at Parkes, New South Wales. The 1000-foot antenna at Arecibo, Puerto Rico is built in a natural limestone sinkhole; it is perhaps the most important of the existing fixed reflectors and is used for radio astronomy, radar astronomy, and for remote sensing of the ionosphere.

Gain stability, phase stability, and low receiver noise temperature are the prime desiderata in a radiometer. Compensation for gain variation by switching between the object signal and a reference standard was achieved by R. H. Dicke in 1946. Many refinements of this technique have been developed. Traveling-wave tubes, masers, parametric amplifiers, and tunnel diodes have all been used for low-noise amplification, particularly in the microwave frequency range, where the average intensity of cosmic sources is low. Newer detection methods that show promise for high-frequency radio astronomy include the use of Josephson junction and other solid-state, cryogenically cooled devices. Multichannel and autocorrelation receivers are used for spectral line studies.

Cosmic Radio Sources In the solar system, radio emission has been detected from the sun, from each of the planets except Pluto, from the Moon and some other planetary satellites including Saturn's rings, from a few large asteroids, and from several comets.

Solar radio waves are observed from the quiet solar atmosphere and from transient phenomena such as active regions and solar flares. Bursts of low-frequency radio emission associated with plasma ejected by flares and erupting solar prominences have been tracked with radio telescopes on orbiting satellites as the plasma moved out from the solar corona and through the inner solar system.

The radio emission from Mercury and Mars is thermal and originates at and near the planetary surfaces. Venus is a much stronger thermal radio source than expected for a blackbody in equilibrium with solar radiation; its radio emission arises in the atmosphere, which is heated by a greenhouse-type process. At microwave frequencies, Jupiter, Saturn, Uranus, and Neptune also are stronger thermal sources than expected, which indicates that their radio emission is partially self-generated in addition to its component of reradiation of energy from sunlight. At low frequencies, Jupiter is a variable, nonthermal source, as revealed by the discovery of Jovian radio bursts in 1955 by B. F. Burke and K. L. Franklin of the Carnegie Institution. The occurrence rate of the bursts is controlled by the position of the Jovian satellite Io. In the decimeter range, Jupiter is also the source of nonthermal continuum emission associated with the planetary magnetosphere.

Lunar radio emission is thermal in character and at some frequencies it varies in strength with the cycle of lunar night and day. Analysis of the signals provided basic data on the character of the near-surface soil and rock prior to the first lunar spacecraft landings. Centimeter-wave observations of the large Jovian moons Callisto and Ganymede reveal thermal emission as expected for a bare satellite surface in equilibrium with solar radiation, but similar measurements of Saturn's large moon Titan, which has an atmosphere, indicate a higher temperature. This confirms that the surface of Titan, at positions far from the subsolar point, is warmed due to the presence of the atmosphere. The rings of Saturn are weak radio emitters and indeed absorb some of the radio emission from the planet itself, but they are strong reflectors of radar at wavelengths around 12 cm. These properties of the rings are consistent with the hypothesis that they consist of numerous lumps of ice, typically of snowball size, although larger lumps may also be present.

Radio emission is detected from some of the larger asteroids at cm wavelengths. Observations of Ceres and Bamberga suggest that the surfaces of the rocky asteroids are covered with dust layers in at least some cases. Radar measurements of asteroids at S band (wavelength 12.6 cm) and X band (3.54 cm) reveal the surface properties of radar albedo, scattering phase function, and polarization as they vary while an asteroid rotates, thus presenting different areas of its surface for observation. Radar measurements have been obtained from the largest asteriods in the asteriod belt between Mars and Jupiter and for several of the small astroids whose orbits take them within the orbit of Mars and thus fairly close to earth.

Continuum radio emission from a comet was first observed in Comet Kohoutek (1973 XII) and Comet West (1976 VI) by R. W. Hobbs, J. C. Brandt, and S. P. Maran. In each case, the emission was transient and has been ascribed to thermal radiation from the icy-grain halo, a cloud of water-ice grains around the cometary nucleus. Much effort has been invested in searches for molecular line radio radiation. The most definitive work has been done on the OH radical, whose radio transitions have been observed both in emission and in absorption (the latter against the galactic background). OH is thought to be a daughter product from the dissociation of cometary water. Studies of OH radio emission in several comets confirm the high production rates of water vapor (itself not conclusively detected) by sublimation from the ice state that are predicted by the "dirty snowball" theory of the cometary nucleus.

Among stars in the galaxy, novae, flare stars, interacting binary systems, red giants, pre-main sequence stars, and pulsars have been studied by radio astronomers. In novae, radio emission originates in the gaseous envelope ejected by the stellar explosion. Flare stars are small, cool (T = 2900 K, typically) objects. Their radio outbursts are of much greater absolute strength than typical solar flare events. Binary stars observed at radio frequencies, notably by R. Hjellming and C. M. Wade of the National Radio Astronomy Observatory, include the famous eclipsing systems Algol and beta Lyrae and several binaries associated with x-ray sources, including Scorpius X-1 and SS 433. SS 433, noted for its twin rotating beams that produce optical radiation with enormous and rapidly changing Doppler shifts, is an especially striking radio source. VLA observations show a characteristic corkscrew pattern in the spatial distribution of radio brightness. This is interpreted as revealing the presence of discrete radio-emitting plasmoids that follow ballistic trajectories once they are ejected from the rotating beams. Continuum radio emission from red giant stars such as Betelgeuse is attributed to their extended outer atmospheres. Pulsating red giants, such as long period and semi-regular variable stars, are often associated with molecular line emission from a circumstellar distribution of small sources of maser radiation. Molecules involved in masering include OH, water, and SiO. Weak continuum radio emission has been detected from several T Tauri stars, which are thought to be objects resembling the sun as it was roughly five billion years ago, still contracting as it approached the main sequence, and possessed of a powerful stellar wind. Pulsars, discovered in 1967 by A. Hewish and S. J. Bell at Cambridge, are sources of discrete, periodic pulsed signals, with typical duty cycles of about 5%. The pulse periods of the over 300 known pulsars range from 0.00156 sec to 3.75 sec. In general, the periods are gradually lengthening. The objects responsible for the emission do not actually emit pulses; rather, the pulsar phenomenon is due to the beaming of nonthermal radiation from rotating, highly magnetized neutron stars. As a pulsar beam sweeps along the surface of the earth (at a rate, in the case of the Crab Nebula pulsar NP 0532, of 10^{24} cm/sec!) it is detected momentarily at a given observatory, and the effect is that of a "pulse." Only about 1% of the known radio pulsars seem to be members of binary star systems (see PULSARS).

Besides the types of stars mentioned above, radio observations of our Milky Way galaxy reveal emission from the interstellar medium and clouds, the galactic cosmic ray gas, H II regions such as the Orion Nebula, planetary nebulae such as the Ring Nebula, supernova remnants such as the Crab Nebula, stellar-wind-blown interstellar bubbles such as the Rosette Nebula, and several large gaseous structures of uncertain origin, the galactic spurs or "giant loops."

At a 1944 Leiden Observatory colloquium, H. C. van de Hulst predicted that a spectral line could be observed by radio astronomers, who previously had worked only in the continuum. He referred to the 1420-MHz hyperfine transition in the ground state of neutral hydrogen, the now-famous 21-cm line. Seven years later, H. I. Ewen and E. M. Purcell at Harvard made the first successful detection of this radiation. The importance of the 21-cm line is twofold: (1) it originates in an extremely abundant constituent of interstellar matter, atomic hydrogen; (2) Doppler shifts are readily measurable in line radiation but not in the continuum. As a result of many 21-cm surveys, notably by the Harvard, Leiden, and Australian groups, the distribution of interstellar atomic hydrogen in the galaxy was mapped and it was possible to investigate the dynamics of the interstellar gas. In 1963, A. H. Barrett, M. L. Meeks, and S. Weinreb at M.I.T. detected the 18-cm lines of OH. Since then, the line radiation of several dozen molecules, including a few ions and some interesting organics such as formaldehyde and methyl alcohol, has been discovered in radio studies of the galaxy. During the mid- and late 1970s, mm-wave surveys of CO line emission were made. CO is second in abundance among interstellar molecules to molecular hydrogen. The latter is not directly observable with radio telescopes, but its abundance is inferred from CO mm-wave line radiation. The CO sky surveys revealed that in the inner portion of the Milky Way, molecular hydrogen is the most abundant constituent of the interstellar gas and comprises more than 90% of the hydrogen present, in contrast to other portions of the galaxy, where hydrogen is mostly atomic or ionized. Much of the molecular hydrogen and CO is localized in so-called giant molecular clouds, regarded as the most massive individual structures in the galaxy. In addition, a number of recombination lines have been detected in the radio spectra of H II regions. These arise from upper levels with very high principal quantum numbers, e.g., $n = 109$ in hydrogen.

Beyond the Milky Way, the known radio sources are galaxies, quasars, and the microwave background radiation, as well as individual stellar and nebular sources in some of the nearer galaxies. Radio astronomers originally considered two categories of galaxies. A weak emitter, or ordinary galaxy (such as our own system, or M31 in Andromeda) typically radiates 10^{38} erg/sec in radio waves, compared with 10^{44} erg/sec in the optical region. The strong emitters, or radio galaxies, each produce up to 10^{45} erg/sec in the radio range alone. In both types of galaxy, the bulk of the radio continuum is accounted for by synchrotron radiation from relativistic electrons traveling through an associated weak, large-scale magnetic field. D. S. Heeschen and C. M. Wade at Green Bank made a systematic study of bright galaxies; they concluded that all normal spiral and irregular galaxies are probably weak radio sources. On the other hand, the strong emitters tend to be giant elliptical galaxies, often distinguished by peculiar optical phenomena. Another, rare type of radio galaxy is the Seyfert galaxy. These objects are spiral galaxies characterized by strong optical emission line radiation from their central regions. In the early 1960s, the interferometric studies of A. T. Moffet and P. Maltby at the California Institute of Technology and of J. Lequeux at Nançay led them to divide resolved extragalactic sources (galaxies and quasars) into three groups on the basis of brightness distribution: simple, double, and core-halo sources. C. Hazard and M. B. Mackey at Sydney used the method of lunar occultations to resolve detail as small as 0.5 second of arc and detected triple and even more complex structure in some sources. Moffet found that the emission in a given lobe of a double source tends to be concentrated at the end furthest from the other lobe, in accord with an expanding model. With the exception of this last result, nearly all the findings of the early investigations of brightness distributions in extragalactic sources have been eclipsed by modern work at much higher spatial resolution, made possible by the advent of larger interferometers, aperture synthesis, and the VLBI technique. Core-halo sources, for example, have disappeared from the astronomers' lexicon. The modern work reveals that radio galaxies possess a *central source*, generally much smaller and less luminous than the associated radio sources located to either side. Jet structures or *beams* connect the central source with the lobe of emission to either side; sometimes two or more co-aligned pairs of lobes display striking symmetry about the central source. The central source is identified as the site of the "machine," the unknown generator of high-energy particles that are ultimately responsible for the radio emission from every aspect of the radio galaxy. The "machine" is widely believed to consist of a massive black hole, powered by accretion of matter from the surrounding central region of the radio galaxy. The jet structures trace the path by which energy in the form of particles and/or waves is transmitted to the lobes. The presence of an accretion disk may account for the characteristic presence of two oppositely directed jets. Deviations of some jet pairs from simple geometry are taken to suggest the encounter of material in the jets with intergalactic plasma associated with the cluster of galaxies in which the source is located, or with motion (e.g., in a binary system orbit) of the central "machine."

VLBI observations reveal superluminal motion of individual plasmoids in some radio galaxies whose distances are known from redshifts. Apparent velocities of several to ten times the speed of light are found. These are ascribed to a sort of optical illusion due to the ejection of the emission sources nearly in the direction of the observer and at a significant fraction of light speed. The superluminal effect arises from the circumstance that the light travel time from source to observer associated with a plasmoid observed at one epoch is not the same as that of the same plasmoid observed (say) a year later.

The identification in 1963 by M. Schmidt at the California Institute of Technology, C. Hazard in Australia, and others of a new class of radio source, the quasistellar objects, now called *quasars*, had a profound impact on astrophysics. Originally thought to be peculiar stars within our galaxy, quasars are now known to be, as a class, the most distant and luminous objects in the universe. Although their radio emission typically is similar to that of a strong radio galaxy and the optical emission rates are up to 100 times greater than those of any known galaxy, they occupy volumes that are extremely small compared to typical galactic dimensions. Increasing evidence from optical studies suggests that quasars are eruptions at the centers of unseen host galaxies that are lost in the glare of the quasars in telescopic photographs. Quasars exhibit many of the same jet and superluminal phenomena described above for radio galaxies. Radio observations also show that quasars are variable in luminosity, radio spectrum, and polarization. The source of quasar energy has been regarded as a major problem. Among the possibilities considered have been gravitational collapse of large masses, a high rate of supernova explosions due to collisions in dense star clusters, the mutual annihilation of matter and antimatter, and energy derived from the slowdown of rotating, magnetized stars. Currently, it is thought that the mechanism may be accretion into a giant black hole, as supposedly occurs in a strong radio galaxy. At least for nearby and thus present-epoch quasars, collisions between the host galaxies and other galaxies may provide the accreting mass. If both strong radio galaxies and quasars are energized by a similar process in the centers of galaxies, what accounts for the distinction between quasars and radio galazies? According to one reasonable theory, quasars represent the form that the strong radio galaxy phenomenon assumes when it occurs in a spiral galaxy rather than in an elliptical galaxy. Seyfert galaxies may be weak forms of the quasar phenomenon, in which the central eruption is not bright enough to drown out the surrounding galaxy in photographs.

Radio Astronomy and Cosmology Radio astronomy has provided the single most important observation available to cosmologists—the discovery of the *microwave background radiation*. Reported in 1965 by A. A. Penzias and R. W. Wilson of the Bell Telephone Laboratories, this radiation appears to arrive in nearly equal amounts from all directions in space. It has a spectrum corresponding with high precision to that of a blackbody at 2.7 K and is almost certainly the redshifted emission from the "Big Bang" that occurred at the origin of the universe. More specifically, it is interpreted as radiation from the last moment after the Big Bang when the universe was still opaque. After that moment, the ionized hydrogen that filled the universe recombined. Since the microwave background consists of emission from the last moment of the opaque early universe, it represents radiation from the most ancient epoch that can ever be observed, and thus from the greatest observable distance in space. Precisely such radiation was predicted by G. Gamow. A slight departure from isotropy in the observed background results from the motion of our galaxy with respect to distant galaxies. Surveys of extragalactic radio sources have been analyzed for comparison with the predictions of cosmological theories as to the number of sources that can be observed in each range of flux density, the relation between the angular diameters and flux densities of sources, and similar tests. All such well established studies are consistent with the universe as an expanding and evolving system.

RADIOACTIVE TRACERS

The use of radioisotopes as tracers rests on the nearly indistinguishable physical and chemical properties of all the isotopes of a given element. Proper incorporation into a material of a radioisotope that can be measured with appropriate radiation detectors provides a means of studying the behavior of the material or a component thereof. Thus, a radioisotope may be used to study the chemistry or physics of an element, a chemical compound, or a mixture of substances. For example, ^{131}I, a radioisotope with an eight-day half-life, has been used to study the distribution of iodine in multiple phase systems, to study the biochemistry of ^{131}I-tagged diiodotyrosine, and to measure the flow rates of underground streams.

Shortly after World War II, the U.S. Atomic Energy Commission made a variety of radioisotopes available from the Oak Ridge National Laboratory. Subsequently, additional suppliers have been established in the United States and in other countries. One may now purchase radioisotopes of a majority of the elements. Useful radiotracers are absent only for the elements He, Li, and B. Most radioisotopes are produced in nuclear reactors, but accelerator-produced species also comprise a useful selection. Suppliers are listed in several guides, such as the one published by the American Nuclear Society.[1]

Facilities for the formation of radioactive tracers directly within a sample or test material have also become available. For example, it is possible to form radioactive iron 59 within a sample of steel by irradiating the sample in a nuclear reactor.

The wide choice of radioisotopic tracers and the availability of sensitive detection systems to fit most circumstances have made possible the use of radiotracer techniques in many branches of science, medicine, and industry. Radiotracers have a number of features that make their use generally attractive. Unlike other types of tracers, they provide unequivocal evidence of their presence by virtue of their own radiation. Most species of radioisotopes are inexpensive (although incorporation into a specific compound can be somewhat costly), and detection equipment can be obtained at moderate expense. Also, due to the excellent detection efficiency of available equipment, it is possible to carry out most experiments without undue health hazards. Investigators trained in the safe handling of radioisotopes can follow gas, liquid, solid, or mixed-state systems at the laboratory, pilot-plant or even full plant scale with complete safety.

The following examples of radiotracer applications comprise but a partial list of uses.

Absorption of gaseous or liquid-phase constituents can be readily studied with the aid of radiotracers. Either the deposition of tracer onto the substrate or the disappearance of tracer from its initial phase may be measured.

Analysis of chemical composition may be accomplished either by utilizing the reaction of tagged reagents or by "isotope dilution." An example of the former method is the use of^{110} Ag-tagged silver nitrate reagent in chloride determinations by the precipitation of AgCl from solution; a sharp rise in liquid-phase radioactivity indicates the point of essentially complete chloride precipitation. Isotope dilution utilizes an isotope of an element to measure the amount of the same element in a sample. It is based on the fact that the amount of radioactivity per unit weight of the element or compound (specific activity) in the tracer reagent will be decreased when the reagent is added to a solution containing the naturally-occurring element or compound. The change in specific activity is an analytical measure of the amount of the element or compound originally present in the sample.

Radiotracers may be used as analytical adjuncts, also. They provide a convenient means of checking the degree of completion of analytical steps, such as precipitation and extraction, and can provide a measure of chemical losses in analytical procedures. They may be used to mark compound locations in chromatographic separation procedures.

Many other aspects of chemistry have been elucidated with radiotracer techniques. Chemical reaction rates, equilibria, and mechanisms have been studied. Diffusion rates, exchange rates, solubility products, partition coefficients, dissociation constants, and vapor pressures have been measured. Processes due to the effects of high-energy radiation, photolysis, and catalysis have been unraveled. Many of the recent advances in biochemistry would not have been possible without the use of radioactive tracers, especially in the study of biological catalysis (enzyme reactions).

Many of the above subjects have been studied in connection with fields other than chemistry. Thus, while diffusion rates are of interest in elucidating rate-limiting chemical processes, they are also of considerable interest in electronics, metallurgy, and process industries. The self-diffusion of alloy components as a function of alloy composition and grain substructure has been investigated. Diffusion in other solid-state materials, such as semiconductors, has been measured. The specific sulfide surface area of metal sulfides supported on alumina has been determined by exchange of normal surface sulfur with ^{35}S-tagged H_2S. The rate of such exchange is of interest, and the final equilibrium state gives a measure of the surface sulfide area. These are examples of problems that are not amenable to solution with techniques other than the radiotracer method.

Industry has obtained marked economic benefits from radiotracer applications. Corrosion and wear studies can be carried out with rapidity and insight otherwise impossible. The corrosion of a steel pipe containing ^{59}Fe (produced by irradiating a section of pipe) can be followed *in situ* by measuring the appearance of radioactivity in the corrosive medium or by following the disappearance of radioactivity of the part. Similarly, wear of an irradiated part such as a piston ring, cylinder sleeve, or gear, can be measured *in situ*. Prior to the availability of radiotracers, such wear studies required frequent dismantling of machinery for weight measurements. Furthermore, it is now often possible to obtain detailed wear or corrosion patterns by autoradiography. The techniques used in wear studies have also been used to study the effectiveness of lubricants and the mechanism of wear prevention.

Radioactive tracers have been used to examine fluid processes. They are highly useful in detecting leaks and are used routinely to mark the interface between two different products moving consecutively through a pipe-line. The gamma rays from an isotope such as ^{140}Ba in soluble form at the interface can be discerned easily through the walls of the pipe. In a similar fashion, flow rates may be measured by quickly injecting a tracer into a stream and noting the time required for the radioactive pulse to travel the distance between two detectors or between the injection point and a single detector. Rapid injection and accurate timing may be avoided where the amount of radioactivity injected and the detection efficiency of a downstream detector are accurately calibrated. The total signal from the tracer is inversely proportional to the velocity with which it goes past the detector. The techniques have been used in pilot plants, refineries, chemical plants, and even to study the flow rates and patterns of rivers and ocean currents.

The disposition of materials in various process units has been evaluated. Stream splitting, recycling, residence times, entrainment in distillations, mixing, and unit inventories have been measured.

The techniques of use in industrial fluid processes also apply in other fields. Stream splitting in capillary gas chromatography sampling units has been studied. Blood flow rate, total blood volume, and heart function are examples of medical applications.

Many of the medical uses of radiotracers have been put to routine clinical practice. The radioimmunoassay (RIA) technique is a case in point.[2] In a typical RIA, antibody to a particular compound is fixed to an insoluble matrix. A known quantity of the insoluble preparation is first incubated with a given amount of unknown solution and then incubated with a known quantity of the compound that has been labeled with radiotracer. The amount of radioactivity on the insoluble phase after rinsing will be inversely proportional to the concentration of the compound in question in the unknown. This phenomenon, which is due to competitive binding, may be calibrated to give accurate determinations.

RIA is routinely used for assaying a wide variety of peptides and proteins. These include numerous hormones, enzymes, and antigens. A variation, known as the radioallergosorbent test (RAST), wherein an antigen is linked to the insoluble phase and an unknown is measured for the presence of antibody by competitive binding with labeled antibody, is also clinically useful.

A relatively new and promising application of radiotracers is positron emission transaxial tomography (PETT).[3] PETT enables measurement of fluid flow, metabolite reaction rate, surface reactions, membrane permeability, and other phenomena. The tool has been particularly useful for investigating tumors and disorders of the heart and brain. New understanding of several mental disorders of organic origin, together with promising procedures for their diagnosis, have been provided by PETT.

RADIOACTIVITY*

Radioactivity is the term applied to the spontaneous disintegration of atomic nuclei. It was one of the first and most important phenomena which led to our present understanding of nuclear structure. Credit for the discovery of radioactivity is usually given to Henri Becquerel, who made the observation in 1896 that penetrating radiation was given off by certain compounds of heavy elements in the absence of any external stimulus. Many other scientists were working in the field of radiation, however, and the announcement by Becquerel led to a flood of discoveries about the nature of the radiations which were emitted. A number of workers determined that certain of the radiations from these radioactive substances could be deflected in a magnetic field, and by 1900 three separate types of rays were identified. They were given the names alpha, beta, and gamma rays.

Distinction is frequently made between natural radioactivity, which was observed by the early workers, and artificial radioactivity which was first produced by F. Joliot and I. Curie-Joliot in 1934. These workers bombarded ^{27}Al with alpha particles to produce ^{30}P. For purposes of our discussion, we shall not distinguish between the sources of the radioactive material.

A discussion of radioactivity requires that mention be made of the stability of nuclei. Stable nuclear species or nuclides exist for all elements having proton numbers in the range from 1 to 83 except for elements 43 and 61 (technetium and promethium). In general, elements having even atomic numbers have two or more stable isotopes, whereas odd-numbered nuclei never have more than two.

The assumption is usually made that all possible nuclides were formed in the original atomic production processes, and that those which remain at the present time do so because of some inherent stability. In general, this stability involves the neutron-proton ratio, and a number of theoretical studies have been undertaken to determine the conditions for the maximum stability for nuclei.

Stability may be considered from three different standpoints: relative to the size and the number of particles in the nucleus, the ratio of the neutrons and protons in the nucleus, and the ratio of the total mass-energy of the nucleus. A nucleus which is unstable with respect to its size will emit alpha particles whereas a nucleus unstable with respect to its neutron-proton ratio may emit a negative or positive electron or may capture an electron. If a nucleus is unstable with respect to its total energy, the excess energy may be given off as gamma radiation which is electromagnetic in nature. Let us consider these emissions in more detail.

Alpha Emission It is evident that there are two types of forces existing in the nucleus. The first is a disruptive force arising from the repulsion of similarly charged particles. In addition, however, there are very strong attractive forces arising from the interactions of the nucleons. These attractive forces are very strong within the nucleus, but drop off quite sharply beyond about 10^{-12} cm from the center of the nucleus. Alpha particles, consisting of two protons and two neutrons, are, with certain exceptions, observed to come only from the larger nuclei. The mechanism of the emission process, however, is not a simple force phenomenon.

If we make calculations involving only the energies of the nucleus and the ejected particle, we should find, for example, that an alpha particle should come from a ^{226}Ra nucleus with approximately 27 MeV of energy. Instead, the emerging particle is observed to have about 5.3 MeV. This difference in energy cannot be explained using classical energy computations. The explanation of the alpha emission is usually given in terms of a "tunneling" effect, which is a quantum mechanical description first developed by Gamow and by Gurney and Condon. There are two equivalent ways of looking at this effect. One is to consider the alpha particle as being in motion inside the nucleus. In this picture, we visualize the particles as striking the potential "wall" of the nucleus. According to the quantum mechanical treatment for a particle striking such a barrier, there is a finite probability of passing through the barrier and appearing on the outside. Calculations making use of this probability give correct values for the observed half life and energies of the alpha particles from radioactive nuclides.

The other description of this process considers the alpha particle as being a wave packet with a very high probability of being found within the nuclear radius, but also having a finite probability of being outside the nucleus. According to

*Editor was unable to locate author. Article is reprinted from first edition.

this notion, the probability of finding the alpha wave packet at a distance greater than the nuclear radius, likewise gives the proper lifetime and energy values. It can be shown that this type of radioactivity is more probable in elements of high atomic number.

Beta Radiation There are over 800 nuclear species which have been artificially produced in the laboratory. Nearly all of these have been produced by the reactions which give rise to a net gain or loss of neutrons from the stable nuclei. In such a case the residual nucleus is characterized by having a neutron-proton ratio higher or lower than stable nuclei of that element. Similarly, if one considers alpha-emitting nuclei as being the "stable" nuclides for elements above lead, certain nuclides may be formed after the alpha emission with neutron-proton ratios higher or lower than the original element. The general decay process for nuclides with differing n/p ratios involves the reorganization of the nucleus in a manner which will leave a nucleus having a neutron-proton ratio corresponding to that requisite for stability.

Let us first consider the case in which a nucleus has a neutron-proton ratio higher than a stable isotope of that element. For example, the nuclei of all stable phosphorous atoms contain 15 protons and 16 neutrons. If a nuclear reaction takes place which leaves a nucleus with 15 protons and 17 neutrons we have a nucleus of ^{32}P. Since only ^{31}P occurs in nature, we know that some adjustment will take place to bring about stability. In this case, one of the neutrons is transformed into a proton, a negative electron, and a neutrino (specifically an anti-neutrino) which is shown in the following reaction:

$$n \rightarrow p + e^- + \bar{\nu}$$

The negative electron cannot exist as part of the nucleus and is ejected from the nucleus along with the neutrino. When the electron is investigated, it is found to be identical to other negative electrons, but when it is formed in this process, it is given the name negatron or negative beta particle. The residual nucleus then contains 16 protons and 16 neutrons. The element possessing 16 protons is sulfur, so the nucleus resulting from this negative beta emission is ^{32}S. In general, then, nuclei with neutron-proton ratios higher than stable nuclei eject a negative electron from each nucleus and are thus transmuted into nuclei of the next higher atomic number.

There are also types of nuclear reactions which may leave a nucleus with a neutron-proton ratio lower than the corresponding stable nucleus. In this type of instability, there are two processes which may compete with one another for the production of a stable nucleus. In the first of these, an extranuclear electron may be captured by the nucleus and combined with one of the protons. The most likely electron taking part in this process is one from the K level. L or M level electrons may be "captured," however. This electron capture reaction may be shown as follows:

$$p + e^- \rightarrow n + \nu$$

A neutrino is also ejected in this process. When this reaction takes place, the nucleus then contains one less proton than before, and is thus a nucleus of one lower atomic number. For example, if ^{55}Fe "decays" by electron capture, the resulting nucleus of ^{55}Mn is stable. This process can take place whenever the neutron-proton ratio is too low for stability.

The reaction which competes with electron capture may occur if the neutron-proton ratio is low, and if there exists a certain minimum mass-energy difference between the unstable nucleus and a possible stable nucleus having one less proton. If there is at least 1.02 MeV mass-energy difference a proton may transform into a neutron, a positive electron (or positron), and a neutrino according to the following equation:

$$1.02\ \text{MeV} + p \rightarrow n + e^+ + \nu$$

The positron is then ejected from the nucleus. The characteristics of the positron are identical to those of the negatron except for its positive charge. A number of cases are known in which both electron capture and positron emission processes take place in the same nuclear species. A radioactive nuclide is characterized as having a certain "branching ratio" when more than one type of decay is possible.

Gamma Radiation The usual modes of decay which involve the reorganization of the nucleus are those described above. In many cases, however, another step is involved in attaining final stability. After one of the nuclear transformations described above takes place, the nucleus may still possess excess energy. In this case, the extra energy is given off directly as gamma radiation. These are electromagnetic radiations which have energies corresponding to the difference in energy levels in the nucleus from which they come. A particular nuclide thus exhibits a certain pattern or disintegration scheme by which it decays. For example, ^{32}P decays by negative beta emissions, which are not followed by gammas. On the other hand, ^{60}Co emits negative beta radiation which is followed in each case by two gamma rays in cascade. These gamma radiations have energy of 1.17 and 1.33 MeV respectively. In general, the gamma radiations are emitted in time periods less than 10^{-12} seconds following the first transmutation step. In some cases, however, excited energy states may exist for significantly longer periods. Experimental determinations of the lifetimes of these slower gamma ray transitions range from 10^{-8} second to several months. If such an excited state exists in a nuclide for a period long enough to be measured experimentally, the nuclide is called a nuclear isomer, and the transition process involving such gamma radiation is called an isomeric transition (I.T.).

It should be mentioned also that gamma radiation is given off following nuclear reactions. Such gamma rays called "capture" or "prompt" are discussed in conjunction with nuclear reactions, although isomeric states are often formed in this manner, and isomeric transitions may leave the nuclei in radioactive rather than stable states.

Decay Schemes and Units Information as to the radioactive transitions which take place in a given case is frequently presented in what is called a decay scheme. A group of simple decay schemes is shown in Fig. 1. These indicate the type of radioactive process which the nucleus undergoes, the energies of the radiations given off, and the branching which may take place. Most nuclei have decay schemes which are much more complex than those represented in the Figure, but they involve only multiple occurrence of the processes which have been described.

Decay Rate It can be seen from the foregoing that a nucleus may change from an unstable to a stable form by one of several decay processes. We can thus speak of the decay rate of a sample of radioactive material in disintegrations per unit time—usually disintegrations per second. This refers specifically to the transformation of the nucleus, and does not give any indication of the kind or energy of the radiations emitted. The unit of activity is the "curie" and is defined to be 3.7000×10^{10} disintegrations per second. Submultiples or multiples of this unit in common use are micro-, milli-, kilo-, and megacurie. A sample containing one millicurie of radioactive material is a sample which decays at the rate of 3.7000×10^{7} disintegrations per second.

We have no way to determine when any given nucleus will decay, but some of the most important work in the early study of radioactivity involved the study of decay rates. It was shown very early that the rate of radioactive decay is proportional to the amount of the radioactive material present. This can be expressed in the following equation:

$$A = -\lambda N$$

in which A is the disintegration rate, N is the number of radioactive atoms present, and λ is a proportionality constant characteristic of each radioactive species. This relationship is sometimes important, but often a more useful relationship is the following:

$$N = N_0 e^{-\lambda t}$$

in which N_0 is the number of atoms present at some reference time, and N is the number of

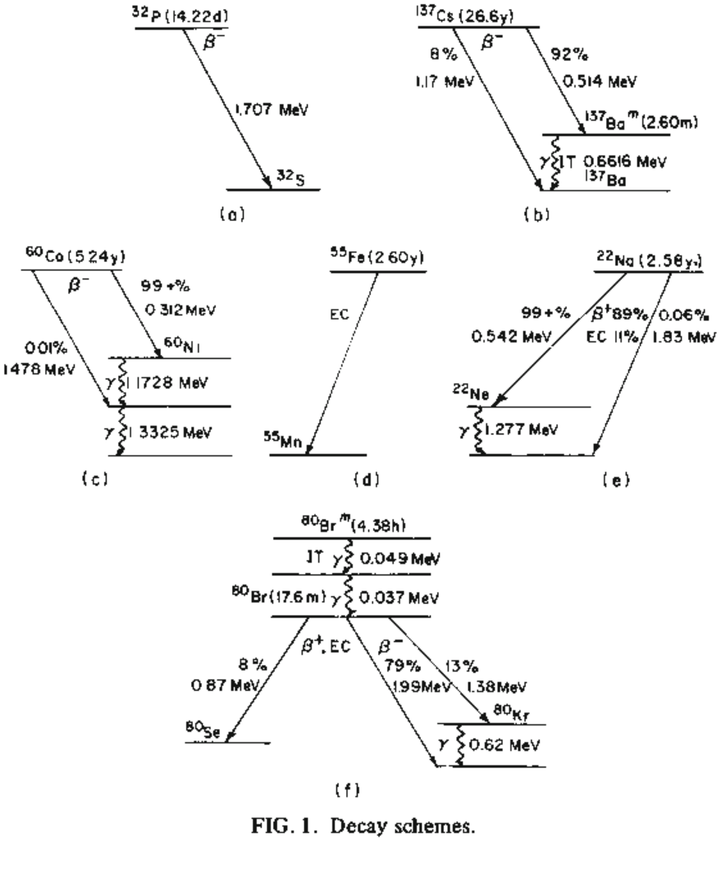

FIG. 1. Decay schemes.

atoms present at some time t later, and e is the base of the natural logarithms. This exponential decay relationship is of fundamental concern in working with radioactive materials, even though it is valid only for a statistically large number of atoms (i.e., all unstable nuclei will eventually decay).

The above equations are valid for any single radioactive species, and the exponential expression states that a given fraction of nuclei will decay in a given time period. In practice, we frequently refer to the time required for one-half of the atoms to decay. This is called the half-life of the radioactive material. It is related to the decay constant in the following way:

$$T_{1/2} = \frac{0.693}{\lambda}$$

It can also be shown that the average life, $\tau = 1.44$ times the half-life.

There are many cases in which a series of radioactive steps takes place. For example, ^{238}U undergoes 14 successive decays before arriving at the stable end product, ^{206}Pb. These steps involve the emission of successive alpha and beta rays along with gamma radiation in some cases. Although the calculations are somewhat more complex, it is possible to determine the disintegration rate of each of the daughter radioactive species formed in these processes. Details of this type of calculations are given in the references below.

RADIOCARBON DATING

Radiocarbon dating is a method of deriving the age of Holocene and late Pleistocene organic materials through a measurement of residual ^{14}C activity. Radiocarbon (carbon-14, C-14, ^{14}C) measurements can be obtained on a wide range of carbon-containing samples including wood, charcoal, marine and freshwater shell, bone and antler, peat and organic-bearing sediments, carbonate deposits such as caliche, marl, and tufa, as well as dissolved CO_2 and carbonates in ocean, lake, and groundwater sources. While the impact of the ^{14}C dating method has been most significant in archaeological research (particularly prehistoric studies), extremely important contributions have also been made in hydrology, oceanography, and geophysical studies. In addition, during the decade of the 1950s, the testing of thermonuclear weapons added large amounts of artificial ^{14}C ("bomb ^{14}C") to the atmosphere, permitting ^{14}C to be used as a geophysical tracer. The dating method was developed immediately following World War II at the University of Chicago by Willard F. Libby and his co-workers James R. Arnold and Ernest C. Anderson. Libby received the 1960 Nobel Prize in Chemistry for the development of the technique.

Basis of the Method Carbon has three naturally occurring isotopes. Two (^{12}C and ^{13}C) are stable. However, the third, ^{14}C, decays by very weak beta decay (electron emission) to ^{14}N with a half-life of approximately 5700 years. Naturally occurring ^{14}C is produced as a secondary effect of cosmic ray bombardment of the upper atmosphere (Fig. 1). As $^{14}CO_2$, it is distributed on a world wide basis into various atmospheric, biospheric, and hydrospheric reservoirs on a time scale much less than its half-life. Metabolic processes in living organisms and relatively rapid turn over of carbonates in surface ocean waters maintain ^{14}C levels at approximately constant levels in most of the biosphere. To the degree that ^{14}C production has proceeded long enough without significant variation to produce an equilibrium or steady-state condition, ^{14}C levels observed in contemporary materials may be used to characterize the original ^{14}C activity in the corresponding carbon reservoirs. Once a sample has been removed from exchange with its reservoir (as at the death of an organism) the amount of ^{14}C begins to decrease as a function of its half-life.

A ^{14}C age determination is based on a measurement of the residual ^{14}C activity in a sample compared to the activity of a sample of assumed zero age (a contemporary standard) from the same reservoir. The relationship between the ^{14}C age and the ^{14}C activity of a sample is given by

$$t = 1/\lambda \ln (A_0/A_s) \qquad (1)$$

where t is radiocarbon years B.P. (B.P. = before the present, where A.D. 1950 = 0 B.P.), λ is the decay constant of ^{14}C (related to the half-life $t_{1/2}$ by the expression $t_{1/2} = 0.693/\lambda$), A_0 is the activity of the contemporary standard, and A_s the activity of the unknown age sample. "Conventional radiocarbon dates" are calculated using this formula using an internationally agreed half-life value (the "Libby half-life" of 5568 ± 30 years) and a specific contemporary or modern standard. Most laboratories define the contemporary standard value by using an

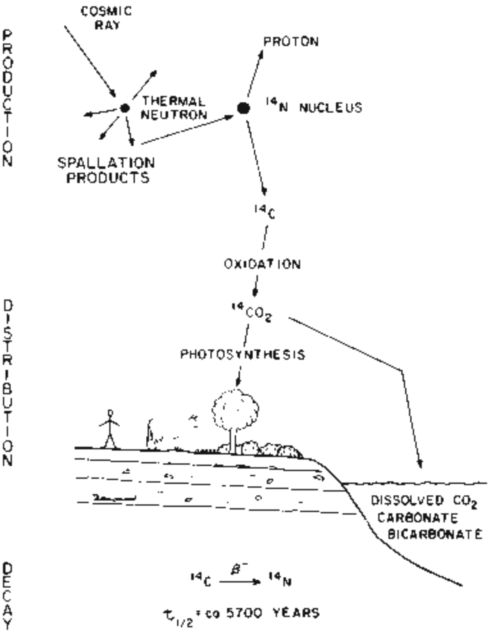

FIG. 1. Production, distribution, and decay of radiocarbon. Although the most probable half-life of radiocarbon is approximately 5730 years, by international convention, radiocarbon age determinations are calculated by laboratories using the "Libby half-life" of approximately 5570 years.

oxalic acid sample prepared by the United States National Bureau of Standards (NBS) or a secondary standard with a known relationship to the NBS standard. The ^{14}C activity of the contemporary biosphere is taken as 0.95 of the counting activity of NBS oxalic acid.

Measurement of Radiocarbon The naturally occurring isotopes of carbon occur in the proportion of approximately 98.9% ^{12}C, 1.1% ^{13}C, and 10^{-10}% ^{14}C. The extremely small amount of radiocarbon in natural materials is one reason why ^{14}C was one of the isotopes which was produced artificially in the laboratory before being detected in natural materials. The routine development of the radiocarbon method was made possible by the development by Libby of a practical method of low-level counting. In all of Libby's early work, the sample was converted to elementary carbon and deposited on a sleeve which fitted inside a screen wall type of Geiger counter. With solid carbon counting the maximum age that could be measured was about 23,000 years and required the use of from 5 to 6 grams of carbon from sample materials. Because of self-absorption of the weak betas in the sample, the efficiency of the detector was only about 5%. Because of this low efficiency and the susceptibility of the elementary carbon to contamination from airborne radioactive fallout, this technique was replaced by either gas counting or liquid scintillation systems.

Currently gas counters are employed for ^{14}C measurements typically using carbon dioxide, acetylene or methane. As with the case with solid carbon systems, the center counter containing the sample gas is surrounded by individual Geiger tubes or an annular or continuous ring guard, all housed within an iron or lead shield assembly (Fig. 2). Because of the 90–98% efficiency in most gas counting systems, the typical maximum age limits can be extended to between 40,000 and 60,000 years depending on the experimental configuration. Counting times typically range from 1 to 4 days. Isotopic enrichment of sample gases permits the maximum age attainable to be extended several additional half-lives. Sample size requirements with gas detectors were generally reduced from that required with the solid carbon method—special detectors recently being designed to permit the measurement of as little as 10 milligrams of carbon. Liquid scintillation systems are also used to measure natural ^{14}C concentrations. This currently involves the conversion of sample material to benzene through a series of chemical steps. The addition of a scintillator chemical allows the beta decay events to be monitored by photomultiplier tubes. Typically, the liquid scintillation method has required somewhat larger amounts of sample materials. However, maximum ages can usually be extended several half-lives beyond that of the typical gas system.

Both of the current conventional decay counting methods—gas or liquid scintillation—share a common problem in that they employ an inherently inefficient means of measuring ^{14}C concentrations in samples. In one gram of contemporary carbon, for example, there are approximately 6×10^{10} atoms of ^{14}C. However, on the average, in one minute only about 15 of them will decay. It has always been recognized that the higher efficiencies of atom-by-atom detection such as that employed in mass spectrometers would allow radiocarbon laboratories to use much smaller samples and, at the same time, extend the maximum ages resolvable beyond that typically possible with decay-counting techniques. Previous attempts to make direct counting measurements using a conventional mass spectrometer failed in practical applications because the radioactive species was obscured by background isotopes in the mass spectrum. The central idea that made direct detection possible was to accelerate sample atoms to high energy. When this occurs, the separation and identification of an isotope of interest is readily made using standard techniques developed in nuclear physics. The ionization loss of a high energy ion in matter provides a measure of the nuclear charge. When combined with magnetic or electrostatic analysis, the required separation and identification can be accomplished.

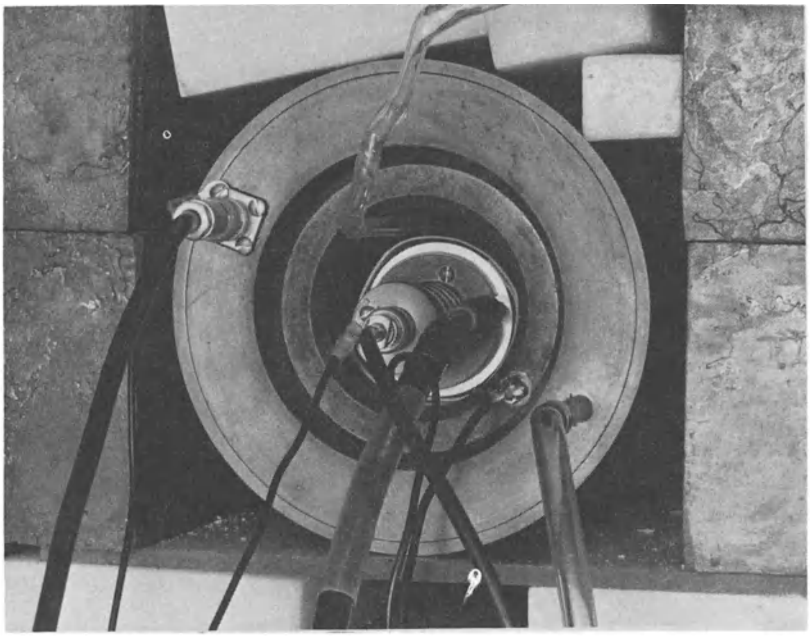

FIG. 2. Sample counter and annular anticoincidence (guard) counter used for low-level radiocarbon measurements. Gas sample is introduced into central counter through glass connection. Surrounding the sample counter is concentric lead shroud. Surrounding both the sample counter and shroud is an annular or concentric guard counter. Sheets of paraffin in which has been mixed borax acid are used to absorb cosmic ray mesons. These have been placed above and below the counter assembly. All have been encased in a lead and steel plate shield. (Photograph courtesy of T. Linick and L. E. Ford, Scripps Institution of Oceanography, University of California, San Diego.)

Most of the facilities involved in direct ^{14}C measurements currently employ tandem accelerator mass spectrometer (TAMS) systems. The elements of this type of instrument are represented in Figure 3. In such a system a significant separation of the ^{14}C from other isotopes takes place in the negative ion source before acceleration and takes advantage of the fact that ^{14}N apparently does not form negative ions that live long enough to pass through the accelerator. Samples are converted to elementary carbon to maximize the produc-

tion of ions in the accelerator. Figure 4 is the TAMS instrument operating at the University of Arizona National Science Foundation Accelerator Facility for Radioisotope Analysis.

Because of the greatly increased efficiency of ion counting systems, sample sizes can be reduced by several orders of magnitude from that typically required by decay counting instrumentation. Sample sizes down to less than 1 milligram of carbon are possible. The time needed for measurement is variable, in part depending on the amount of sample available, since, unlike decay counting systems, the sample is consumed during measurement. Maximum sample age values that can be measured using particle accelerators are limited by the background present in the instrument being used. Achieving background reduction and instrumental stability is one of the major problems currently being addressed by those operating accelerator systems.

Accuracy of Radiocarbon Determinations The measurement of the residual ^{14}C activity in an organic sample will provide an accurate determination of its true age if it can be assumed that (1) the production of ^{14}C by cosmic rays has remained constant long enough to establish a steady-state or equilibrium in the $^{14}C/^{12}C$ ratio in the atmosphere; (2) there has been complete and rapid mixing of ^{14}C throughout the various atmospheric, hydrospheric, and biospheric carbon reservoirs; (3) the carbon isotope ratio within sample materials has not been altered except by ^{14}C decay since they ceased to be part of one of the carbon reservoirs and; (4) the total amount of carbon in all reservoirs has remained essentially constant. In addition, the half-life (or decay constant) of ^{14}C must be known with sufficient accuracy and it must be possible to measure natural levels of ^{14}C to appropriate levels of accuracy and precision. Finally, there must be a direct and specific association between a sample to be analyzed and the event or phenomena for which temporal assignment is desired.

Studies by specialists in many different disciplines over the last three decades have shown that the primary assumptions on which the method rests have been violated both systematically and to different degrees for particular sample types and environmental contexts. Various strategies have been developed to provide calibration and correction procedures for ^{14}C determinations.

Variability in Radiocarbon Production Rates. Hints of systematic discrepancies between ^{14}C

values on known-age samples were reported very early in the ^{14}C literature. Almost all ^{14}C determinations obtained on early Egyptian archaeological materials yielded age values consistently too young by about 300–600 years. In the late 1950s, ^{14}C determinations were obtained on a series of tree ring samples which showed consistent variation in ^{14}C activity in the atmosphere on the order of several percent over the last 1300 years. Primarily because of the geophysical implications of these deviations, a number of laboratories and researchers have directed their attention to the magnitude and extent of what has come to be called the *secular variation* (long term) and *De Vries* (short term) variations in ^{14}C values over time.

The data base which has contributed most directly to the intensive study of secular variation and De Vries effects has been provided by dendrochronologically dated wood from the giant California sequoia (*Sequoia gigantea*), the European oak (*Quercus sp.*) and, most importantly, the bristlecone pine (*Pinus longaeva*). Radiocarbon determinations on dendrochronologically dated wood, have been undertaken by several laboratories. The data produced as part of these studies have provided radiocarbon specialists with the ability to *calibrate* individual ^{14}C determinations. Figure 5 provides an example of a plot of such data assembled by Klein et al. (1980).

The most obvious feature of these data is the long-term *secular variation effect*. It has been suggested that this phenomenon exhibits a sine wave function with an apparent period of about 8500 to 9000 years, and a maximum deviation of ca. 8–10% (650–800 years) at about 4500 to 5000 B.C. In examining Fig. 5 one can appreciate the observation that "radiocarbon years" and "calendar years" are not always equivalent. If such had been the case, all of the data points would lie along the thin horizontal line in Figure 5. However, some of the points lie below the line, indicating that the ^{14}G values for that period are "too old" while those lying above the line are "too young."

Most researchers agree that the most probable cause for most of the secular variation effects are changes in the intensity of the earth's geomagnetic dipole field. A decrease in the intensity of the field strength, for example, would allow an increase of the cosmic ray flux in the vicinity of the earth and therefore an increase in the production rate of ^{14}C.

For the period where bristlecone pine calibration is currently available, several investigators have published tables or charts which are intended to assist those interested in calibrating their ^{14}C determinations in light of primarily the bristlecone pine values. Such tabulations are useful if appropriate caution is exercised. First of all, the calibration process assumes that all other physical effects responsible for affecting the accuracy of the ^{14}C values have been identified and appropriate correction values applied. For example, inasmuch as calibration data is based on samples from the terrestrial biosphere (tree-rings), it is imperative that if one wishes to calibrate samples from other car-

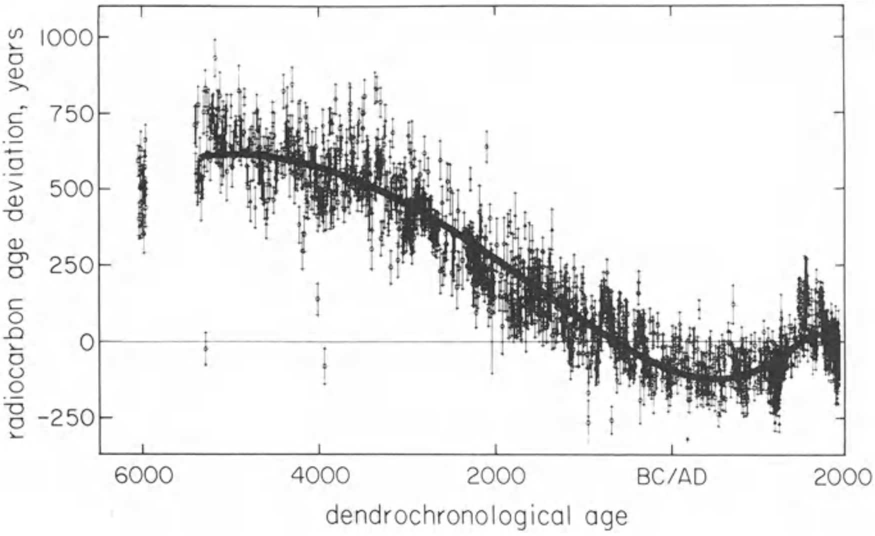

FIG. 5. Secular variation effect: relationship between ^{14}C and dendrochronological data. The ^{14}C data are plotted in terms of ^{14}C age deviation in years from the age of the dendrochronologically dated wood samples. After Klein et al. (1980), with a change in the vertical units. (P. Damon, personal communication.)

bon reservoirs that these values be first corrected in light of documented variations in initial ^{14}C activities in these reservoirs as well as any $^{13}C/^{12}C$ variations. Even more important is the need to take cognizance of intervals where shorter-term or *De Vries effects* made calibration efforts less precise.

If we examine closely the plots in Fig. 5 we note the short-term or high-frequency variations. It was initially suggested that these anomalies were artifacts of statistical fluctuations in the ^{14}C data. Although there is now a consensus that De Vries effects are real geophysical phenomena, there is still some uncertainty as to the cause(s) as well as the magnitude and duration of these episodes in the period before 1200 years ago. Figure 6 presents a plot of the De Vries anomalies over the last 7,000 years based on the composite bristlecone pine ^{14}C data prepared by Klein et al. (1980). This plot results from the subtraction of the main trend of the sine wave function (describing the secular variation effect) from each data point. The residual values can then be used to characterize the short term anomalies. Several researchers have obtained ^{14}C determinations on tree ring samples with shorter time segments from several other localities. These can be used to compare the magnitude and duration of these anomalies. While these show a general correspondence, there are several intervals during which some discordance seems to be indicated. Thus, some small latitude dependent variation may also be present.

A number of factors have been offered to account for much of the De Vries variations. Probably most of the effects are caused by solar or heliomagnetic modulations in ^{14}C production. It has been suggested that the process involves changes in the solar corona which affects the solar wind, which in turn deflects cosmic rays in the vicinity of the earth. The most obvious physical feature associated with variations in solar activity are changes in the number of sunspots over time. Observations made over the last few centuries have recorded sunspot numbers and these records have been compared to variations observed in the bristlecone pine tree ring record. Although good correlations can be obtained, a much better fit of the data has been achieved by correlating variations in ^{14}C activity with an index reflecting short-term low-frequency geomagnetic variations on the sun.

Variability in Radiocarbon Distribution. One of the major advantages of the ^{14}C method is its potential ability to provide directly comparable age determinations on a worldwide basis for all organic materials. For this potential to be realized, however, ^{14}C must be rapidly and uniformly mixed throughout all carbon-containing reservoirs. If such conditions prevail, the contemporary ^{14}C content of all organic samples will be essentially identical. However, in a number of situations, it has been determined that such an assumption cannot be made. The classic illustration of this problem is the determination that living organisms from a fresh water lake with a limestone bed exhibited apparent ^{14}C ages of up to 2,000 years. In this case, the ^{14}C activity of these organisms have been diluted by carbonates derived from the limestone. From a ^{14}C standpoint, this lime-

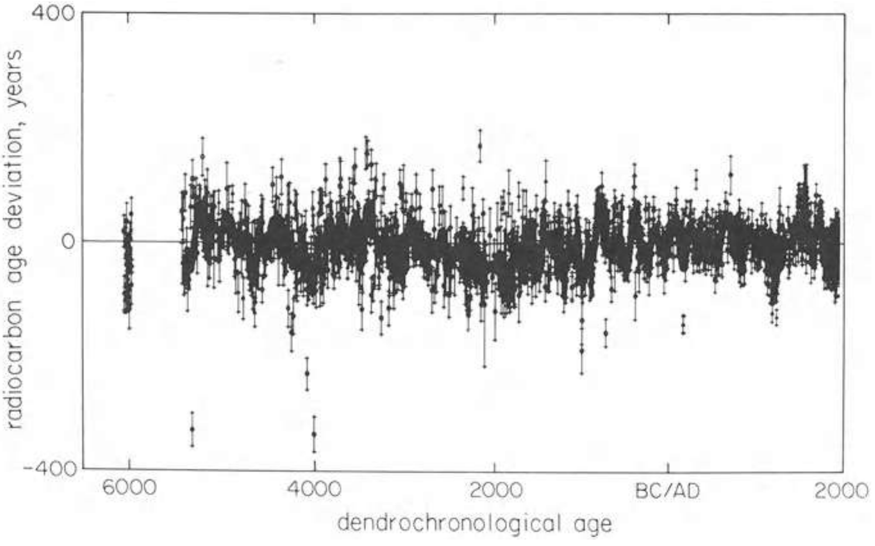

FIG. 6. The De Vries effect. High frequency or short term variation in ^{14}C activity. Plot results from the subtraction of secular variation function (Fig. 5). After Klein et al. (1980), with a change in the vertical units. (P. Damon, personal communication.)

stone was "dead" since, being of great geologic age, it did not contain any measurable ^{14}C.

One effect of the recognition that a sample's general and specific geochemical environment can affect initial ^{14}C concentrations has been to focus attention on the reliability of certain types of samples. For example, the use of shell in ^{14}C dating has been the subject of continuing discussion. Terrestrial shells or gastropods from fresh water sources certainly merit concern since they can take up carbonates which are not in equilibrium with atmospheric ^{14}C. On the other hand, well-preserved marine shells from open ocean environments have increasingly been employed in ^{14}C studies in areas where upwelling effects along continental margins have been examined.

Variability in Carbon Isotope Ratios. For the ^{14}C dating method, the basic physical measurement used to index time is the ^{14}C/^{12}C ratio. An accurate estimate of the age of sample using the ^{14}C method assumes that no change has occurred in the natural carbon isotope ratios except by the decay of ^{14}C. Several physical effects other than decay, however, have been shown to alter the carbon isotope ratio and thus have introduced the need to correct the ^{14}C values affected. One problem has to do with the fractionation of carbon isotopes under natural conditions. A second problem involves situations where carbon-containing compounds not indigenous to a sample are physically or chemically added, resulting in the sample's contamination.

While all of the isotopes of carbon follow the same chemical or physical pathways, the rate at which this occurs varies as a function of their difference in mass. The studies of Harmon Craig in the early 1950s pointed to the need to consider variations in the stable carbon isotopic ratios (^{13}C/^{12}C) if one wished to obtain precise and comparable ^{14}C/^{12}C measurements. Fortunately, most of the stable carbon isotope values on materials such as charcoal and wood exhibit little variation. Thus little, if any, correction in the ^{14}C ages values is normally required. Problems arise, however, when ^{14}C values from a variety of sample types such as grasses, grains, seeds, succulents, marine carbonates, and terrestrial organics must be compared. In such cases, it is necessary to measure the ^{13}C/^{12}C ratios and use this data to normalize the ^{14}C values onto a common scale.

Contamination of materials intended for ^{14}C analysis presents a problem for some types of samples. Obviously, the sources and effects of the introduction of foreign organics are complex depending on the nature and condition of the sample material, the characteristic(s) of the geochemical environment(s) within which the sample has been embedded, and the time frame over which such action(s) occurred. A range of sample pretreatment techniques have been developed to deal with different types of potential contamination. The high rating given to charcoal and wood is based on the fact that such samples can be subjected to pretreatment by strong acids and bases, and thus the removal of absorbed carbonates and soluble soil organic compounds can be greatly facilitated.

Development of Other Quaternary Dating Methods. ^{14}C values have been extensively employed to provide known-age reference points to facilitate the development of other dating methods applicable to Quaternary materials. Its use, for example in the development of the amino acid racemization method for late Quaternary bone and shell samples has been crucial. Concordance of ^{14}C and amino acid racemization-deduced values on bone samples was instrumental in the initial acceptance, by some scientists, of the validity of somewhat controversial racemization-deduced age values on certain samples. More recent studies, including an increasing number of clearly anomalous racemization determinations, has resulted in an increasing recognition that a number of problems with the method need to be resolved. This same process has been involved in the research on the obsidian hydration method.

RAMAN EFFECT AND RAMAN SPECTROSCOPY

The Raman effect is the phenomenon of light scattering from a material medium, whereby the light undergoes a wavelength change in the scattering process. For a given medium, the Raman scattering per unit volume is of the order of one-thousandth of the intensity of the ordinary or Rayleigh scattering, in which there is no change of wavelength (see LIGHT SCAT-

TERING). The Raman-scattered light bears no phase relationship with the incident light, whereas the Rayleigh light is a residual effect resulting from the departure of the incident and the scattered light from complete mutual coherence. The Raman intensity per molecule is thus independent of the state of the medium, apart from a certain small refractive index effect. The Rayleigh intensity per molecule, on the other hand, depends strongly on the degree of randomness of the spatial positions and orientations of the molecules of the medium; it is small for a crystal at absolute zero and greatest for a gas at low density.

Scattering of light with change of wavelength was predicted in 1923 by Smekal, inspired by the discovery of the Compton effect. The Raman effect was discovered experimentally in 1928 in India by Raman and Krishnan, who showed that the spectrum of the scattered light of liquids and solids, strongly illuminated with monochromatic light, contains frequencies which are not present in the exciting light and which are characteristic of the scattering medium. Independently, and almost simultaneously, Landsberg and Mandelstam in Russia discovered the effect in crystals.

Until the advent of lasers in the early 1960s methods of observing Raman spectra were usually modifications of the arrangement introduced originally by R. W. Wood. The specimen, for example, a liquid contained in a glass or quartz tube 1 cm in diameter and 20 cm long, was strongly illuminated along its length by mercury arcs, with filters interposed between the arcs and the tube to isolate monochromatic exciting radiation (435.8, 404.7, or 253.7 mm) if necessary. The scattered radiation was observed along the axis of the tube through a plane window at one end. The other end of the tube was usually drawn out into a cone, which, when blackened, formed a dark background against which the weak scattered light could be observed with a minimum of stray radiation. The scattered light was analyzed by a spectrograph or spectrometer of high light power. Modifications of the Wood arrangement involving high-intensity water-cooled mercury arcs and Raman tubes with a very long pathlength achieved by a mirror arrangement were introduced around 1950, and used for extensive investigations of the rotational and vibrational Raman spectra of gases. These developments have been summarized by Stoicheff.[1]

The experimentally confirmed laws of Raman scattering are as follows:

(a) The pattern of Raman lines, expressed as *frequency* shifts from the exciting line, $\Delta\nu_i$ ($i = 1, 2, \cdots$), is independent of the exciting frequency.

(b) The pattern of Raman frequency shifts, $\Delta\nu_i$, is symmetrical about the exciting line. However, the lines on the low-frequency side of the exciting line (Stokes lines) are always more intense than the corresponding lines on the high-frequency side (anti-Stokes lines). The ratio of the intensities of corresponding anti-Stokes and Stokes lines is $I_a/I_s = \exp(-\Delta\nu_i hc/kT)$, where the Raman shift $\Delta\nu_i$ is expressed as usual in cm^{-1}. Thus anti-Stokes lines for $\Delta\nu_i > \sim 1000$ cm^{-1} are too weak to be observed at room temperature.

(c) A given Raman line shows a degree of polarization which depends on the origin of the line and on the experimental arrangement. For strictly transverse observation, i.e., observation at right angles to the incident light, the depolarization factor, ρ_n, has a value in the range 0 to 6/7 for unpolarized incident light.

Figure 1 shows a schematic diagram of the Raman spectrum of carbon tetrachloride. The four Raman shifts, $\Delta\nu_i$ ($i = 1, 2, 3, 4$), are 218,

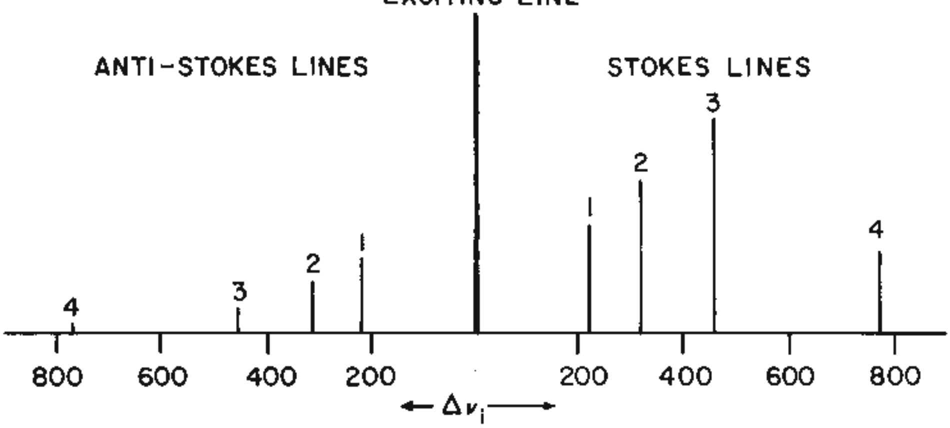

FIG. 1. Schematic diagram of the Raman spectrum of carbon tetrachloride. The heights of the Raman lines represent their relative intensities.

314, 459 and 775 cm^{-1}; the corresponding values of ρ_n are 6/7, 6/7, 0, and 6/7.

The Raman shifts, $\Delta\nu_i$, correspond to energy differences (in cm^{-1}) between discrete stationary states of the scattering system. Thus, in the quantum picture, the incident photons collide *elastically* with the molecules to give Rayleigh scattering, or *inelastically* to give Raman scattering, the latter process being much less probable than the former. For a Stokes Raman line, the photon furnishes energy to raise the molecule from a lower to a higher state; for an anti-Stokes line, the molecule must furnish energy to the scattered photon and move to a lower energy state. The anti-Stokes line thus originates in a less highly populated state and is weaker than the corresponding Stokes line. The Raman process can be described classically, but not as accurately, as the modulation of the scattered light wave by the internal motions of the scattering molecule, the Raman lines constituting "sidebands" of the Rayleigh "carrier" frequency.

A rigorous theory of the Raman effect, based on the quantum theory of dispersion, has been given by Placzek.[2] The process of light scattering can be visualized as the absorption of an incident photon of frequency, ν_e, by a molecule in a given initial state, thus raising the molecule to a "virtual" state from which it immediately returns to a final state emitting the scattered photon. Figure 2 illustrates the production of the Rayleigh line and Stokes and anti-Stokes Raman lines for a two-level system. If the exciting frequency ν_e is far away from any allowed electronic absorption of the molecule, the intensity of a Stokes line $\Delta\nu_i$ varies with ν_e according to the law, $I_i \propto (\nu_e - \Delta\nu_i)^4$. As ν_e approaches an electronic absorption the intensity increases more rapidly; this is the region of so-called *resonance* Raman scattering.[3] Finally, if ν_e is such that the virtual state coincides with a real energy state of the system, the Raman effect goes over into molecular fluorescence provided the states involved can combine with one another according to the selection rules.

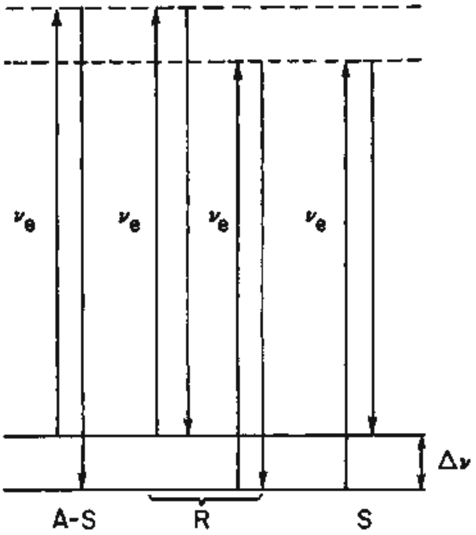

FIG. 2. Illustrating the production of Stokes (S) and anti-Stokes (A-S) Raman lines and the Rayleigh line (R) by an exciting frequency, ν_e, for a two-level system. The dashed lines represent virtual states of the system.

In principle, the Raman shifts, $\Delta\nu_i$, can represent energy differences between electronic, vibrational or rotational energy states. In practice, Raman spectroscopy has been concerned chiefly with the determination of vibrational frequencies of polyatomic molecules from the scattered light spectrum and the correlation of the observed frequencies with possible modes of vibration of the molecules. In this role, Raman spectroscopy forms an important complement to near-infrared spectroscopy which also furnishes precise information on molecular vibration frequencies.[4]

The so-called polarizability theory of Placzek[2] is an approximate theory which is particularly useful in relating observed vibrational Raman lines to the normal vibrations of the scattering molecule. In the equation, $\mathbf{m} = \alpha\mathbf{E}$, $\mathbf{m}$ is the electric dipole induced in the molecule by the oscillating light field $\mathbf{E}$. The constant of proportionality, α, is the molecular polarizability, which can be developed in a Taylor series in the vibrational coordinate q,

$$\alpha = \alpha_0 + (\partial\alpha/\partial q)_0 q + (1/2)(\partial^2\alpha/\partial q^2)_0 q^2 + \cdots$$

The intensity of the fundamental Raman band, corresponding to the $v = 0$ to $v = 1$ transition where v is the quantum number of the vibration, depends essentially on the *rate of change of polarizability*, $\alpha' \equiv (\partial\alpha/\partial q)_0$, with respect to the coordinate q. Like α_0, the polarizability of the molecule in the equilibrium position ($q = 0$), α' is a tensor quantity. The vibration is active in Raman scattering if, because of the symmetry properties of the vibration, α' is not identically zero. Also the depolarization, ρ_n, of a Raman band can be related by the polarizability theory to the symmetry of the vibration. Thus, the single polarized ($\rho_n = 0$) line of carbon tetrachloride at 459 cm^{-1} (Fig. 1) can be identified immediately with the "breathing" vibration of the tetrahedral $\mathrm{CCl_4}$ molecule, and the three depolarized ($\rho_n = 6/7$) lines with the three degenerate vibration forms of the molecule.

Since the infrared activity of a molecule depends on the molecular dipole, whereas the Raman activity depends on the molecular polarizability, the selection rules for two types of spectra can be very different. For example, all four fundamental vibrations of $\mathrm{CCl_4}$ are active in Raman scattering (Fig. 1), whereas only two of these ($i = 2, 4$) are active in infrared absorption. An extreme case occurs for molecules with a center of symmetry: vibrations which are active in infrared absorption are not active in Raman effect and vice versa. The selection rules for rotational transitions in infrared absorption and in light scattering also differ: they are $\Delta J = 0, \pm 1$ for the former and $\Delta J = 0, \pm 1, \pm 2$ for the latter, where ΔJ is the change in the rotational quantum number J.

Mercury lamps as sources of ordinary or spontaneous Raman scattering have now been superseded by gas lasers, particularly the He-Ne laser operating at 632.8 nm and the argon ion laser operating at 488.0 or 514.5 nm. The higher flux density, monochromaticity, directionality, and polarization of the laser beam combine to make it an almost ideal means of exciting Raman spectra. As a result there has been an extraordinary expansion of Raman studies in the last twenty years (see, for example, Refs. 5 and 6). The higher monochromaticity of laser sources has given a new impetus to molecular structure studies by Raman spectra of gases. With mercury lamp sources a practical resolution of 0.3 cm^{-1} at best could be achieved, whereas resolutions of 0.1 cm^{-1} and 0.003 cm^{-1} are obtainable with a multimode and a single mode laser, respectively. These higher resolutions have of course required the development of suitable recording equipment.[7]

The directionality and polarization properties of the laser beam are particularly advantageous in Raman studies of crystals.[8] The direction of propagation of both the incident beam and the observed scattered beam, as well as the polarization vectors of these beams, can be set in various well-defined relationships with respect to the crystal axes of the specimen; the result is that much precise information can be obtained concerning the structure and the elementary excitations of the crystal. The usual components of the Raman spectrum of a crystal can be assigned to (a) *internal* vibrations (vibrons), i.e., the vibrations of the molecules or ions of the crystal coupled by the intermolecular forces; and (b) *external* vibrations (phonons), i.e., optically active vibrations of the crystal lattice. Other elementary excitations in particular crystals have also been detected recently by laser Raman spectra: spin waves (magnons) in ferromagnetic and antiferromagnetic crystals, coupled photon-electric dipole exciton modes (polaritons) in dipole crystals, and spin waves of angular momentum (librons) due to the almost free rotation of molecules in the ordered phase of ortho-enriched solid hydrogen. Phonon excitations in metals and electronic Raman transitions of ions in solids have also been studied. The discovery of *spin-flip* Raman transitions in wide band-gap semiconductors in a magnetic field has led to the introduction of tunable spin-flip Raman lasers. A new effect is *surface enhanced Raman scattering* (SERS) in which the scattering from a monomolecular layer of a substance absorbed on a metal surface is enhanced by a factor of as much as 10^6 over the scattering from the free molecule, the degree of enhancement increasing with the roughness of the metal surface; for recent articles on this subject see Part III of Ref. 6.

In addition to its importance in the study of ordinary or *spontaneous* Raman scattering, the laser has led to the discovery of four phenomena, which are of considerable significance in present-day Raman research; these are *stimulated* Raman scattering, the *inverse* Raman effect, the *hyper* Raman effect, and *coherent anti-Stokes* Raman scattering. Each of these effects depends on the intense electric field produced in a material medium when it is illustrated by the focussed beam of a giant pulse (Q-switched) laser such as the ruby system or the neodymium gas system. Since the electric field intensity at the focus of the beam can be as high as 10^9 V m^{-1}, nonlinear contributions to the electric moment induced in the molecule can arise and new effects are observed.

In stimulated Raman scattering the giant laser pulse causes a coherent stimulated emission of a Stokes Raman frequency $\nu_e - \Delta\nu_i$, when the incident intensity exceeds a certain threshold value.[9] As a rule, only one Raman frequency is emitted and this corresponds to the line with the greatest peak intensity in the spontaneous Raman spectrum. At higher incident intensities, harmonics (not overtones) of the first Stokes emission appear at $\nu_e - 2\Delta\nu_i$, $\nu_e - 3\Delta\nu_i$, $\cdots$ along with corresponding anti-Stokes frequencies.

When a substance is irradiated by the radiation ν_e of a giant-pulse laser and simultaneously by a continuum lying at frequencies higher than ν_e, the Raman shifts $\Delta\nu_i$ appear as absorption lines at frequencies $\nu_1 + \Delta\nu_i$; this is the so-called inverse Raman effect[10,11]. In this case all the Raman-active molecular transitions can appear in the spectrum. Since the spectrum is generated in liquids and solids in a time of ~ 40 nsec, and since there are possibilities of reducing the time much further, the effect can perhaps furnish a high-speed spectroscopic method for studying short-lived molecular species and other transient phenomena. The use of laser excitation combined with recording by image-converter tubes also has attractive possibilities for high-speed Raman spectroscopy.[12]

The hyper Raman effect[13] occurs when the incident electric field E is so large that nonlinear susceptibility terms are no longer negligible. Thus, the equation $\mathbf{m} = \alpha\mathbf{E}$ must be written

$$m_k = \alpha_{k\ell}E_\ell + \tfrac{1}{2}\beta_{k\ell m}E_\ell E_m + \tfrac{1}{6}\gamma_{k\ell mn}E_\ell E_m E_n + \cdots (k, \ell, m, n = x, y, z),$$

where the *hyperpolarizabilities* β, γ, $\cdots$ are tensors of the 3rd, 4th, $\cdots$ orders. The term in β gives rise to scattering at $2\nu_e$ and $2\nu_e \pm \Delta\nu_i$, and the further terms to higher harmonics. The selection rules for hyper Raman scattering are of course different from those for the ordinary case,[14] and when further developments in the recording of extremely low intensities have been made, the effect will constitute an important extension of ordinary Raman scattering.

Coherent anti-Stokes Raman scattering (CARS) was discovered some time ago;[15] however, its general usefulness has become apparent only in recent years when powerful tunable pulsed lasers became available. (Recent papers are given in Refs. 6 and 16.) The CARS experiment is a parametric process in which two waves, one at the constant frequency ν_1 and one at a continuously variable frequency ν_2, are in spatial and temporal coincidence in the scattering medium; a coherent radiation of frequency $\nu_3 = \nu_1 + (\nu_1 - \nu_2)$, among others, is produced. If ν_2 is varied so that $\nu_1 - \nu_2 = \Delta\nu$, where $\Delta\nu$ is the separation of two states of the medium, then $\nu_3 = \nu_1 + \Delta\nu$ corresponds to an anti-Stokes Raman line. The possibilities of producing coherent, directed and intense Raman lines in this way are most attractive.

RARE EARTHS

The seventeen rare-earth elements are those of group IIIb of the periodic table, including scandium (Sc), yttrium (Y), lanthanum (La), and the lanthanides: cerium (Ce), praseodymium (Pr), neodymium (Nd), promethium (Pm), samarium (Sm), europium (Eu), gadolinium (Gd), terbium (Tb), dysprosium (Dy), holmium (Ho), erbium (Er), thulium (Tm), ytterbium (Yb), and lutetium (Lu). These elements are of great interest to theoretical and experimental researchers because of the systematic manner in which many of their physical and chemical properties are expected to vary across the lanthanide series.

The rare earth yttria (actually yttrium oxide plus several of the heavy rare-earth oxides) was discovered near Ytterby, Sweden, in 1794. Ceria (containing several light rare-earth oxides) was discovered some years later. In the 19th Century, because of the difficulty in separating the rare-earth elements and in removing impurities, it was thought that many different rare earths existed. During this period, over 70 different rare earths were reported in the literature. With the advent of spectroscopy (especially the work of J. Becquerel at the turn of the century), Mendeleev's periodic table (from which he predicted the existence and properties of the as yet undiscovered scandium), and Moseley's work on X-rays, the actual number and properties of the lanthanides were better understood. The discovery of lutetium in 1907 completed the lanthanide series (except for promethium, which has no stable isotopes and was not isolated until 1947).

Rare earths are obtained commercially from the minerals monazite (for light rare earths) and xenotime (for heavy rare earths). Other minerals containing substantial quantities of rare earths are bastnaesite, samarskite, euxenite, and gadolinite, although these are, for the most part, not used commercially. Rare-earth minerals are found in Africa, Asia, and the Americas. In the United States they are found in the Blue Ridge, Piedmont, and Coastal Plain of the southeastern states, eastern Idaho through southwestern Montana, Colorado, southern California, and Alaska.

Rare earths are also obtained as by-products of fission reactions. The difficulty in separating the rare earths was once an impediment in performing research on these elements. The early fractionation methods were quite slow and inefficient, and involved large quantities of solvent and material. However, it was discovered that certain rare earths, such as cerium, europium, and ytterbium could exist in valence states other than the normal trivalent state, and that oxidation and reduction reactions could be used to separate these rare earths from the others. With the advent of the ion-exchange techniques pioneered by groups at Iowa State University and Oak Ridge National Laboratory, it is now possible to obtain high-purity samples of any of the rare earths.

Atomic Properties The rare earths are characterized by the progressive addition of electrons in the $4f^n$ subshell that is largely shielded from the environment by the outer orbitals $5s^2$, $5p^6$, $5d^{0,1}$, or $6s^2$. These features produce the interesting physical and chemical properties. The ground electronic configurations of neutral Sc, Y, and La are $[\mathrm{Ar}]3d^1 4s^2$, $[\mathrm{Kr}]4d^1 5s^2$, and $[\mathrm{Xe}]5d^1 6s^2$, respectively; the ground configurations of the lanthanides are given in Table 1. The common oxidation state of all the rare earths is the trivalent state; however, compounds are known in which Ce, Pr, and Tb are tetravalent, others in which Sm, Eu, and Yb are divalent.

The trivalent lanthanides have a $[\mathrm{Xe}]4f^n$ ground-state configuration (see Table 1). Their spectroscopic and magnetic properties derive from the partially filled $4f$ shell. The angular momenta of these $4f$ electrons can combine in many ways to produce a variety of electronic states within the $4f^n$ configuration. The ground electronic states of the trivalent lanthanides follow *Hund's rule*, which can be summarized as follows: if n is the number of $4f$ electrons, then

(a) S, the spin angular momentum, is $n/2$ if $n \leqslant 7$ and $(7 - n)/2$ if $n > 7$;

(b) L, the orbital angular momentum, is the maximum value consistent with S and the Pauli exclusion principle;

(c) J, the total angular momentum, is $|L - S|$ if $n \leqslant 7$ and $L + S$ if $n > 7$.

The *Hund ground states* obtained from this rule (written in the usual spectroscopic notation ${}^{2S+1}L_J$) are shown in Table 1. Excited electronic states within the $4f^n$ configuration are complex and not uniquely specified, in general, by S, L, and J.

Russell-Saunders coupling (L-S coupling) is a good approximation for the ground states of the lanthanides; thus, L and S are nearly (though not exactly) good quantum numbers. The magnetic properties of the trivalent ions are summarized by the Lande g-value, given (in L-S coupling) by

$$g_J = 1 + \frac{S(S+1) + J(J+1) - L(L+1)}{2J(J+1)}.$$

Actual values of g_J obtained in intermediate coupling calculations differ slightly from the L-S values; the latter are given in Table 1.

The free-ion spectrum of Pr^{3+} has been well studied, and all states of $\mathrm{Pr}^{3+}(4f^2)$ have been identified except for ${}^1S_0$. (This state has, however, been observed in some solids.) Free-ion spectra of other trivalent rare earths have been observed as well, although level identifications are far from complete. Most of the information that we currently possess concerning the spectroscopic properties of trivalent rare earths has been obtained from solution spectra and from

spectra of rare-earth doped solids. Several comprehensive reviews are included among the references.

Nuclear Properties The rare-earth elements present a rich display of isotopes for study by the nuclear physicist, with between 10 and 20 isotopes known for each element. Only one or two stable isotopes exist for the odd-Z elements (none exist for promethium); in contrast, several stable isotopes are known for each of the even-Z elements.

Table 2 summarizes some of the nuclear properties of isotopes with greater than 5% abundance. About half of these have spinless nuclei; the other half have nuclear spins ranging from $\frac{1}{2}$ to $\frac{7}{2}$ (in units of $\hbar$) with accompanying electric quadrupole moments and magnetic dipole moments, which are given in the table. The last column of Table 2, giving the thermal neutron cross sections, is of practical interest. Elements having high cross sections, such as Sm, Eu, Gd, and Dy, are incorporated into control rods for regulating nuclear reactors and in other applications (such as nuclear shielding) in which high nuclear cross sections are desirable.

Rare-Earth Metals The physical properties of the rare-earth metals are summarized in Table 3. These metals exhibit many of the features common to rare-earth compounds in general. Within structures of the same type, the lattice constants decrease systematically with increasing atomic number. This decrease in the unit cell size is a manifestation of the *lanthanide contraction*, which is a decrease in the size of the trivalent ion as more electrons are progressively added to the incomplete $4f$ shell. The Eu and Yb ions in the corresponding metals are in the divalent state, with half-filled $(4f^7)$ and filled $(4f^{14})$ shells, respectively. With these two exceptions, the melting points, boiling points, and densities vary systematically across the lanthanide series, providing further manifestations of the lanthanide contraction.

Rare-earth metals are relatively good conductors, with conductivities about 50 times smaller than that of silver. In addition, La becomes superconducting at approximately 5 K. Of particular interest are the magnetic properties of the rare-earth metals. Nearly all the rare earths with unpaired electrons become antiferromagnetic, with Néel temperatures T_N ranging from 19.2 to 230 K. Ferromagnetism has been observed in all the heavy rare earths with unpaired electrons, with the Curie temperature T_c of Gd approaching room temperature. The magnetic moments of the trivalent ions in the rare-earth metals are large compared with those of other magnetic materials, due to the large values of J for these ions ($\mu \sim Jg_J\mu_B$, where $\mu_B = e\hbar/2m$ is the Bohr magneton and m is the electron mass; see Table 1).

Cerium is an interesting exception to the general trend in the rare-earth metals. Three different allotropes of Ce metal are known to exist at low temperatures and pressures, known as α, β, and γ (other forms exist at elevated temperatures and pressures). All three allotropes can exist at room temperature, although γ-Ce (whose properties are given in Table 3) is reported to be the most stable. All three forms have noninteger valence; α-Ce has valence ≈ 3.67, and the β and γ allotropes have valence slightly greater than 3. Tendency toward tetravalence is also exhibited by a number of Ce compounds and is a consequence of the stability of the [Xe] configuration of Ce^{4+}. Because of this tendency toward the magnetically inert tetravalent state, Ce metal does not exhibit a magnetic phase transition.

Rare-Earth Compounds The rare earths form complexes in aqueous solution in which the rare-earth ion is surrounded by a layer of H_2O molecules; under these conditions, the chemical properties of the rare earths are similar. This led early workers to believe (falsely) that chemical similarity was an intrinsic property of the rare earths. The hydrated ions are strongly electrolytic. Many compounds can be formed by precipitation from solution; most compounds of interest, however, are formed by other methods.

Binary halides, chalcogenides, and pnictides of the rare earths are well studied and possess a wide variety of physical and chemical properties. Several chalcogenides of Sm, Eu, and Yb undergo pressure-sensitive insulator-metal or semiconductor-metal phase transitions corresponding to a change in valence (electron delocalization). The oxides in particular are an interesting series of compounds. Examples are the sesquioxides R_2O_3 for all R, where R represents a rare earth, and R_nO_{2n-2}, where n is an integer, particularly R_7O_{12} and RO_2 $(n \to \infty)$ for R = Ce, Pr, and Tb. Similarly, sulfides of the rare earths including R_2S_3, RS, and RS_2 also exhibit a wealth of varying crystalline structures and other physical properties that have received growing attention over the past several years. Other, more complex anhydrous compounds of the rare earths have applications in various areas of science and technology; some of these are $RAlO_3$, $R_3Al_5O_{12}$, RVO_4, and R_2O_2S.

The spectroscopic properties of rare-earth doped insulating solids are of interest because of their applications to numerous devices, especially lasers. A rare-earth ion doped into a solid experiences a *crystal field* due to the surrounding ions in the crystal. This crystal field (which is shielded by the outer $5s^2 5p^6$ shell of the rare-earth ion) has two effects: (1) it splits each electronic state of the free ion into a number of Stark components; (2) it breaks the inversion symmetry of the free ion, thereby permitting the parity-forbidden electric-dipole transitions within the $4f^n$ shell to take place (provided the rare-earth ion is at a site that lacks inversion symmetry). Laser action based

TABLE 2. NUCLEAR PROPERTIES OF STABLE RARE-EARTH ISOTOPES

[c] Divalent.

[d] Estimated.

on transitions within the $4f^n$ shell has been observed in many rare earths; a notable example is $Y_3Al_5O_{12}$ (YAG) doped with Nd^{3+}, which is the most powerful laser known at present.

Uses Aside from the uses of rare earths discussed above, mixed rare-earth compounds and metals serve a variety of industrial purposes. *Mischmetal*, composed of cerium and other light rare earths, is used in lighter flints and in alloys. Mixed rare earths are also used as catalysts in the cracking of petroleum to produce gasoline. Carbon arcs containing rare-earth mixtures are used in electrodes for extremely bright lights in making motion pictures and in searchlights.

The light rare earths find frequent applications in optics. For example, lanthanum compounds are frequently used in the manufacture of low-dispersion lenses. CeO_2 and other rare-earth oxides are used for polishing glass used in optical systems. Didymium mixtures (oxides of Pr + Nd) are used as absorbers in safety goggles worn to protect the eye from intense, harmful radiation (e.g., welder's goggles). Erbium oxide often performs the same function in the infrared. Rare-earth hydrides can store large amounts of hydrogen and thus serve as fuel-storage materials for "clean" energy. Rare-earth sulfides are efficient as the conversion materials in solar photovoltaic cells. Rare-earth chelates are useful in many biochemical reactions and participate in human physiology. Rare-earth radioactive isotopes probe the body for diseases such as cancer.

Rare-earth compounds play an important role in electronics. Rare-earth garnets are important materials for ferrites. The compounds Y_2O_2S, Y_2O_3 and YVO_4, doped with Eu^{3+}, are used as the red phosphor component in color television tubes. The unique magnetic properties of the rare earths make them attractive candidates for permanent magnets; $SmCo_5$ is but one example. Also, paramagnetic compounds of the rare earths, with their large saturation magnetic moments, are used in magnetic cooling. Onnes first produced temperatures below 1 K by this method with gadolinium sulfate.

RECTIFIERS

Rectification Rectification is a process which imparts unidirectional symmetry to a system. It removes the inversion symmetry, and dictates the forward and reverse directions to the system. Electrical rectification is used to convert an alternating current (ac) to a direct current (dc). Rectifiers are the devices which can be used to accomplish the electrical rectification.

Ideal Rectifier An ideal rectifier is a perfect conductor for forward current and a perfect insulator for reverse current. If R_f is the forward resistance and R_b is the reverse resistance, an ideal rectifier has the ratio of R_b/R_f approaching ∞. The ratio R_b/R_f is used as a figure of merit for rectifiers.

Vacuum Diode Vacuum diodes are used for all purposes from low-voltage signal rectification to fairly high power rectification. The current-carrying capacity of the diode is usually limited by the ability of the anode to dissipate heat. The plate dissipation in watts is obtained by multiplying the plate current by the plate-to-cathode voltage. There is a maximum peak inverse voltage above which the tube breaks down and electrons flow from anode to cathode. There is also a maximum heater-to-cathode voltage above which there is breakdown between heater and cathode. The cathode of the diode is heated, directly or indirectly, to the temperature of thermionic emission of electrons. When the anode is positive with respect to the cathode, a current is passed through the diode. When the anode is negative with respect to the cathode, no charge will flow through the tube.

Hot-Cathode Gaseous Rectifiers In gaseous rectifiers, an inert gas is contained in a closed vessel at very low pressure. The hot cathode emits electrons toward the anode when the anode is positive with respect to the cathode. The electrons collide with molecules of the gas and produce positive ions and free electrons. The electrons travel to the anode and the positive ions travel to the cathode. A current is established when the potential reverses, and the cathode is positive with respect to the anode. The electrons are drawn to the cathode. Ionization ceases and current no longer flows. Tungar and Rectigon rectifiers are examples of hot-cathode gaseous rectifiers. The anode is made of graphite, and the cathode is a coiled tungsten filament heated by an electric current. An inert gas, such as argon, is contained in a bulb at reduced pressure. In the Tungar rectifier, the gas pressure is approximately 5 cm of Hg. Usually, the gas pressure varies from 0.01 mm to several cm of Hg.

Mercury-Arc Rectifiers Mercury, in this case, is both the cathode and source of mercury vapor which can be ionized. The ionization potential of mercury is 10.39 V. If the cathode-to-anode voltage exceeds this value, the emitted electrons will have enough energy to ionize the mercury atoms. The positive mercury ions move toward the cathode. When mercury vapor condenses, it returns to the cathode pool. There is no deterioration of the cathode with use. When the rectifier is in operation, a mercury arc concentrates on the surface of the mercury at the cathode and produces the cathode spot. It is a region of high temperature at which ionization can occur readily. The cathode spot may reach a temperature of 2087°C, and the mean temperature of the cathode pool is of the order of 100°C. The anode may be of either iron or graphite. The ordinary arc drop is of the order of 12 to 18 volts in single-tank rectifiers and may go as high as 30 volts in multi-anode tank rectifiers.

Grid-Controlled Gaseous Rectifiers By means of the potential applied to the grid of a gaseous rectifier tube, its plate current can be controlled. The hot-cathode thyratron has a cathode made of a small nickel cylinder. The cathode is heated by a single tungsten filament. The cathode assembly is surrounded by three concentric nickel cylinders, with spaces between, to heat-shield the vanes and thus minimize the watts per ampere emission. The grid consists of perforated metal completely surrounding both cathode and anode. The electrons and ions go through the perforations of a disk in passing between cathode and anode. The grid controls the arc anly to the extent of either initiating it or preventing it from starting. The grid controls the firing of the tube by varying the phase of the voltage applied to the grid. Thyratrons are capable of rectifying relatively large values of power with ratings such as 65 amp at 2,500 volts.

Power Rectifiers with Grid Control Large power mercury-arc rectifiers can be equipped with grid control. The energized grid controls and regulates the output voltage of the power rectifier. After a backfire has occurred, the grid restores the rectifier to normal operating conditions by the quick application of a negative potential to it. Grid control is made by variation of the magnitude of the grid voltages. Large power rectifiers can have 6 to 12 anodes with ratings up to 1,000 amp and 20,000 volts. The multianode single-tank rectifier requires a continuous arc and is susceptible to backfiring due to diffuse ionization. It also has a high arc drop, usually between 25 and 30 volts.

Ignitron The ignitron is a single half-wave mercury-arc rectifier in which the ignition of the arc and its control are both accomplished by the same element. The main anode is made of graphite, and the cathode is a mercury pool. The starting ignitor is a pointed rod of high-resistance refractory material, the pointed end of which dips into the mercury pool. When a positive current impulse, usually of 20 to 40 amp, is delivered to the ignitor, a spark occurs at the junction of the ignitor and the mercury pool and this spark instantly develops into a small cathode spot, which ionizes the mercury. If the anode is sufficiently positive, an arc strikes from anode to cathode. The entire process requires only a few microseconds. The arc is extinguished during the following half-cycle, when the anode-cathode potential reverses, and the current for the half-cycle goes to zero. The power output can be controlled by timing the firing by shifting the phase of the pulse to the ignitor. Efficiency increases with voltage rating. The efficiency at an output voltage of 100 volts of an ignitron with 20 volts arc drop cannot exceed 83.3%; at 200 volts the efficiency would be 91% and at 600 volts nearly 97%. At 2,000 volts the efficiency approaches 99%.

Solid State Rectifiers Rectification can result from the presence of potential barriers at the surface or within the bulk of the crystalline semiconductor material. These barriers impede the flow of current in one direction, which is the reverse direction. At the same time they enhance the flow of current in the opposite direction, which is the forward direction. Solid state rectifiers can be classified as *contact* rectifiers and *junction* rectifiers.

Contact Rectifiers Contact rectifiers are based on the Schottky effect. They consist of metal-to-semiconductor contacts. The semiconductor has a different work function than the metal. The metal-to-semiconductor contact has a potential barrier, i.e., Schottky barrier, which results in rectification. When the semiconductor is biased positively with respect to the metal (reverse bias), the electrons in the metal move toward the barrier but have insufficient energy to overcome it. Electrons in the semiconductor move away from the barrier, and this depletion widens the space-charge region of ionized donors. In the case of forward bias, the potential barrier is reduced, and electrons flow more easily from semiconductor to the metal. The electrons entering the metal have energies much greater than the Fermi energy in the metal. They are called *hot electrons.* The conduction in this case is done by the majority carriers. Contact rectifiers can be either in the form of plate rectifiers or point contact rectifiers.

Plate Rectifiers Plate rectifiers take the form of thin semiconducting layers with metallic electrodes on either side. The thin layer permits the ohmic series resistance of the bulk material to be as small as possible. Plate rectifiers can be made of selenium, cuprous oxide, titanium dioxide, or cupric sulfide, among others.

Point-Contact Rectifiers The semiconducting material, in the form of a chip, either single crystal or polycrystalline, is soldered to a metal support. The point contact is a thin wire which is welded or soldered to a second external electrode. The point contact is adjustable during assembly, but remains fixed after testing. The semiconductor material may be silicon or germanium. The crystal and the whisker are mounted in a cartridge. A tapping process, which involves a number of slight mechanical taps to the cartridge assembly, improves the rectifying properties and the stability of the point contact. An electrical forming treatment can stabilize the voltage-current characteristics. For example, the passage of a large forward current, about 100 mA or more for a period of between 1 and 50 milliseconds, lowers the forward resistance permanently and increases the reverse resistance of an *n*-type germanium diode. Rectifiers can also be made of lead sulfide (PbS), lead selinide (PbSe), lead telluride (PbTe), aluminum antimonide (AlSb), gallium antimonide (GaSb), indium phosphide (InP), or gallium arsenide (GaAs).

Junction Rectifiers Rectification can result when there is a junction region between two semiconductor regions which have different types of majority carriers, such as a junction between a *n*-type layer and a *p*-type layer. In the *p*-type layer, holes are the majority carriers. They move toward the *n*-type layer where there are few holes, leaving behind negatively charged acceptor ions. The electrons, which are the majority carriers in the *n*-type layer, move toward the *p*-type layer where there are few electrons, leaving behind positively charged donor ions. Because the Fermi levels are different for the *p*-type layer and the *n*-type layer, the *p-n* junction causes a potential barrier to be formed as these two Fermi levels are brought together to be equal to one Fermi level in the junction. This potential barrier is the source of rectification in the junction rectifier. When an external reverse voltage is applied to the *p-n* diode, the minority carriers flow through the junction and they are the source of current flow. Silicon rectifiers can be operated at ambient temperatures up to 200°C and at current levels of hundreds of amperes and voltages as high as 1000 volts.

Silicon-Controlled Rectifiers A silicon-controlled rectifier (SCR) is basically a four-layer *p-n-p-n* device that has three electrodes. They are a *cathode*, and *anode*, and a control electrode called the *gate*. Under forward bias condition where the anode is positive with respect to the cathode, the SCR has two states. At low values of forward bias, the SCR exhibits a very high impedance. This is the "off" state where a small forward current flows. As the forward bias is increased to a certain voltage value, the current increases rapidly, and the SCR device switches to the "on" state. This voltage value is called the *breakover voltage*. When the SCR is in the "on" state, the forward current is limited by the impedance of the external circuit. Under reverse bias where the anode is negative with respect to the cathode, the SCR exhibits a very high internal impedance, and only a small amount of current (the *reverse blocking current*) flows. The device remains in this state with a small current until the reverse voltage exceeds the *reverse breakdown voltage limit*. Then, the reverse current increases rapidly, and the SCR suffers irreversible damage.

Thyristors Thyristors are semiconductor devices that are similar to thyratron tubes. They include bistable semiconductor devices that have three or more junctions and devices that can be switched between conducting states. SCR is one type of thyristor.

REFLECTION

If a perfectly smooth and flat interface exists between two homogeneous media, the ratio of the reflected to the incident intensity of light striking the interface is called the *reflectivity*. A real surface, however, is not ideally smooth and undistorted so that the situation is complicated by surface conditions such as films, roughness, and disorder in the crystal lattice at the surface introduced by the polishing process. The measured ratio is thus usually termed the *reflectance* to distinguish it from the former more- or less-idealized situation.

The reflectivity of a material is intimately connected with its band structure.[1] In a single atom, the electrons surrounding the nucleus can have only certain discrete energies. In a solid or liquid, neighboring atoms interact with each other changing these discrete energy levels into energy bands. The energy band structure depends not only on the type of atoms involved but also on the interatomic spacing, and hence in a crystalline material on the lattice structure. In a noncrystalline solid or in a liquid, the correlation function takes the place of the crystalline lattice. The highest occupied energy band may be completely filled with electrons, as in the case of a dielectric or semiconductor, or only partially filled, as for a metal. If the band is not completely full, electrons may absorb energy from the incident light beam and be raised to higher energies in the band, thus affecting the reflectivity of the material. These *intraband* transitions of the conduction electrons, or, in case of a nearly filled band, holes (the absence of electrons), largely determine the reflectivity of metals and some semiconductors in the infrared region of the spectrum. At shorter wavelengths, the light has sufficient energy to raise the electrons from one energy band to another, and the reflectivity is then also affected by these *interband* transitions.

In dielectric materials, where the occupied band having the highest energy is completely filled and the gap between allowed energy bands is large, the energy in the incident light beam cannot be absorbed either in intraband transitions or, except at very short wavelengths, in interband transitions. Such materials are therefore often transparent over an extended wavelength region in the ultraviolet, visible and near infrared, and have a nonzero reflectivity in this wavelength region only because of the difference in the speed of light in the material and in the surrounding medium. However various types of imperfections, termed F centers, M centers, etc., may exist in the lattices of crystalline materials, and electrons trapped in such centers can strongly absorb certain energies, thus affecting the reflectivity. In the intermediate and far infrared, dielectrics and many semiconductors absorb because the incident light excites vibrations in their crystal lattices. Since the frequencies of these lattice vibrations are quantized, this so-called phonon absorption results in maxima in the reflectivity spectra, termed restrahlen bands.

Other mechanisms also contribute to the reflectivity. Some which should be mentioned are transitions between a localized impurity level and an energy band, absorption by a bound hole-electron pair or exciton, and indirect or phonon-assisted interband transitions.

Electromagnetic Theory The reflectivity of any magerial can be calculated from electromagnetic theory[2,3] if the optical constants of the material are known. This theory, which is based entirely on Maxwell's equations, is phenomenological in that it does not attempt to explain why materials behave as they do, but rather sets forth relationships which exist between various properties of the material. In order to calculate the reflectance of a material from this theory, the two optical constants, n and k, must be known. The index of refraction n is equal to the ratio of the phase velocity of light in vacuum to the phase velocity in the material. The extinction coefficient k is equal to $\lambda/4\pi$ times the absorption coefficient α of the material; α is thus a measure of the fraction of light absorbed by a unit thickness of the material. These parameters, which are frequently combined into the complex refractive index $\bar{n} = n - jk$, arise in the solution to the wave equation and completely describe all the optical properties of the material.

The equation for the propagation of an electromagnetic wave can be obtained directly from Maxwell's equations, and in Gaussian units can be written

$$\nabla^2 \mathbf{E} = \frac{\epsilon}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2} + \frac{4\pi\sigma}{c^2}\frac{\partial \mathbf{E}}{\partial t} \qquad (1)$$

where ∇^2 is the Laplacian operator $\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$, $\mathbf{E}$ the electric field strength of the traveling wave, t the time, c the velocity of light and ϵ and σ the dielectric constant and conductivity of the material, respectively, at the frequency of the wave. The solution representing a plane wave traveling in the z direction is

$$E = E_0 e^{j\omega(t - \bar{n}z/c)} \qquad (2)$$

where $\omega = 2\pi\nu$ is the angular frequency of the wave, E_0 the amplitude, and $\bar{n}$ the complex refractive index. By matching E_0 and its first derivative on either side of a smooth, plane interface between a transparent material of index n_0, the medium of incidence, and a second material of index $\bar{n}_1$, one can obtain r, the ratio of the reflected to the incident amplitude, called the *amplitude reflection coefficient*:

$$r = \frac{\eta_0 - \bar{\eta}_1}{\eta_0 + \bar{\eta}_1} \qquad (3)$$

where η_0 and $\bar{\eta}_1$ are the effective indices. At normal incidence, $\eta_0 = n_0$ and $\bar{\eta}_1 = \bar{n}_1 = n_1 - jk_1$.

At non-normal incidence, Snell's law may be used to determine the angle of refraction ϕ_r corresponding to a given angle of incidence ϕ_i. For the case when both materials are nonabsorbing, Snell's law states

$$\frac{\sin\phi_i}{\sin\phi_r} = \frac{n_1}{n_0} \qquad (4)$$

It is also necessary to specify the state of polarization of the incident light. Since $\mathbf{E}$ is a vector quantity, it is always possible to resolve it into two components, the so-called p and s components, polarized parallel to and perpendicular to the plane of incidence (the plane containing both the incident beam and the normal to the surface). There are then two effective indices, η_p and η_s, for each medium at a given angle of incidence. For nonabsorbing materials they are defined as

$$\eta_s = n\cos\phi \qquad (5)$$

$$\eta_p = \frac{n}{\cos\phi} \qquad (6)$$

where ϕ is the angle of incidence or refraction in the medium of index n. In the medium of incidence, ϕ becomes ϕ_i while in the second medium, ϕ becomes ϕ_r. If the second medium is absorbing ($k \neq 0$), $\cos\phi$ becomes complex, making η_s and η_p also complex. They may then be most easily calculated from the following expressions:[4]

$$\bar{\eta}_s = A - jB \qquad (7)$$

$$\bar{\eta}_p = C - jD \qquad (8)$$

where

$$A^2 - B^2 = n_1^2 - k_1^2 - n_0^2\sin^2\phi_i \qquad (9)$$

$$AB = n_1 k_1 \qquad (10)$$

$$C = A\left[1 + \frac{n_0^2\sin^2\phi_i}{A^2 + B^2}\right] \qquad (11)$$

$$D = B\left[1 - \frac{n_0^2\sin^2\phi_i}{A^2 + B^2}\right] \qquad (12)$$

The *intensity reflection coefficient* or *reflectivity* R, defined as the ratio of the intensities of the reflected and incident light, is obtained by multiplying the amplitude reflection coefficient of Eq. (3) by its complex conjugate. At normal incidence for an absorbing material

$$R = \frac{(n_1 - n_0)^2 + k_1^2}{(n_1 + n_0)^2 + k_1^2} \qquad (13)$$

At non-normal incidence, the expressions for R_s and R_p for absorbing materials become quite complicated. However, for nonabsorbing materials

$$R_s = \frac{\sin^2(\phi_i - \phi_r)}{\sin^2(\phi_i + \phi_r)} \qquad (14)$$

and

$$R_p = \frac{\tan^2(\phi_i - \phi_r)}{\tan^2(\phi_i + \phi_r)} \qquad (15)$$

Equations (14) and (15) are the intensity expressions for Fresnel's equations. From Eq. (15) it is seen that when $\phi_i + \phi_r = 90°$, $R_p = 0$ so that all of the reflected light is polarized in the s direction. The angle of incidence for this case is called the polarizing angle and is given by

$$\tan \phi_i = \frac{n_1}{n_0} \tag{16}$$

A plot of the reflectivity R_p and R_s as a function of angle of incidence is shown in Fig. 1(a) for a transparent material in air and in Fig. 1(b) for an absorbing material. Note that the R_p curve for the transparent material goes to zero while the R_p curve for the absorbing material does not.

The phenomenon of total internal reflection is important for transparent materials. If light passes from a more optically dense (higher index) medium of index n_0 to a less optically dense (lower index) medium of index n_1, when $\sin \phi_i = n_1/n_0$, the angle of refraction in the less dense medium is 90°, as can be seen from Eq. (4). At larger angles of incidence, the light is totally internally reflected in the more dense medium. This method of obtaining a surface whose reflectivity is 100 per cent is widely used in optical instruments such as binoculars and periscopes, which contain internally reflecting prisms.

Whenever light is reflected from a surface, a change in phase occurs in the electric vector. For the case of a normal incidence reflection in air from a dielectric, the phase change β is 180°, while for a reflection in the more dense medium, β is 0°. When the reflection is from an absorbing material, β depends on the optical constants of the material,[5] and $\tan \beta$ is given by the ratio of the imaginary to the real part of Eq. (3). If the medium of incidence is air,

$$\tan \beta = -\frac{2k}{n^2 + k^2 - 1} \tag{17}$$

for a normal incidence reflection from an absorbing material with $\bar{n} = n - jk$. At nonnormal incidence, the phase change on reflection is different for the p and s components. By a technique called ellipsometry,[6] this difference in phase can be measured and used, along with other data, to determine the optical constants of a material. If a surface film is present, the phase difference between the p and s components can also be used to measure its growth. Films as thin as a monolayer or less can be detected in this way.

As was indicated at the beginning of this section, Maxwell's equations by themselves do not give sufficient information to relate the optical constants of a material to basic atomic parameters. A fundamental problem in the theory of the optical properties of solids is thus to supplement electromagnetic theory in such a way as to relate the optical constants of a material to nonoptical quantities which can be experimentally determined. If Eq. (2) is substituted into Eq. (1), one obtains the basic equations relating the optical constants to the dielectric constant and conductivity measured at optical frequencies:

$$n^2 - k^2 = \epsilon \tag{18}$$

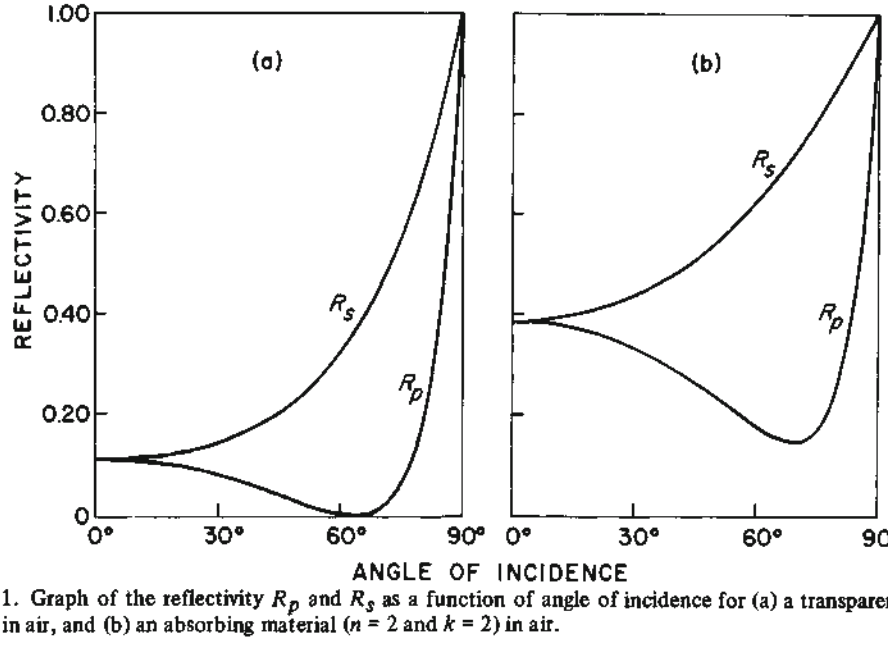

FIG. 1. Graph of the reflectivity R_p and R_s as a function of angle of incidence for (a) a transparent material (n = 2) in air, and (b) an absorbing material (n = 2 and k = 2) in air.

$$nk = \sigma/\nu \tag{19}$$

The problem is how to relate ϵ and σ to the dielectric constant and conductivity at zero frequency, ϵ_0 and σ_0, or to atomic parameters such as the effective mass m^*, number of free carriers per cubic centimeter N, oscillator strength f, etc. A classical simple harmonic oscillator theory first proposed by H. A. Lorentz in 1880 has been successfully used to solve this problem for materials in which the absorption is caused by forced vibrations, while a companion classical theory proposed by P. Drude in 1901 has had similar success for materials where the absorption is due to free electrons and holes. Quantum mechanical treatments give rise to equations having the same form as the classical ones, but containing parameters whose values can be calculated rather than having to be empirically determined. Although these theories will not be discussed here, it can be pointed out that, to a very good approximation, the reflectivity of good conductors in the infrared region is given by[7]

$$R = 1 - \left[\frac{2\omega}{\pi\sigma_0}\right]^{1/2} [(1 + \omega^2\tau^2)^{1/2} - \omega\tau]^{1/2} \tag{20}$$

where the relaxation time τ is given by

$$\tau = \frac{m^*\sigma_0}{Ne^2} \tag{21}$$

and e is the electronic charge. At sufficiently long wavelengths, $\omega\tau \ll 1$ and the reflectivity is then given by the Hagen-Rubens relation

$$R = 1 - \left[\frac{2\omega}{\pi\sigma_0}\right]^{1/2} \tag{22}$$

which may also be obtained directly from Eqs. (13), (18) and (19). Both Eqs. (20) and (22) are in good agreement with experiment.

Reflectance of Real Surfaces In the preceding discussion, it has been assumed that there are two homogeneous media separated by a perfectly smooth and flat interface. In actual fact this situation does not occur, and it is necessary to consider how the deviation of real surfaces from this model affects the observed reflectance. Consider first the effect of surface roughness. For a perfectly smooth surface, all light is reflected at the specular angle, which is equal to the angle of incidence. At the other extreme, the angular dependence of light reflected from a perfectly diffuse reflector is independent of the angle of incidence, and Lambert's law then holds. This law may be stated

$$I_d(\theta) = I_0 \cos\theta \tag{23}$$

where I_0 is the total amount of light reflected per unit area normal to a perfectly diffuse plane reflector, and $I_d(\theta)$ that reflected per unit area at an angle θ to the normal. The reflectance of actual rough surfaces can be separated into "specular" and "diffuse" components, although the diffuse component usually does not obey Lambert's law exactly. If the heights of the surface irregularities are of the order of a wavelength or more, the reflectance is mostly diffuse and depends strongly on the shape of the irregularities. However, if they are very small relative to the wavelength, most of the light is reflected specularly, the amount depending only on the height of the irregularities. For a random height distribution of surface irregularities, the specular reflectance at normal incidence R_s is given by[8]

$$R_s = R_0 e^{-(4\pi h/\lambda)^2} \tag{24}$$

where R_0 is the total reflectance of the surface, h the rms height of the surface irregularities, and λ the wavelength. R_s/R_0 is very sensitive to small values of h/λ. For example, if h is as small as 0.025 λ (in the visible h would then be only 12 nm, or one-half a microinch), the specular reflectance will be decreased by 10 per cent. The surfaces of mirrors used in optical instruments must thus be extremely smooth. Typically the rms roughness of such mirrors is about 2.5 nm (0.1 microinch) rms and may be as small as 0.8 nm (0.03 microinch) rms. Roughness of 2.5 nm are large enough to reduce the reflectance of metals slightly in the infrared via the anomalous skin effect.[9] In addition, at wavelengths near the surface plasmon frequency for a metal the reflectance may be reduced significantly for 2.5 nm rms surfaces by optical excitation of surface plasmons.[10] This effect is of primary importance in the ultraviolet, but for metals such as silver it extends into the visible region. Since the excited plasmons may decay by incoherent reemission, scattered light may also increase where plasmon excitation occurs.

The reflectance may also be affected by distortion of the crystal lattice at the surface caused by the polishing process. The amplitude penetration depth δ of light into an absorbing medium, given by

$$\delta = \lambda/2\pi k \tag{25}$$

is usually only a few tens of nanometers or roughly one microinch for metals or semiconductors in the intrinsic absorption region. On the other hand, lattice distortion introduced by optical polishing may extend for many hundreds of nanometers below the surface, so that the reflection takes place entirely in the disturbed surface layer. Fortunately, the lattice distortion on the surface can be nearly eliminated in many cases by using proper electropolishing techniques.[11] Optical polishing can also produce changes in the reflectance of dielectrics and noncrystalline materials such as optical glass.

Finally, surface films can have a large effect on the reflectance. Although naturally occurring oxide films are important mainly in the ultraviolet, the reflectance may be substantially modified at any wavelength by overcoating the material with one or more evaporated thin films. Over a limited wavelength region, nearly any desired reflectance characteristic may be obtained in this way, and this technique is widely used in the optical industriy.[12] Perhaps the most familiar example of the application of a thin film is the antireflection coating on lenses. Others are the "cold" mirrors used in projection systems, the multilayer coatings which control the temperature of space vehicles by adjusting the reflectance of their outer surfaces, and finally the highly reflecting, low-absorbance dielectric multilayer films used with lasers. Some of these latter coatings have reflectances well over 99% at the laser wavelength.

Often the multilayer coatings consist of alternating high and low refractive index films, each a quarter wavelength in optical thickness. (The optical thickness of a film is the product of its physical thickness and its refractive index.) The limiting reflectance R for very high reflectance coatings is determined by the absorption in the film materials and at alternate film interfaces. It is given by[13]

$$R = 1 - \left[\frac{\lambda}{2}(\alpha_L + \alpha_H) + 4A_{HL}\right] \cdot \left[1 - \left(\frac{n_L}{n_H}\right)^{2N+1}\right]\frac{1}{n_H^2 - n_L^2} - 4\frac{n_S}{n_H^2}\left(\frac{n_L}{n_H}\right)^{2N}(1 + A_{HS}) - \left(\frac{4\pi h}{\lambda}\right)^2 \tag{26}$$

where n_S is the (nonabsorbing) substrate refractive index and n_H and n_L are the real parts of the refractive indices for the high and low index films making up the multilayer coating. The absorption coefficients of the high and low index films are α_H and α_L, respectively. As mentioned previously, the absorption coefficient α of a material is related to its extinction coefficient k by the relation

$$\alpha = 4\pi k/\lambda. \tag{27}$$

As a result, α gives the power loss per unit distance in the material traversed by a light ray, and is often expressed in units of cm^{-1}. In deriving Eq. (26) it is assumed that the optical thickness of each of the layers is $\lambda/4$ or an odd multiple thereof, that the layers are alternately of high and low refractive index, N being the number of high/low layer pairs, and that a high index layer is next to the substrate as well as being the outermost layer of the coating. The interface absorption A_{HL} is found between each high index layer and the next inner low index layer. Similarly A_{HS} is the interface absorption between the innermost high index layer and the substrate. Since a standing wave electric field is set up in the coating and goes nearly to zero at the surface and at each low index-high index interface, absorption does not occur at the outer surface of the coating and at each alternate interface. If the low refractive index layer is next to the substrate, the next to the last term in Eq. (2) involving the substrate refractive index n_S is replaced by[13]

$$\frac{-4}{n_S}\left(\frac{n_L}{n_H}\right)^{2N}.$$

The last term in Eq. (26) represents light scattered by the substrate-film combination. If the films contour the surface exactly, as is usually the case to a good approximation, then the single interface expression for scattered light given by Eq. (24) can be used to calculate scattering from a multilayer coating by simply substituting the multilayer reflectance for the single surface reflectance R_0.

Equation (26) represents only one of a great number of possible interference coatings which could be used to modify the reflectance of a surface. Another common design is the antireflection quarter-wave coating, which is commonly used on camera lenses and other transmissive optics to minimize reflectance. Both single and multilayer coatings are used for this purpose. If a single layer coating of a quarter-waver optical thickness is used and the absorption is assumed to be negligible, the reflectance R of the interface is

$$R = \left(\frac{n_S - n_L^2}{n_S + n_L^2}\right)^2. \tag{28}$$

This expression approaches zero if $n_L \simeq \sqrt{n_S}$. In this case the normal incidence reflectance of the surface completely disappears.

REFRACTION

Refraction is the name given to the bending of a ray of light as it crosses the boundary separating two transparent media having differing propagation velocities.

In an attempt to discover a law connecting the directions of the light rays in the two media, W. Snell (1621) observed that there is a constant ratio between the lengths PB, PC of the two rays (Fig. 1) measured from the point of incidence P to any line such as DD′ drawn parallel to the normal PN at the point of incidence. Later Descartes recognized that Snell's construction is equivalent to the mathematical expression

$$n \sin I = n' \sin I'$$

when I, I' are the angles of incidence between the two rays and the normal, and n, n' are the *refractive indices* of the two media respectively. The ratio of n' to n is called the "relative" refractive index of the two media.

Huygens' Wavelets C. Huygens (1690) attempted to explain how a wave front progresses through a transparent medium. He supposed that each point on the wave front acts as an independent source of wavelets which expand at the velocity of light, the new wave front being the common envelope of all the little wavelets. After an instant of time, each point in the new wave front becomes a source of new wavelets, and so on. In a homogeneous isotropic medium, the wavelets will be spheres, and the new wave front is a parallel curve to the original wave front. The light energy travels along *rays* which are everywhere perpendicular to the wave fronts. Malus (1808) showed that the rays and wave fronts remain always orthogonal as the beam of light from an object point traverses an optical system.

The absolute refractive index of a medium is defined as the ratio of the velocity of light in vacuum to its velocity in the medium. Because the presence of matter has the effect of making light travel more slowly, all absolute refractive indices are necessarily positive and greater than unity. Since the frequency of the light waves must remain constant, the wavelength in a dense medium will be less than the wavelength in vacuum in proportion to the refractive index of the medium. Refractive indices of liquids and crystals generally drop with increasing temperature; glasses are, however, often exceptional in this regard.[1]

Refractive indices range from as low as 1.3 for some liquids such as water, through 1.5 to 1.9 for various types of glass, 2.5 for diamond, up to as high as 4.0 for some materials (germanium) in the infrared. These exceptionally high indices are generally associated with complete opacity in the visible part of the spectrum.

Dispersion It is found that the refractive index of all common materials rises with increasing frequency of the light (shorter wavelengths) leading to the phenomenon of *dispersion*. Because of this, a glass prism bends blue light more than red, thus spreading a ray of white light into its component colors (Fig. 2). For a prism of very small angle A, the deviation angle D is given by

$$D = A(n - 1)$$

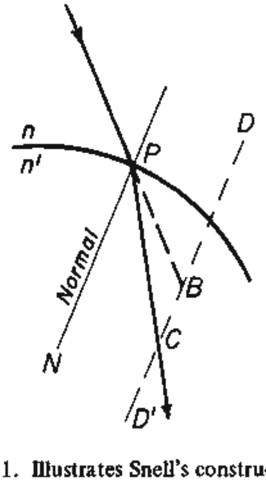

FIG. 1. Illustrates Snell's construction.

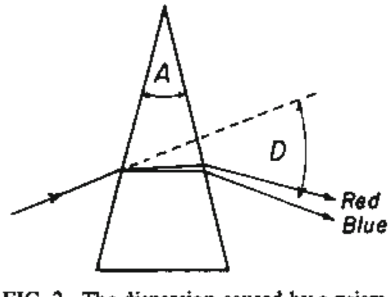

FIG. 2. The dispersion caused by a prism.

and the angular dispersion Δ between wavelengths a and b is given by

$$\Delta = A(n_b - n_a).$$

It has been customary to define the dispersive power w of a material as the ratio of the dispersion between the F and C Fraunhofer lines to the mean deviation, i.e., the deviation for the D Fraunhofer line. Thus

$$w = (n_F - n_C)/(n_D - 1).$$

The vacuum wavelengths of these 'lines are C = 0 6563μ, D = 0.5893μ, and F = 0.4861μ. In the optical industry, the reciprocal of the dispersive power is, however, more generally used; i.e.,

$$V = 1/w = (n_D - 1)/(n_F - n_C).$$

This so-called "V-value" or "Abbe number" of optical glass ranges from about 25 for the densest flints up to about 70 for the lightest fluor crowns. Liquids and crystals are known in which the V-numbers range from about 16 (methylene iodide) to 95 (calcium fluoride).

Many attempts have been made to develop a formula connecting the refractive index of a material with the wavelength of the light. The best known and most comprehensive is that proposed by Sellmeier,[2] namely,

$$n^2 = 1.0 + \sum \frac{b\lambda^2}{c^2 - \lambda^2}.$$

Here n is the refractive index corresponding to wavelength λ, while b and c are constants. The constant c represents the center of an absorption band for which the refractive index becomes infinite; there are thus as many terms under the summation sign as there are absorption bands to be considered. For most transparent materials, it is sufficient to include one absorption band in the ultraviolet and one in the infrared.

This general formula may be reduced to a simpler form for a limited spectral range, some well-known simplifications being

$$n = a + b/\lambda^2 + c/\lambda^4 + \cdots \qquad \text{(Cauchy)}$$

$$n = 1 + b/(c - \lambda) \qquad \text{(Hartmann)}$$

$$n = a + b/\lambda + c/\lambda^{7/2} \qquad \text{(Conrady)}$$

Herzberger[3] has shown that the refractive index of a transparent substance such as glass can be accurately represented by a four-constant formula of this type:

$$n = a + b\lambda^2 + cL + dL^2$$

where $L = 1/(\lambda^2 - 0.028)$.

Birefringence, or Double Refraction Glasses, liquids, and some (e.g., cubic) crystals are *isotropic*, meaning that the velocity of light in the medium is independent of direction and the Huygenian wavelets are spherical. However, there are other crystals which are *anisotropic*. These have the property that a beam of light on entering the crystal is split into two perpendicularly polarized beams, one of which (the "ordinary") behaves normally, while the other (the "extraordinary") behaves abnormally in that the wave front is not perpendicular to the direction of propagation.

These two wave fronts can be explained by supposing that two Huygenian wavelets are formed at any point of incidence, the ordinary wavelet being spherical while the extraordinary wavelet is an ellipsoid, (Fig. 3).[4] The advancing wave front is the common tangent to a row of wavelets, and the ray, or direction of travel, is found by joining the point of origin of the wavelet to the point of contact between the wavelet and the advancing wave front. The spherical wavelets thus yield a ray which is perpendicular to the wave front, but the ellipsoidal wavelets do not.

All anisotropic crystals possess either one or two directions ("optic axes") along which a ray of light is not divided into two. These are represented by the axes of symmetry of the ellipsoidal wavelets. Evidently if parallel light is travelling along an optic axis, the two advancing wave fronts will be parallel to one another and the two rays will coincide (see POLARIZED LIGHT).

Refraction by an Inhomogeneous Medium Suppose we have a parallel plate of material of which the refractive index varies laterally across the plate. A ray entering such a plate perpendicularly to its surface will suffer no refraction itself since the incidence angle is zero, but because there is a gradient of refractive index at right angles to the ray, the ray inside the plate will be bent towards the high-index region and will follow a curved path. This is readily seen if we remember that the ray will be perpendicular to the wave front and that each point on the wave front travels at a rate which is inversely proportional to the refractive index at that point. To determine the curvature of the ray inside the medium, we may refer to Fig. 4 in which CC′ represents the surface of a nonhomogeneous medium, and A′A, B′B represent two very close rays entering perpendicular to the surface. We shall suppose the velocity of light in the material to be v at A and $(v + dv)$ at B, the refractive indices being $(n + dn)$ and n respectively. Typical wavelets have been added at A and B, having radii AD and BE which are proportional to the

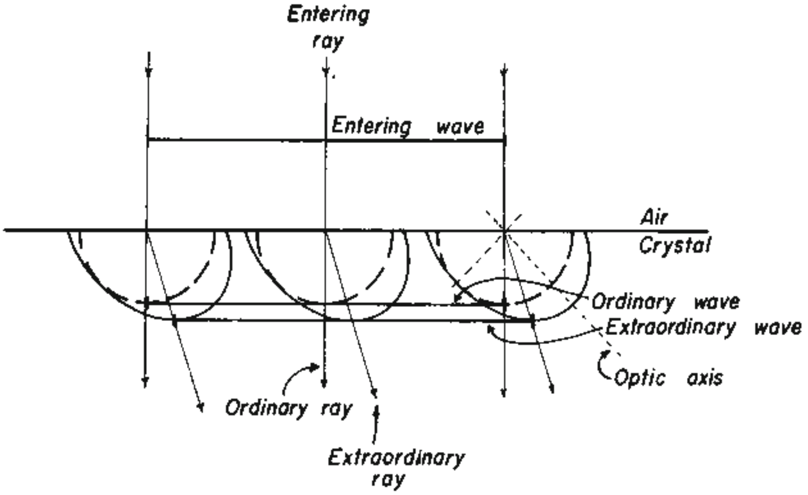

FIG. 3. Explanation of double refraction.

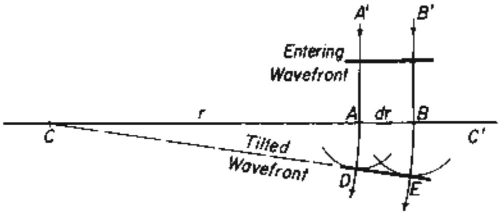

FIG. 4. Bending of a light ray in an inhomogeneous medium.

velocities v and $(v + dv)$. Hence the refracted wave front is ED; this intersects the surface at C, which is therefore the instantaneous center of curvature of the rays within the medium.

If r is the radius of ray AD,

$$\frac{CA}{CB} = \frac{r}{r + dr} = \frac{AD}{BE} = \frac{v}{v + dv} = \frac{n + dn}{n}.$$

Neglecting second-order infinitesimals this gives

$$\frac{1}{r} = -\frac{1}{n}\left(\frac{dn}{dr}\right).$$

The curvature of the ray is, therefore, proportional to the rate of change of refractive index in a direction perpendicular to the ray itself.

This property of inhomogeneous media provides the explanation of mirages and also the well-known atmospheric refraction which makes celestial objects appear to be raised up by as much as half a degree for objects situated near the horizon.

An extensive literature[5] has recently appeared dealing with the passage of light through gradient-index materials, as these may eventually replace aspheric surfaces in lenses. Short glass rods having a radial index gradient (so-called GRIN rods) have the property of forming images of external objects. The increasing use of fiber-optic communication channels over long distances requires fibers having a gradient of refractive index across the fiber to equalize the time of transit of light along all possible paths within the fiber.

REFRIGERATION

Refrigeration is the process of cooling or freezing a substance to a temperature well below that of the surroundings and maintaining it in the cold state. The simplest device for this purpose consists of a box or a cryostat immersed in a cooling agent such as cold running water, circulating air cooled by melting ice, liquid air, liquid helium, etc. Generally, the coolant must be replenished periodically, an inconvenient and often inefficient procedure. Since the invention of vapor-compression and vapor-absorption refrigeration methods, recirculating mechanical refrigerators have become commonplace. Other refrigeration methods exploit the thermoelectric properties of semiconductors, the magneto-thermoelectric effects in semi-metals, or the diffusion of ^{3}He atoms across the interface between distinct phases of liquid helium having high and low concentrations of ^{3}He in ^{4}He.

A refrigerator operating in a cyclic process may be considered a heat pump, for it continually extracts heat from a low-temperature region and delivers it to a high-temperature region. It is rated by its *coefficient of performance*, defined as the ratio of the heat removed from the cold region (room, box, cryostat) per unit time to the net input power for operating the device, in symbols $K = Q_t/P$. Vapor-absorption and thermoelectric refrigerators have lower coefficients of performance than vapor-compression refrigerators, but they have other characteristics that are superior, such as quietness of operation and compactness.

Vapor-compression Refrigerator This machine consists of a compressor, a condenser, a storage tank, a throttling valve, and an evaporator connected by suitable tubes with intake and outlet valves, as shown schematically in Fig. 1. The refrigerant is a liquid which partially vaporizes and cools as it passes through the throttlinį valve. Among the common refrigerants are ammonia, sulfur dioxide, and certain halide compounds of methane and ethane. Perhaps the most widely used of these in industry is ammonia and in the household dichlorodifluoromethane ("Freon-12"). Nearly constant pressures are maintained on either side of the throttling valve by means of the compressor. The mixed liquid and vapor entering the evaporator is colder than the near-surround; it absorbs heat from the interior of the refrigerator box or cold room and completely vaporizes. The vapor is then forced into the compressor where its temperature and pressure increase as it is compressed. The compressed vapor finally pours into the condenser where it cools down and liquefies as the heat is transferred to cold air, water, or other fluid flowing by the cooling coils.

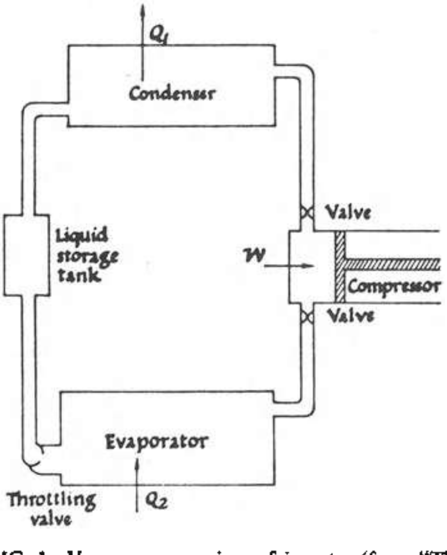

FIG. 1. Vapor-compression refrigerator (from "Thermophysics," by Allen L. King, San Francisco, W. H. Freeman and Co., 1962).

Comparative tests have shown that the coefficient of performance of vapor-compression refrigerators depends very little on the nature of the refrigerant. Because of mechanical inefficiencies, its actual value may be well below the ideal value–ordinarily, between 2 and 3.

Vapor-absorption Refrigerator In this system there are no moving parts; the added energy comes from a gas or liquid fuel burner or from an electrical heater, as heat, rather than from a compressor, as work. A simplified diagram of it is shown in Fig. 2. The refrigerant is ammonia gas, which is liberated from a water solution and transported from one region to another by the aid of hydrogen. The total pressure throughout the system is constant and therefore no valves are needed.

Heat from the external source is supplied to the generator where a mixture of ammonia and water vapor with drops of ammoniated water is raised to the separator in the same manner as water is raised to the coffee in a percolator. Ammonia vapor escapes from the liquid in the separator and rises to the condenser, where it cools and liquefies. Before the liquefied ammonia enters the evaporator, hydrogen, rising from the absorber, mixes with it and aids in the evaporation process. Finally, the mixture of hydrogen and ammonia vapor enters the absorber, where water from the separator dissolves the ammonia. The ammonia water returns to the generator to complete the cycle. In this cycle heat enters the system not only at the generator but also at the evaporator, and heat leaves the system at both the condenser and the absorber to enter the atmosphere by means of radiating fins.

No external work is done, and the change in internal energy of the refrigerant during a complete cycle is zero. The total heat $Q_a + Q_c$ released to the atmosphere per unit time by the absorber and the condenser equals the total heat $Q_g + Q_c$ absorbed per unit time from the heater at the generator and from the cold box at the evaporator; so $Q_e = Q_a + Q_c - Q_g$, and therefore the coefficient of performance is $K = Q_e/Q_g = \{(Q_a + Q_c)/Q_g\} - 1$.

The vapor-absorption refrigerator is free from intermittent noises; but it requires a continuous supply of heat, as from bottled gas or electrical generators. Refrigerators of this type are found in camps and farm houses not supplied with commercial electric power and in apartment houses where unnecessary noise is prohibited.

FIG. 2. Vapor-absorption refrigerator (from "Thermophysics," by Allen L. King, San Francisco, W. H. Freeman and Co., 1962).

Dilution Refrigerator Below a temperature of 0.87 K liquid mixtures of ^{3}He and ^{4}He at certain concentrations separate into two distinct phases, a concentrated (^{3}He-rich) phase floating on a denser (^{4}He-rich) phase with a visible surface between them. The concentrations of ^{3}He in the two phases are functions of temperature, approaching 100 per cent in the concentrated phase and about 6 per cent in the dilute phase at 0 K. The transfer of ^{3}He atoms from the concentrated to the dilute phase, like an evaporation process, entails a latent heat, an increase in entropy, and a lowering of temperature. This effect is utilized in the dilution refrigerator for obtaining temperatures of extremely low values.

The diagram in Fig. 3 shows the main components of a recirculating dilution refrigerator. The pump forces helium vapor (primarily ^{3}He) from the still into the condenser, where it is liquefied at a temperature near 1 K in a bath of rapidly evaporating ^{4}He, through a flow controller consisting of a narrow tube of suitable diameter to obtain an optimum rate of flow, and then through the still where its temperature is further reduced to about 0.6 K. The liquefied ^{3}He next passes through a heat exchanger (sintered copper or sintered silver) so as to reduce its temperature to nearly that of the dilution chamber, by giving up thermal energy to the counterflowing dilute phase, before entering the concentrated phase therein. The diffusion of ^{3}He atoms from the concentrated into the dilute phase within this chamber can produce steady temperatures of very low values (2.5 mK or less). Liquid ^{3}He from the dilute phase then passes through the heat exchanger to the still where it is warmed to transform the liquid to the vapor phase that goes to the pump thus completing the cycle. Modified versions of this system have been constructed, sometimes with an added single-cycle process for produc-

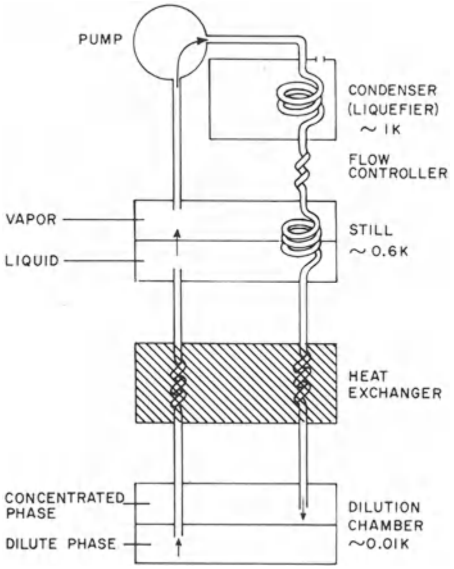

FIG. 3. Schematic showing components of a ^{3}He-^{4}He recirculating dilution refrigerator.

ing temporarily even lower temperatures. The low-temperature limit in any of these systems is determined largely by two important sources of inefficiency that cannot be completely eliminated; heat leakage, especially severe because of the extreme range of temperatures, and recirculation of some ^{4}He with ^{3}He.

Thermoelectric Refrigerator This device utilizes the thermoelectric effect, discovered by Peltier in 1834 (see THERMOELECTRICITY), wherein heat is either absorbed or generated at the junction of two different conductors, or semiconductors, depending on the direction of an electrical current through it. For satisfactory operation in refrigerating devices the thermojunctions should be made of materials having not only high thermoelectric coefficients but also high electrical conductivities, so as to reduce Joule heating, and low thermal conductivities, so as to minimize heat losses by conduction. These requirements are best met by semiconductors such as lead telluride and bismuth telluride.

A thermoelectric refrigerator unit consists of one or more stages of series-connected n-type and p-type semiconductors as illustrated in Fig. 4(a). The charge carriers are electrons in the n-type semiconductor and holes in the p-type semiconductor. When a difference of potential is maintained across AB with B at the higher potential, the negative electrons carry both kinetic and potential energy away from C as they move toward B in the n-type semiconductor; the positive holes do the same as they move away from C toward A in the p-type semiconductor. Since energy is carried away from C to AB in both arms of the thermocouple, junction C becomes cold and junctions AB become warm. Temperature differences as large as 75 C have been obtained in a single-stage unit. Larger temperature differences may be produced by arranging several stages in cascade as illustrated by the two-stage system in Fig. 4(b). In this way a temperature of −118°C was reached in a small seven-stage thermoelectric refrigerator only 38 mm high, employing bismuth telluride alloys in the thermojunctions and water at 27°C as the heat sink.

The coefficient of performance of a multistage thermoelectric refrigerator is no greater than that of one of its units. Let the temperature difference between AB and C in Fig. 4(a) be ΔT. As a result of the Peltier effect, the cold junction cools down at the rate $\bar{\alpha}(T_m - \frac{1}{2}\Delta T)I$, where $\bar{\alpha}$ is the mean value of the Seebeck coefficients for the n-type and p-type semiconductors, T_m is the mean temperature of the thermocouple, and I is the current through it. But due to Joule heating and thermal conduction from the warm to the cold junction, the rate of cooling at C is only $Q_t = \bar{\alpha}(T_m - \frac{1}{2}\Delta T)I - \frac{1}{2}I^2R - \lambda\Delta T$, where the total resistance of the couple $R = (l_p/A_p\sigma_p) + (l_n/A_n\sigma_n)$ and its thermal conductance $\lambda = (A_pk_p/l_p) + (A_nk_n/l_n)$ in which A_p and A_n are the cross-sectional areas of the p-type and n-type semiconductors, l_p and l_n are their lengths, σ_p and σ_n are their electrical conductivities, and k_p and k_n are their thermal conductivities. The power supplied externally must just equal the total Seebeck and Joule terms, namely, $P = \bar{\alpha}I\,\Delta T + I^2R$. The coefficient of performance, therefore, is

$$K = Q_t/P = \frac{\bar{\alpha}(T_m - \frac{1}{2}\Delta T)I - \frac{1}{2}I^2R - \lambda\Delta T}{\bar{\alpha}I\,\Delta T + I^2R}$$

It reaches a maximum value when the products of the thermal and electrical conductances for the two semiconductors have the same value and when the electrical resistance at the junctions is much smaller than R. The optimum current then is given by the equation $(IR)_{\text{opt}} = \bar{\alpha}\,\Delta T[\sqrt{1 + ZT_m} - 1]^{-1}$ where Z is the *figure of merit* of the thermocouple,

$$Z = \bar{\alpha}^2/[(k_p/\sigma_p)^{1/2} + (k_n/\sigma_n)^{1/2}]^2$$

The maximum value of K can now be written in the form

$$K_{\max} = \frac{T_m(\sqrt{1 + ZT_m} - 1)}{\Delta T(\sqrt{1 + ZT_m} + 1)} - \frac{1}{2}$$

Thus $K_{\max}$ increases with an increase in the figure of merit, reaching the value $(T_m - \frac{1}{2}\Delta T)/\Delta T$ for very large Z. This is the coefficient of performance for an ideal thermodynamic machine.

The thermoelectric refrigerator is useful where space is at a premium or where, for other reasons, mechanical refrigerators are inconvenient.

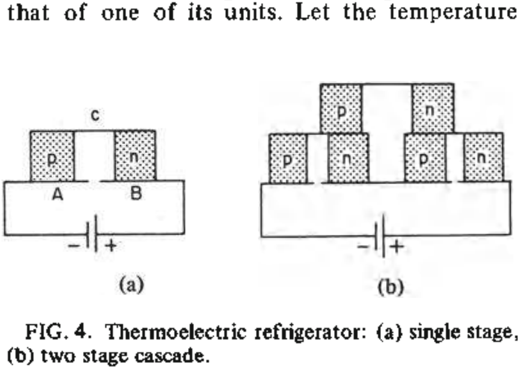

FIG. 4. Thermoelectric refrigerator: (a) single stage, (b) two stage cascade.

Thermomagnetic and Magnetothermoelectric Refrigerators In 1958 O'Brien and Wallace suggested that by means of the Ettingshausen effect, one should be able to achieve cooling for refrigeration purposes (see HALL EFFECT AND RELATED PHENOMENA). This suggestion has been followed up with some success at low temperatures and even with the heat sink near room temperature by a special "cascading" device. In 1962, Smith and Wolfe discovered that the thermoelectric figure of merit for bismuth-antimony alloys can be increased by means of a magnetic field and that this enhancement is especially pronounced at low temperatures. These effects may be applied advantageously to refrigeration at low ambient temperatures.

RELATIVITY

The basic ideas of modern relativity theory are largely due to one man: Albert Einstein (1879–1955). Both main branches of pre-Einstein physics (mechanics and electromagnetism) had relied on an absolute space. To Newton this had served as the agent responsible for a particle's resistance to acceleration; to Maxwell—in the guise of an "aether"—it was the carrier of electromagnetic stresses and waves and thus, in particular, of light. Relativity may be defined briefly as the abolition of absolute space. Special relativity (1905) abolished it in its Maxwellian sense, and general relativity (1915) in its Newtonian sense as well.

Before looking at the theoretical background of relativity, we shall mention some of its more striking practical implications. According to special relativity, for example, a rod moving longitudinally at speed v through an inertial frame is shortened, relative to that frame, by a factor $\gamma = (1 - v^2/c^2)^{-1/2}$, where c is the speed of light. This factor increases with v; when v is as large as $\frac{1}{7}c$, γ is only 1.01, but at higher speeds it grows rapidly and becomes infinite when $v = c$. The rate of a clock moving at speed v is decreased by the same factor γ; this is one aspect of the revolutionary prediction that time, also, is not absolute and that, for example, after journeying at high speed through space, one could, upon return, find the world aged very much more than oneself. In fact, time and space become merged in a four-dimensional continuum in which neither possesses more absoluteness than, e.g., the x-separation between points in a Cartesian plane, which depends on the choice of axes. According to special relativity, time- and space-separations between events are similarly non-absolute and depend, in fact, on the motion of the reference frame. The mass of a body moving at speed v is also increased by the factor γ and thus becomes infinite at the speed of light. This illustrates another prediction of the theory—that no body or physical effect can travel faster than light. But the single most important result of special relativity, in Einstein's opinion, was the equivalence of mass m and energy E according to the formula $E = mc^2$.

Although the original impact of special relativity was mainly theoretical and philosophical—its main effects show up only under certain extreme conditions—technology since 1905 has made such vast strides (atomic power, particle accelerators, Mössbauer effect, etc.) that today special relativity is one of the most practical and, at the same time, best verified branches of all physics.

The same cannot yet be said for general relativity, whose results are still largely theoretical and speculative. But its ideas are hardly less striking. General relativity is the modern theory of gravitation. Like special relativity, it pictures the world as a four-dimensional space-time continuum, but according to general relativity this is curved by the matter present in it. Particles and light rays are postulated to move along geodesics ("straightest possible" curves) in this four-space, and all reference to a "force" of gravity or to an absolute three-space as the standard of nonacceleration has disappeared. It is one of the marvels of this theory that, starting from such utterly different premises, it nevertheless reproduces within experimental accuracy almost all the well-established results of Newton's (inverse square) gravitational theory. In the few cases where its predictions differ to a presently measurable extent from Newton's theory (as for the advance of the perihelia of the planets), general relativity has been borne out by observation. Furthermore, general relativity first led to the construction of many interesting cosmological models, such as closed and finite universes; it implies the existence of gravitational waves and thus the need to quantize the gravitational field; and it contains such exotic possibilities as "black holes" (into which space itself falls at the speed of light, so that *nothing*, not even light, can come out).

That gravity can be "explained" by theories as diverse as Newton's and Einstein's well illustrates the character of all physical theories: they are no more than mathematical *models* of certain parts of nature; they cannot aspire to be ultimate truths.

The theoretical basis of special relativity is Einstein's *principle of relativity* which asserts that all the laws of physics are equally valid in all inertial frames of reference. This is an extension to the whole of physics of a relativity principle which the laws of mechanics have long been known to obey. Newton, as Galileo before him, illustrated this with the familiar example of a ship, "where all motions happen after the same manner whether the ship is at rest or is carried forward in a right line." The reason why Einstein's principle was revolutionary is that the known properties of light seem to contradict it at once. In our quasi-inertial terrestrial reference frame (which was assumed to coincide more or less with Maxwell's aether), light is propagated rectilinearly in all directions at constant speed, in accordance with Maxwell's theory. This fact is often called the *law of light propagation*. But the validity of this law in *all* inertial frames would imply, for example, that a light signal emitted at the instantaneous coincidence of two observers O and O′ who are moving uniformly relative to each other, each fixed in an inertial frame, spreads spherically with *both* observers considering themselves to remain permanently at the center of the expanding signal-sphere. Hence a light signal would always recede from an observer at the same speed, no matter how fast he chases it. The adoption of the principle of relativity together with the law of light propagation thus seems to lead to absurdities. But, in fact, that is not so: it merely leads to the downfall of the classical ideas of space and time. It was part of Einstein's genius to recognize that these ideas were dispensable and could be replaced by others.

Two types of argument can be made in support of Einstein's principle. The first is experimental: all experiments devised to discover the frame of Maxwell's aether (in which *alone* the law of light propagation had been expected to hold), such as the well-known MICHELSON-MORLEY EXPERIMENT (1887), failed to give positive results, though such results would have been well within range of observability. The second argument is theoretical, and rests on the unity of physics. For example, mechanics involves matter, which is electromagnetically constituted; electromagnetic apparatus involves mechanical parts; and so forth. If then, physics cannot be separated into strictly exclusive branches, it would seem unlikely that the laws of different branches should have different transformation properties, i.e., relativity for mechanics but not for electromagnetism.

Consider now two observers O and O′ like the ones mentioned earlier, and a light signal emitted at their coincidence. If each observer remains at the origin of a Cartesian reference system and sets his clock to read zero when the signal is emitted, the events on the light front must satisfy both the equations

$$x^2 + y^2 + z^2 - c^2t^2 = 0$$
$$x'^2 + y'^2 + z'^2 - c^2t'^2 = 0 \qquad (1)$$

where primes distinguish the space and time coordinates used by O′ from those used by O. Now suppose the two observers arrange their corresponding *y* and *z* axes to remain parallel, and their *x* axes to coincide. In classical kinematics, with this configuration of reference systems, the so-called *Galilean transformation equations*

$$x' = x - vt, \quad y' = y, \quad z' = z, \quad t' = t \qquad (2)$$

relate the corresponding coordinates of any event, where v is the relative velocity between O and O′. But under this transformation, the two equations (1) are not equivalent. Einstein showed that for these equations to be equivalent, the transformation equations must necessarily be

$$x' = \gamma(x - vt), \quad y' = y, \quad z' = z,$$
$$t' = \gamma(t - vx/c^2) \qquad (3)$$

where $\gamma = (1 - v^2/c^2)^{-1/2}$. These are the well-known *Lorentz equations* which constitute the mathematical core of the special theory of relativity. They replace equations (2), to which they nevertheless approximate when v is small. The most striking of equations (3) is the last. It implies that events with the same value of t do not necessarily correspond to events with the same value of t', which means that *simultaneity is relative*. Setting $x = 0$ in that equation also shows that the clock at the origin of O goes slow by a factor γ in the frame of O′. But, setting $x = vt$, we see that the clock at the origin of O′ similarly goes slow in the frame of O. Setting $t = 0$ in the first of equations (3), we see that a rod, fixed in the frame of O′ along the x' axis, appears shortened by a factor γ in the frame of O; this phenomenon too can be shown to be symmetric between the frames.

An important property (and, in fact, the *defining* property) of equations (3) is that they leave invariant the differential quadratic

$$ds^2 = dx^2 + dy^2 + dz^2 - c^2dt^2 \qquad (4)$$

which is, of course, related to the equivalence of equations (1). This leads to the possibility of mapping events in a four-dimensional pseudo-Euclidean *space-time* in which an absolute *interval ds* exists, and in which the language and results of four-dimensional geometry can thus be applied. For example, a uniformly moving particle is described simply by a straight line in this space-time, while a nonuniformly moving particle corresponds to a curve in space-time, whose curvature represents its acceleration.

Equation (4) determines the new space-time background to all physics, replacing the older concepts of absolute 3-space and absolute time. All physics must be made consistent with this new background. Special relativity is therefore often called a "metatheory," since it imposes certain requirements on *all* physical theories.

Thus it was the first task of special relativity to review the existing laws of physics and to subject them to the test of the new relativity principle by seeing whether they were invariant under Lorentz transformations. Any law found lacking had to be modified accordingly.

Since Newton's laws of mechanics are invariant under the transformation (2) and *not* (3), it was necessary to amend these laws so as to make them "Lorentz invariant." It was found possible to do this by retaining the classical laws of conservation of mass and momentum *as axioms*, but postulating that the mass of moving bodies increases by the factor γ, a fact amply borne out by modern particle accelerators. This led to the theoretical discovery of the equivalence of mass and energy—most spectacularly exemplified by the atomic bomb, which *transmutes* mass into energy.

In contrast to Newton's theory, Maxwell's vacuum electrodynamics was compatible with Einstein's theory. Lorentz, independently of Einstein, but without realizing the full significance of his result, had already discovered equations (3) as precisely those which leave Maxwell's equations invariant. In other words, Maxwell's equations already were "Lorentz invariant" and needed no modification. (Hence the validity of the law of light propagation in all inertial frames.) Nevertheless relativity has considerably deepened our understanding of Maxwell's theory. Other branches of physics, like optics, hydrodynamics, thermodynamics, nonvacuum electrodynamics, etc., all underwent modifications to make them Lorentz invariant. Only Newton's inverse square gravitational theory proved refractory; several Lorentz invariant modifications of it were proposed but none was entirely satisfactory.

Einstein eventually solved the gravitational problem in an unexpected way. He rejected Newton's absolute space as the cause of inertia on the grounds that "it is contrary to the spirit of science to conceive of a thing which acts but cannot be acted upon." His general theory of relativity ascribes to the space-time continuum discovered by special relativity the role of an inertial guiding field (free particles and light follow geodesics) but allows this field to be affected (curved) by the matter in it.

This extension was made possible by the so-called *principle of equivalence*. To Newton, an inertial frame was, primarily, the (infinite) frame of "absolute space" in which the stars were assumed to be fixed, and, secondarily, any frame moving uniformly relative to absolute space. Thus a Newtonian inertial frame exhibits its defining property, viz., that in it free particles move uniformly and rectilinearly (Newton's first law), only in the regions far from attracting masses, since elsewhere there *are* no free particles. In 1907 Einstein replaced this global definition with a local one: a *local* inertial frame is a freely falling non-rotating reference system. (The meaning of "local" is here determined by the extent to which the nonuniformity of the gravitational field is negligible.) We have all had vicarious experience of local inertial frames by watching astronauts in their freely falling space vehicles. In Newton's theory such frames, though accelerating relative to absolute space, are nevertheless equivalent to inertial frames from which gravity has been eliminated. For example, Newton's first law is here in full evidence. The reason for this is the fact that in a gravitational field *all* particles accelerate equally. And this, in turn, is due to the equality of "gravitational mass" (the analog of electric charge) and "inertial mass" (the measure of a particle's resistance to acceleration)—a puzzling coincidence in Newton's theory. Einstein once again made the generalization from mechanics to the whole of physics. His principle of equivalence asserts that all the laws of physics are the same in each local inertial frame. It is these frames, therefore, which are the real province of the principle of relativity. Special relativity thereby becomes a local theory.

An elementary consequence of the principle of equivalence is the bending of light in a gravitational field. For, if light travels rectilinearly in the local inertial frame, and *that* accelerates freely in the gravitational field, the light path is evidently curved in the field. No property of light other than its uniform motion in a local inertial frame has been used in this argument. This, in turn, suggests that one might ascribe the bending of light to an inherent space curvature, rather than to the nature of light. In much the same way, the characteristic motion of free particles in a gravitional field suggests that they follow "natural" paths (geodesics) in a curved space-time. Their motion is independent of everything except their initial position and velocity. It should be noted, however, that for a geodesic law of motion to be possible, space and time *must* be welded into four-dimensional space-time. Free motions could not be represented by geodesics in a *three*-dimensional curved space. For a geodesic is uniquely determined by a point and a direction at that point. But an initial point and an initial direction do *not* uniquely determine a free path in a gravitational field. *That* depends also on the initial speed. In space-time, on the other hand, a direction is equivalent to a (vector-) velocity. And it *is* the case in Newton's theory that an initial point and velocity uniquely determine a free path in a gravitational field. Note that all this depends on the equality of inertial and gravitational mass, which is therefore a *sine qua non* of Einstein's general relativity. Consequently this equality has been subjected to the most stringent tests (e.g., by R. H. Dicke et al. in the 1960s) and is now considered verified to at least one part in 10^{11}.

As we have seen, special relativity forces a four-dimensional metric structure [Eq. (4)] on the events within an inertial frame. By patching together the structures of all the local inertial frames, we obtain the structure of the world of general relativity. Locally, i.e., in special relativity, it can be regarded as flat. But it is evident that, if the very pleasing geodesic law of motion is to hold, the presence of matter must impress a curvature on this space-time. For example, the planets move in patently curved paths around the sun (in four-dimensions these are helicoidal rather than elliptical); for these paths to be geodesics, the space-time around the sun must be curved. Just how matter curves the surrounding space-time is expressed by Einstein's field equations

$$G_{ij} = -\frac{8\pi G}{c^4} T_{ij} \tag{5}$$

which look deceptively simple. Technically, they represent ten second-order partial differential equations for the metric of space-time. This metric enters the 16 components of the "Einstein (curvature) tensor" G_{ij}, of which only 10 are independent, for $G_{ij} = G_{ji}$. G is the constant of gravitation; T_{ij} is the so-called energy tensor of the matter, and its components represent a generalization of the classical concept of mass density.

The exact solution of Eq. (5) has been possible only in a limited number of physical situations. For example, in 1916 Schwarzschild gave the exact solution for the space-time around a spherical mass m (e.g., the sun):

$$\begin{aligned} ds^2 &= (1 - a/r)^{-1}\, dr^2 + r^2 (d\theta^2 + \sin^2\theta\, d\phi^2) \\ &\quad - (1 - a/r)c^2\, dt^2 \end{aligned} \tag{6}$$

where $a = 2Gm/c^2$, r is a measure of distance from the central mass, t is a measure of time, and θ and ϕ are the usual angular coordinates. Note that when $m = 0$, Eq. (6) reduces simply to the flat space-time of Eq. (4), written in polar coordinates, and its geodesics would be straight lines (in space and time). But for Eq. (6), the geodesics in the symmetry "plane" $\theta = \pi/2$ are found to satisfy the equation

$$\frac{d^2u}{d\phi^2} + u = \frac{Gm}{h^2} + \frac{3Gmu^2}{c^2} \tag{7}$$

where $u = 1/r$ and h is a constant (essentially the orbital angular momentum). This differs formally from the classical orbit equations only by the presence of the last term, which is very small. But as a consequence of that term, the solution of Eq. (7) is

$$\begin{aligned} u &= Gmh^{-2}(1 + e\cos p\phi), \\ p &= 1 + 3G^2m^2h^{-2}c^{-2} \end{aligned} \tag{8}$$

instead of the classical solution which has $p = 1$. Now r is a function in ϕ of period $2\pi/p$ instead of 2π, and therefore the orbital ellipse precesses. For the planet Mercury, for example, the secular precession predicted is 42″ (seconds of arc), and this agrees well with observation. In the space-time defined by Equation (6) one also finds that light-signals which pass close to the central mass are bent by an angle twice as big as that predicted on a simple Newtonian corpuscular theory of light; and again observations bear out the relativistic prediction. A third "crucial" prediction is the reddening of light as it "climbs" up a gravitational potential gradient. (The redshift in traversing as little as 70 feet of the earth's field has been measured and bears out the theory.)

A new test of general relativity was suggested in 1964 by I. I. Shapiro. This consists in bouncing a radar signal off a planet or spacecraft passing behind the sun. Theory predicts a time delay (of about 250 microseconds) when the signal grazes the sun, which adds a "bump" to the apparent orbit. By now this test has confirmed the predictions to an accuracy of 0.3%, bettered only by the redshift test. (Nevertheless the latter is considered weaker, since it only tests the *last* metric coefficient in (6).) Also begun in 1964 (but still not completed) were preparations for an experiment in which a gyroscope will be carried in an artificial satellite around the earth. According to general relativity the axis of the gyroscope should precess by a certain amount which will be measured. An advantage of this experiment is the relative absence of other effects overlaying the relativistic effect, but an evident difficulty is the manufacture of the instrument to the required tolerances.

The detection of gravitational waves would also greatly support the theory. Direct detection has been reported by the pioneer in this field, J. Weber, since the 1960s, but no other group has been able to duplicate his results. If, indeed, the pulses observed by Weber are gravitational, their generation would require huge energies—amounting to the annihilation from our galaxy of a hundred suns a year. However, an indirect indication of the existence of gravitational waves has recently been found by J. H. Taylor et al. in a binary star system that apparently loses rotational energy at just the rate at which it should radiate gravitationally.

Meanwhile the search for stellar black holes (relativistic remnants of collapsed stars) continues. In recent years the evidence has been mounting that a certain x-ray source in the constellation of the Swan, Cygnus X-1, has the required black-hole characteristics, and this may lead to the first positive identification. Astronomers believe on theoretical grounds that our galaxy should contain millions of stellar black holes.

Our account of ongoing "tests" for general relativity should not convey the impression that its validity is in doubt. *All* good physical theories are rich in predictions and it is in the nature of physicists to test these. As for its practicability, general relativity is on the way to becoming a service discipline for astrophysics and cosmology, where the fields are sufficiently extreme to preclude Newtonian gravity. On the theoretical side, enormous progress has been made in recent years in the understanding of many of the outstanding problems of classical (i.e., non-quantum) general relativity. Currently there is much interest in the problems of quantizing gravity, and of combining relativistic gravity and quantum mechanics in a consistent way. The days when general relativity was a "dormant" theory are definitely past.

RELAXATION

By relaxation is understood the phenomenon that an observable time elapses between the moment when a system in equilibrium is subjected to a momentary change in condition and the moment when the system is again in equilibrium.

A good example of a simple system showing relaxation is an unchanged capacitor with a capacitance C connected in series with a resistance R, to which circuit a constant voltage U is applied at a time $t = 0$. The charge Q of the capacitor at time t is given by the differential equation

$$U = \frac{Q}{C} + R\frac{dQ}{dt} \qquad (1)$$

the solution of which is:

$$Q = CU(1 - e^{-\frac{t}{RC}}) \qquad (2)$$

Hence the charge Q does not follow the sudden change of U but shows an exponential increase towards the final value CU (see Fig. 1). The time $\tau = RC$ is referred to as the relaxation time of the system. Obviously τ governs both the rate of charging and the rate of discharge: if the capacitor with a charge Q_0 is shortcircuited via a resistance at the time $t = 0$, then the charge at time t is given by the single exponential equation

$$Q = Q_0 e^{-\frac{t}{\tau}}.$$

Multiexponential behavior of the type

$$y = a_0 + \sum_{n=1}^{N} a_n e^{-\frac{t}{\tau_n}}$$

is found in case the time dependence of a system is not described by Eq. (1) but by a set of N coupled linear differential equations.

Relaxation is met with in various fields of physics, e.g.:

(a) If a spring connected in parallel with a dash-pot is suddenly loaded with a constant force, it will take some time until this system is again in equilibrium.

(b) If an electrically or magnetically polarizable substance is suddenly placed in a constant electric or magnetic field, it will take some time until the electric or magnetic dipoles have orientated themselves in the field.

(c) If the irradiation of a phosphorescent substance is suddenly stopped, the phosphorescence does not cease immediately but continues for some time during which the intensity decreases exponentially.

An electrical analogy can be devised for all these cases. For instance, if in case (a) we substitute a voltage for the force, a charge for the displacement, the reciprocal of a capacitance for the spring constant f, and a resistance for the coefficient of friction η, we obtain exactly the differential equation [Eq. (1)]. The relaxation time τ will then be $\tau = \eta/f$, which quantity depends on temperature since as a rule η greatly

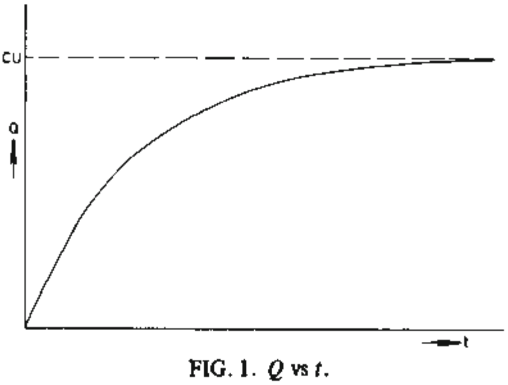

FIG. 1. Q vs t.

varies with temperature. Generally, the relaxation times in electrically and magnetically polarizable media also vary with temperature.

If we subject a system having relaxation properties to a periodically varying change in condition instead of one sudden change in condition, some characteristics are revealed which are likewise typical of relaxation. Let us again take the RC circuit as an example, this time applying to it a voltage $U = U_0 \sin \omega t$. Solution of the differential equation [Eq. (1)] yields the following expression for the charge Q of the capacitor:

$$Q = \frac{CU_0}{\sqrt{1 + \omega^2 \tau^2}} \sin (\omega t - tg^{-1}\ \omega\tau)$$

The charge has a component Q' which is in phase with the voltage applied and a component Q'' which is shifted 90° in relation to the voltage applied. Q' and Q'', usually referred to as the real and the imaginary component of Q, respectively, are given by:

$$Q' = CU_0 \frac{1}{1 + \omega^2 \tau^2}$$

$$Q'' = CU_0 \frac{\omega\tau}{1 + \omega^2 \tau^2}$$

The variation of Q' and Q'' with $\omega\tau$ is shown in Fig. 2 where $\omega\tau$ has been plotted logarithmically in order to obtain symmetrical curves.

Q'' is a measure of the energy dissipated in the circuit per cycle; it has its maximum value at $\omega = 1/\tau$ and a negligibly small value at much higher and much lower frequencies.

Furthermore, Q'' reaches half its maximum value at $\omega = 3.73/\tau$ and $\omega = 0.27/\tau$ so that the half-width value $\Delta\omega$ of the Q'' curve expressed in angular frequency units is $3.46/\tau$. At $\omega = 1/\tau$, Q'' just has half its maximum value.

Hence, by measuring Q' and Q'' vs frequency, we have various possibilities for determining the relaxation time. The quantity $Q''/Q' = \omega\tau$ is called the *loss tangent* and plays an important role in characterizing a material.

If a dielectric solid is subjected to a periodically changing electric stress and the real (in-phase) and imaginary (out-of-phase) components of the dielectric constant of the substance are determined, curves will be found having a shape as shown in Figs. 2(a) and 2(b), from which the relaxation time can be determined. The mechanical relaxation time of an elastic solid can be determined in a similar manner.

In some cases, not one but several absorption peaks with the corresponding changes of the real component are found in this kind of experiment, from which it can be concluded that several relaxation mechanisms are involved. This phenomenon is frequently observed in polymers where the various components, such as short chains, long chains, cross-linked chains, etc., have different possibilities of moving and therefore have different relaxation times. There are also cases in which there is a more or less continuous distribution of relaxation times, and consequently, an absorption which is practically independent of frequency.

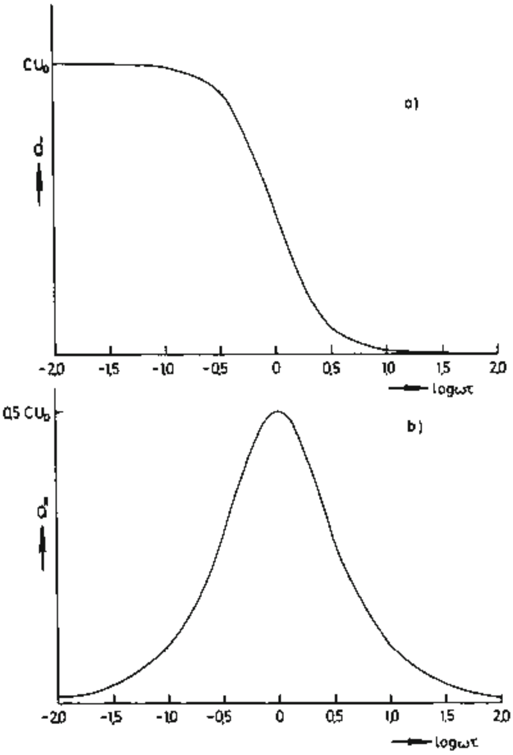

FIG. 2. Q' (a) and Q'' (b) vs log $\omega\tau$.

Since the above-mentioned electric circuit has no inductance (which corresponds to the masses of the particles in magnetic, electric and mechanical systems), there can be no resonance either.

As an example of a system having both resonance and relaxation properties, we will consider a liquid substance containing magnetic nuclei, e.g., hydrogen nuclei, which at the time $t = 0$ is placed in a magnetic field H. In this substance a magnetic moment M is built up in the direction of H by the fact that the original random orientation of the magnetic dipoles of the nuclei changes under the influence of the magnetic field into a distribution of such a nature that a resulting moment M arises in the direction of the magnetic field. M is determined by an equation analogous to Eq. (2), namely:

$$M = M_0 \left(1 - e^{-\frac{t}{T_1}}\right)$$

where M_0 is the final value of M and T_1 is a relaxation time known as longitudinal or spin-lattice relaxation time, which is associated with the interaction between the magnetic dipoles and their surroundings.

Now, if the direction of the magnetic field is suddenly changed, M will make a precessional motion about the new H due to the fact that the resulting angular momentum J is coupled to the magnetic moment M of the nuclei via the relation $\gamma = M/J$ where γ is the magnetogyric ratio of the nuclei.

The angular frequency of the precessional motion.is given by:

$$\omega = \gamma H$$

On behalf of the precessional motion, the magnetic moment M has not only a longitudinal component M_l in the direction of the new magnetic field but also a transverse component M_t at right angles to the new magnetic field. Whereas it would seem logical to expect that M_l would increase and M_t decrease exponentially with the relaxation time T_1 due to the relaxation mechanism, in reality this is not so.

Experiments have shown that M_t decreases faster than the increase of M_l so that apart from the longitudinal relaxation time T_1 there must also be a separate transverse relaxation time T_2 which invariably is smaller than or equal to $2T_1$. The existence of a T_2 besides T_1 can be explained by the fact that apart from the return of individual magnetic moments of the nuclei to the direction of H (which is characterized by T_1), it is also possible for these individual magnetic moments—which together form M—to continue their precessional motion along the same conical shell though getting out of phase by mutual interaction. In the latter case, M_t decreases whereas M_l remains unchanged.

Just as with nonresonating systems, periodically changing quantities can be successfully introduced in resonating systems. In the case of a substance containing magnetic nuclei, this is done by applying, beside a stationary magnetic field H_z in the z-direction, also a periodically changing magnetic field $2H_1 \sin \omega t$ in the x-direction. This is known as a nuclear magnetic resonance experiment. In this case, a periodically changing magnetization intensity is created in the x-direction whose real (in-phase, dispersion) component M' and imaginary (out-of-phase, absorption) component M'' are given by:

$$M' = \gamma M_0 H_1 \frac{T_2^2(\gamma H_z - \omega)}{1 + T_2^2(\gamma H_z - \omega)^2 + \gamma^2 H_1^2 T_1 T_2}$$

$$M'' = \gamma M_0 H_1 \frac{T_2}{1 + T_2^2(\gamma H_z - \omega)^2 + \gamma^2 H_1^2 T_1 T_2}$$

where M_0 is the magnetic moment when no periodically changing magnetic field is applied. These quantities can both be determined experimentally.

The variation of $M'/\gamma M_0 H_1 T_2$ and $M''/\gamma M_0 H_1 T_2$ has been plotted against $T_2(\gamma H_z - \omega)$ in Fig. 3, it having been assumed that H_1 is so small that $\gamma^2 H_1^2 T_1 T_2$ is much smaller than 1. It will be seen that the curves differ considerably from those in Fig. 2. The absorption curve has its maximum at the value $\gamma H_z = \omega$ which value has nothing to do with the relaxation times but only with the concurrence of the precessional frequency γH_z of the magnetic moment in the magnetic field H_z with the frequency of the periodically changing magnetic field. Hence it is clearly a matter of resonance absorption. The half-width value $\Delta\omega$ of the absorption curve, expressed in terms of a frequency, is $2/T_2$. The $M'/\gamma M_0 H_1 T_2$ curve is the curve of anomalous dispersion, which at $\gamma H_z = \omega$ has just the value 0, which is invariably found with resonating systems. With increasing values of H_1 both curves get wider and wider and the absorption curve eventually becomes 0 throughout. This phenomenon is called saturation. T_1 and T_2 can be calculated in principle from curves plotted for different known values of H_1; in practice, pulse techniques have to be used, often combined with Fourier transform techniques. Both relaxation times are very much dependent on temperature and frequency, and on the phase of the substance under test.

The same phenomena are observed in the case of resonance of unpaired electrons, known as electron spin resonance.

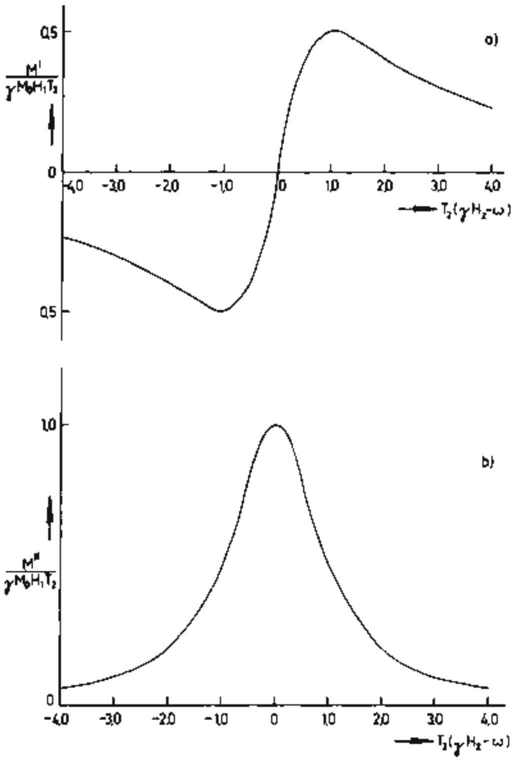

FIG. 3. Shape of the dispersion (a) and absorption (b) curves.

Generally speaking, the investigation of relaxation times provides information on the surroundings of relaxing particles and thus can contribute to knowledge about the structure and the internal mobility of substances, which is very important for physicists, chemists, and biologists.

Furthermore, profound knowledge of relaxation times is essential in many instances to the control of physical processes (e.g., the creation of low temperatures by magnetic means) and physical techniques (e.g., the maser technique).

REPRODUCTION OF SOUND

History In 1807 the British physicist Thomas Young designed the first device capable of making a graphic record of sound waves. His description of the principle of sound recording is as clear and valid today as it was then, and it may serve here:

> "The situation of a particle at any time may be represented by supposing it to mark its path, on a surface sliding uniformly along in a transverse direction. Thus, if we fix a small pencil in a vibrating rod, and draw a sheet of paper along, against the point of the pencil, an undulated line will be marked on the paper, and will correctly represent the progress of the vibration."

The recording stylus of Young's device had to be touched directly with the sound source. The "phonautograph" developed by Léon Scott de Martinville in 1856 was able to record sound from the air, via a horn, parchment diaphragm, and hog-bristle stylus. Both the Young and Scott devices made a helical trace on a rotating cylinder. Neither recording could be played back because the recorded trace was not deep or stiff enough to guide the vibrations of a reproducing stylus.

In April 1877, Charles Cros deposited with the French Academy of Sciences a sealed package containing the description of a complete record-reproduce system. Cros planned to use metal records photoengraved from an original tracing in lampblack, but never carried out his plans. In the fall of that year, Edison constructed a "phonograph" whose recording stylus made indentations on tinfoil wrapped on a pre-grooved cylinder. Although these indentations were partly deformed by the playback stylus, a weak, distorted, but intelligible version of the human voice could be reproduced.

Modern disc recording is closer to the Cros system than to Edison's; commercial recordings are stampings from a hardened mold. Virtually all original recordings for home use are first made on magnetic tape. They are then cut into a master disc made of a relatively soft material, lacquer, and end up as a metal stamper from which mass impressions can be made in a vinyl composition.

Modern Recording Systems Current recording media include magnetic tape, transparent film, and grooved discs. The most widely used is the disc.

If the disc cutter head is fed with constant electrical energy over the frequency spectrum, it will produce constant average velocity in the recording stylus. Since the wave length of the recorded signal is doubled with each lower octave, constant stylus velocity would produce impractically large groove excursions in the bass range. Progressive bass attenuation is therefore introduced below a frequency which has now been standardized at 500 hertz, called the *turnover* frequency, in such an amount that the amplitude of groove modulation for signals below this frequency remains the same at a given power. A compensatory boosting of the bass frequencies must be employed in the playback amplifier.

A second problem in disc recording has to do with surface noise introduced by irregularities in the record material and picked up by the needle. The noise is distributed fairly evenly over the frequency spectrum on the basis of energy per cycle. Since each higher octave covers twice the number of cycles, this noise may be considered primarily a treble phenomenon (see NOISE, ACOUSTICAL).

The signal to the recording cutter is again altered, this time by progressive treble boost. In playback, a compensatory treble attenuation is introduced which brings the recorded signal back to normal and at the same time significantly reduces the amount of surface noise. This system of recording *preemphasis* does not change the treble content of the final reproduced sound, but it increases the amplitude of the high-frequency groove modulations relative to the random surface irregularities in the recorded material.

These changes of frequency balance in the recorded signal are called *equalization*; the particular equalization curve is called the *recording characteristic*.

In a more recent technique for reducing recording noise, the signal is subjected to amplitude compression before recording, that is, the dynamic range of the signal is reduced by an amplifier whose gain increases automatically as the amplitude of the signal decreases. The overamplified weak signal elements can then be recorded at a higher level relative to intrinsic recording noise such as tape hiss and surface noise, without increasing the recording level of strong signals and creating tape overload or groove overcutting. The signal may be divided into several frequency channels with separate compressors for each channel, so that signals in one frequency region do not control compressor action in another. In reproduction a matching expansion system (whose gain increases with signal amplitude) restores the original dynamic range to the signal, which now has reduced recording noise.

This technique substantially increases the dynamic-range capability of the recording system. It has an effect very similar to that of recording equalization, but it is controlled by signal amplitude rather than signal frequency.

Digital Recording When sound is recorded digitally the acoustic waveform is no longer represented in the recording medium by an analogous, continuously varying waveform. The original waveform is instead "sampled": Successive readings of its instantaneous amplitude are taken at short intervals, and these readings are recorded as binary-code pulses that define a series of discrete amplitude values. The current sampling rate is 44.1 thousand times a second, which means a reading every 22.7 μsec. The frequency bandwidth required for digital stereo recording is the sampling rate multiplied by a factor representing the accuracy with which each sample can be recorded, and is typically of the order of 2 MHz.

Digital playback apparatus reconstructs the sound, producing instantaneous voltages at clock-controlled intervals to match the recorded amplitude values. Digital tape recording has been used for some commercial master tapes since the late 1970s, and digital discs become available in the early 1980s. The bandwidth required is much too great for mechanical record/pickup systems, so that these have been abandoned in favor of laser disc systems.

Since the reproducing amplifier is operating at a clock-controlled rate that matches the original sampling rate, each digital sample must be delivered at exactly the right time. Inevitable small variations in tape-mechanism or turntable speed are compensated for by an electronic memory in the reproducer, which stores signals a little bit ahead, and the average speed of the playback device is controlled by a servo or clock mechanism.

The aim of digital recording is to eliminate flutter and rumble, to reduce distortion, to improve the signal-to-noise ratio, and to increase the dynamic range that the system can accommodate.

The Modern Disc Reproducing System A pickup, also called a cartridge, traces the groove modulations through a needle or stylus, whose vibrations are converted to an electrical signal. The most common types of electrical generator employed in cartridges are the ceramic (piezoelectric), moving magnet, moving coil, and variable reluctance. It is the task of the cartridge to translate faithfully the wave forms of the groove into an electrical signal. Some of the problems in cartridge design have to do with the stiffness of the moving needle system, which tends to wear the record, and with the mass of the needle tip, which tends to resonate with the semi-elastic record material at high frequencies.

The turntable must revolve the record at a constant speed. Periodic variations in this speed are called *flutter* (the onomatopoetic term for very slow flutter is *wow*). Any noise introduced into the signal by the moving parts (via the pickup) is called *rumble*. A pivoted arm holds the cartridge in place over the record groove, with the vibration axis of the cartridge approximately tangent to the groove over the entire radius of the record.

The amplifier, which may be on one or more chassis, has two sections: the *preamplifier* and the *power amplifier*. The former is a voltage amplifier which performs the functions of input program selection, tone control, volume control, compensation for the frequency equalization introduced in recording, and voltage amplification of the input signal to the point where it can drive the power amplifier. The latter builds up the electrical signal power so that the signal is able to drive the loudspeaker or speakers.

An amplifier is a device whose output energy is greater than, but in the same form as, the input signal energy. The amplifier must therefore borrow energy from an outside source, normally the electrical power line. There are many types of basic amplifying devices. The two that are used almost universally in sound reproduction are the vacuum tube and the transistor.

The loudspeaker converts the electrical output of the amplifier into acoustical energy, usually through a vibrating diaphragm. The loudspeaker and the cartridge, because they are mechanical devices with their own resonances and characteristic behavior, are more intransigent to precise control by the input signal than electronic circuits.

A reproducing system is designed for minimum noise, distortion, frequency discrimination over the audible spectrum, and transient ringing;

speakers must also have adequate treble dispersion.

Stereophony Stereophonic sound is recorded on two separate channels from separate microphone inputs. Just as each lens of a stereoscopic camera takes a complete picture, each microphone channel picks up all of the sound, one from a right-oriented perspective and the other from a left-oriented perspective. When the two channels are played back through separate right and left speakers, more of the sense of the acoustical atmosphere of the concert hall is recreated; a corollary of this is an increased clarity of inner melodic voices. The ability of the listener to determine the apparent position of different musical instruments is a less important part of the stereo effect.

In stereo disc recording, one channel is, in effect, recorded on the left groove wall, and the other channel on the right groove wall. The reproducing stylus must execute a complex motion containing both vertical and horizontal components in order to follow the modulations of both groove walls simultaneously. These complex movements are analyzed into two vectors by two separate generating elements, each at 45° to the vertical and on opposite sides. Each generating element produces the electrical signal for one channel.

Recent developments have been aimed at recapturing the acoustical atmosphere of the concert hall more accurately. In one system, additional speakers at the back and sides of the listening area are used to reproduce delayed signals that simulate reflections from more distant walls. Another system uses four separate channels, two to reproduce rear-hall sound at the rear of the listening room. As in two-channel stereo, there is sometimes a misplaced emphasis on directional effects at the expense of concert-hall ambience.

The ultimate design goal of sound reproducing equipment is not to create "better" sound, but to efface the imprint of the equipment, so that the original musical quality is recreated.

RESONANCE

The phenomenon which scientists call resonance can be identified in many different physical systems of widely varying sizes. For instance, a father who pushes his small child on a swing finds that with each successive push the swing goes higher. An astronomer who examines the spectrum of the sun notes the appearance of a series of dark lines superposed on the continuous red to violet band of colors. The solid state physicist who observes the amount of electromagnetic radiation transmitted through a waveguide at a particular microwave frequency finds it can be sharply reduced if certain materials are placed in the guide and a magnetic field is applied. All of these effects are examples of resonance, yet the actual physical mechanisms are different and the explanations require different analytical procedures depending on whether the system is governed by classical or quantum theory.

In the case of the father pushing the swing, the resonance can be explained as a direct consequence of Newton's laws of classical mechanics. In simple terms, it occurs when an outside agent (the father) pushes the system (swing with child) with a periodic force having the same frequency as the natural frequency of the system itself. The natural frequency is the frequency with which the system oscillates if it is displaced from its normal position of equilibrium and then released to swing freely back and forth. If the external push is timed so as to be exactly in step with the natural frequency, one can think of the swing as being steadily accelerated in its natural direction of motion. When the natural direction of motion changes at the end points of the path so does the push. Elementary kinematics then predicts that such a steady acceleration will cause both the displacement and the maximum velocity to increase continuously and eventually become very large. It is this extreme magnitude of displacement and velocity which is the most noticeable aspect of resonance in a mechanical system. However, less apparent visually, yet equally important, is the rate of energy transfer between the source and the system at resonance. The external agent transfers energy in the form of mechanical work to the system. At resonance, the average rate of this energy transfer per cycle becomes a maximum. This property of maximum rate of energy transfer is of great value when analyzing the effect of radiation on microscopic systems such as atoms and nuclei whose physical behavior must be explained by the laws of quantum physics rather than classical physics. In these systems as in mechanical systems a necessary condition for resonance is that the frequency of the radiation must match a frequency which is in some way associated intrinsically with the system. But here the coordinates of position and velocity are no longer suitable ones to use in describing the response at resonance. Nevertheless, the resonant system is still characterized by the general property that the rate of energy transfer into it is a maximum. In order to bring out the essential features of resonance involving both the behavior of position and velocity and the rate of energy transfer, it is simplest to examine a mechanical system consisting of a mass on a spring with frictional damping.

Resonance in a Simple Mechanical Oscillator We begin with a mass M attached to a fixed point by a spring with a force constant K and a damping resistance R. In addition the mass is acted upon by a periodic external force of frequency $\nu, F = F_0 \cos 2\pi\nu t$. The displacement of the mass from its normal equilibrium position is represented by x. The acceleration d^2x/dt^2 of the mass M is determined by the resultant of these three forces, all along the x-direction: $-Kx$, the elastic restoring force; $-R(dx/dt)$, the damping force proportional to the instantaneous velocity dx/dt; and the external force $F_0 \cos 2\pi\nu t$. Newton's second law of motion, which states that resultant force = mass × acceleration, can be expressed by a second-order inhomogeneous linear differential equation:

$$M\frac{d^2x}{dt^2} + R\frac{dx}{dt} + Kx = F_0 \cos 2\pi\nu t. \quad (1)$$

However, in order to discuss resonance it is first necessary to describe the behavior of the spring system when no external driving force is being applied. If the mass is displaced from its normal equilibrium position and then released, it will move in simple harmonic motion with the natural frequency ν_1 given by

$$\nu_1 = \frac{1}{2\pi}\sqrt{\frac{K}{M} - \frac{R^2}{4M^2}}, \quad \left(\frac{K}{M} > \frac{R^2}{4M^2}\right). \quad (2)$$

This result can be derived mathematically by setting the term on the right-hand side of Eq. (1) equal to zero thus making the equation homogeneous. It can be solved for $x(t)$ by standard methods (see references 1 and 2). The solution is:

$$x = Ae^{-(R/2M)t} \sin (2\pi\nu_1 t + \phi) \quad (3)$$

where A and ϕ are constants depending on the initial position and velocity. For example, if the mass starts from a position $x = x_0$, with zero velocity, then $A = x_0$ and $\phi = 90°$, and Eq. (3) becomes

$$x = x_0e^{-(R/2M)t} \cos 2\pi\nu_1 t. \quad (4)$$

Since the solution is the product of a negative exponential function and a sinusoidal function, the amplitude of the displacement will diminish a little bit more with each succeeding cycle of oscillation and eventually the displacement becomes zero again. This is called a damped harmonic oscillation and is physically what we see any time a real spring or pendulum is disturbed and then allowed to oscillate freely. The damping of the oscillations can also be looked upon as representing a conversion of mechanical energy into heat which is proceeding at the instantaneous rate $R(dx/dt)^2$.

We now consider the solution of the inhomogeneous equation [Eq. (1)]. From the theory of linear differential equations, the solution of an inhomogeneous equation can be expressed as the sum of solutions of the homogeneous and inhomogeneous equation. Thus a general solution can be written down in which one term is the solution [Eq. (3)] while the second is the particular integral satisfying Eq. (1).

$$x = Ae^{-(R/2M)t} \sin (2\pi\nu_1 t + \phi) + \frac{F_0}{2\pi M}\frac{\cos(2\pi\nu t - \alpha)}{\sqrt{4\pi^2(\nu_0{}^2 - \nu^2)^2 + \dfrac{\nu^2R^2}{M^2}}} \quad (5)$$

where $\nu_0 = (1/2\pi)\sqrt{K/M}$ is the natural frequency for the undamped oscillator and α, the phase angle between the applied force and the displacement, is defined by

$$\tan \alpha = \frac{\nu R}{2\pi M(\nu_0{}^2 - \nu^2)}. \quad (6)$$

Since the first term in Eq. (5) becomes vanishingly small and can be neglected after a period of time has elapsed, it is called the transient part of the solution. The particular integral maintains a constant amplitude as long as the driving frequency does not change, and it is called the steady-state part of the solution.

The steady-state solution for the instantaneous velocity is also of great interest

$$v = \frac{dx}{dt} = \frac{F_0\nu}{M}\frac{\cos(2\pi\nu t - \beta)}{\sqrt{4\pi^2(\nu^2 - \nu_0{}^2)^2 + \dfrac{R^2\nu^2}{M^2}}} \quad (7)$$

where β, the phase angle between applied force and velocity, is defined by

$$\tan \beta = \frac{2\pi M(\nu^2 - \nu_0{}^2)}{\nu R}. \quad (8)$$

It is seen that both displacement and velocity have amplitudes which depend on the frequency of the applied force. The form of Eq. (5) and (7) is such that there must exist frequencies for which each achieves a maximum value. The frequencies which produce these maximum values can be found by differentiating the displacement or velocity function with respect to frequency, setting the derivative equal to zero, and solving for ν. In this way, it is deduced that the amplitude of x becomes a maximum when

$$\nu = \sqrt{{\nu_0}^2 - \frac{R^2}{8\pi^2 M^2}} \qquad (9)$$

while the amplitude of v becomes a maximum when

$$\nu = \nu_0 \qquad (10)$$

This latter frequency ν_0 which is the natural frequency of the undamped oscillator is customarily referred to as the resonance frequency of the oscillator. The phase difference between the force and velocity at resonance is zero. Thus the velocity will achieve its largest magnitude in the part of the cycle when the push is greatest, confirming what we sense intuitively in pushing a swing. The displacement resonance occurs at a frequency slightly different from the resonance frequency, but the difference becomes smaller as R decreases. The velocity resonance is of significance in discussing energy because the rates of energy transfer into and out of the oscillator depend on velocity. The external periodic force is doing work on the oscillator at the instantaneous rate of Fv, while the oscillator is working against the damping force at the instantaneous rate of $-Rv^2$. Thus energy is being simultaneously absorbed and dissipated. Since the instantaneous rates vary periodically with time, it is more meaningful to calculate average rates per period and then compare. Such a calculation (see reference 1) shows that the average rate of energy absorption is exactly equal to the average rate of energy dissipation and has the magnitude $({F_0}^2/2R)\cos^2\beta$. At velocity resonance $\cos^2\beta = 1$, and these rates of absorption and dissipation will have maximum magnitudes of ${F_0}^2/2R$. The average rate of energy absorption can be expressed as

$$\bar{\dot{W}} = \frac{\pi \nu_0 {F_0}^2}{KQ\left[\frac{1}{Q^2} + \left(\frac{\nu}{\nu_0} - \frac{\nu_0}{\nu}\right)^2\right]} \qquad (11)$$

where Q (for quality) is defined as $2\pi\nu_0 M/R$. $\bar{\dot{W}}$ is plotted in Fig. 1. The treatment of resonance in terms of rate of energy absorption is useful in many kinds of systems.

There is an exact analogue to this analysis in the electrical circuit consisting of an inductance L, a capacitance C, and a resistance R in series and driven by an alternating emf, $E_0 \cos 2\pi\nu t$. The differential equation for the variation of charge q with time is

$$L\frac{d^2q}{dt^2} + R\frac{dq}{dt} + \frac{q}{c} = E_0 \cos 2\pi\nu t \qquad (12)$$

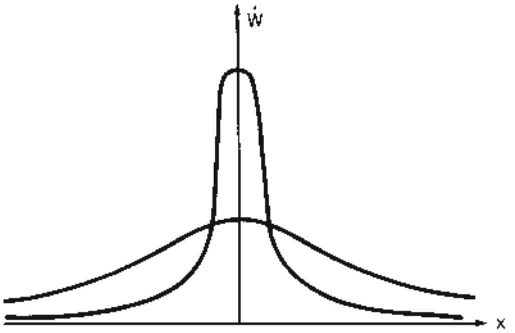

FIG. 1. Rate of energy absorption $\bar{\dot{W}}$ as a function of $x = (\nu/\nu_0) - (\nu_0/\nu)$. For large Q the resonance peak is high and narrow; for small Q it is low and wide. From "Physical Mechanics," R. Bruce Lindsay, Fig. 10.6, p. 290. D. Van Nostrand Co. 1961.

and resonance will occur under the same corresponding conditions as for the mechanical oscillator (see ALTERNATING CURRENTS).

Resonance in Coupled Systems A system of particles with n degrees of freedom in which the particles are coupled together by elastic restoring forces will possess a set of n natural or normal frequencies. If the motion is started with an arbitrary distribution of initial displacements and velocities, the subsequent time-dependent motion of each particle will appear as a superposition of all the normal frequencies. However, through a proper choice of initial conditions it is possible to excite any one of n so-called normal modes. A normal mode is characterized by all of the particles oscillating with one particular normal frequency. For each normal frequency there will be a corresponding normal mode. As an example, a coupled system of two identical particles has two normal frequencies, hence two normal modes. For the lower frequency the normal mode is one in which the particle displacements are exactly in phase with each other. For the higher frequency they are exactly out of phase with each other. If a periodic external force is applied with a frequency matching one of the normal frequencies, the entire system will be excited into resonance in the normal mode appropriate to that particular frequency. Just as with the simple mechanical oscillator, the magnitudes of the maximized amplitudes are limited by whatever damping forces are acting and the rate of energy absorption equals the rate of energy dissipation. This mechanism is the basis for the excitation by resonance of standing waves in continuous elastic media such as solid structures and fluid columns. A standing wave is the configuration of the displacements of all the individual points when vibrating in a normal mode. A string held under tension between two fixed points will vibrate in a normal mode if a transverse frequency is applied which equals an integral multiple of the velocity of transverse waves in the string divided by twice the length. The instantaneous visual appearance of the standing wave corresponding to the lowest normal frequency is a sine curve with its point of maximum vibration, called an antinode, located midway between the fixed ends. This sine curve vibrates transversely back and forth between maximum positive and maximum negative displacements with the normal frequency. If the frequency is doubled, the corresponding standing wave has two antinodes separated by a point of no vibration, called a node, at the midpoint. Standing longitudinal sound waves can be set up in columns of air which are enclosed by tubes that are terminated by closed or open ends. A node will always be found at a closed end. An antinode will always be found just beyond the mouth of an open tube. The excitation of such standing waves by resonance with the appropriate external driving frequency results in an enhancement of the intensity of the sound. One of the most spectacular illustrations of the power of resonance was the destruction of the Tacoma Narrows Bridge on November 7, 1940 by large-amplitude torsional oscillations set up in its main span by strong cross winds.

Resonance Phenomena in Atomic and Nuclear-Sized Systems The exact theory explaining the processes whereby systems composed of atoms and nuclei absorb and emit energy is based on the principles of quantum theory. Nevertheless, such processes still show some physical analogy to resonance in a mechanical oscillator. A simple example is the single atom consisting of one or more electrons bound to a nucleus by predominantly electrostatic forces. Quantum theory predicts that the atom can exist only in a set of discrete energies in contrast to the continuous range of energies which in principle is available to a large-size satellite system such as the earth and moon. If the atom changes from a higher-energy state E_j to a lower-energy state E_i, energy in the form of electromagnetic radiation is given off and the frequency of the radiation ν_{ij} is related to the energy difference between the two states by the equation:

$$\nu_{ji} = \frac{E_j - E_i}{h} . \tag{13}$$

h is the well-known Planck constant of action and has a value of 6.625×10^{-27} erg sec. This frequency and others which connect discrete energy states consistent with the so-called selection rules for the atom can be pictured as a set of frequencies characteristic of the particular atom. By analogy with resonance in a mechanical oscillator absorption of energy at a maximum rate might be expected to occur when there is radiation incident on the atom with a frequency which matches one of these frequencies. In quantum mechanics, the meaningful index for such a process taking place is the probability that an energy transition will occur a time t after being exposed to the radiation. When calculated, this probability is found to be proportional to

$$\frac{1 - \cos 2\pi(\nu_{ij} - \nu)t}{(\nu_{ij} - \nu)^2} \tag{14}$$

(see references 2 and 8).

Even though this probability function is not of the same mathematical form as the expression for rate of energy absorption derived in the section on "Resonance in a Simple Mechanical Oscillator," because of its dependence on $(\nu_{ij} - \nu)^2$ instead of $(\nu_0{}^2 - \nu^2)^2$, it can be looked upon as establishing a condition for a resonance type process. It predicts that the likelihood of resonance absorption becomes very large when the external frequency approaches something resembling a natural frequency of the atom. A distinctive example of this kind of resonance absorption is the phenomenon in the solar spectrum described in the introduction. The radiation from the hot core of solar gases is characterized by a continuous spectrum. In passing through the cooler gases of the sun's outer atmosphere, radiation will be absorbed at those frequencies which match frequencies of atomic transitions in the cool gas. These blocked out lines in the continuous spectrum show up as dark lines against the background. They are called Fraunhofer lines. The rare gas helium was first discovered as a consequence of these observations.

Another important class of atomic-scale resonance phenomena concerns the behavior of atoms and nuclei in static magnetic fields when subjected to radio frequency (rf) magnetic fields. If the frequency of the rf field matches the Larmor precession frequency of the particle's magnetic moment vector about the direction of the static field, a resonance absorption of energy from the rf field can occur. The phenomenon is called electron spin resonance (ESR) if the magnetic moment is associated with unpaired electron spins of the atom and nuclear magnetic resonance (NMR) if the moment is associated with the spin of the nucleus. The ESR frequency of an atom with a single unpaired electron spin of 1/2 in a static magnetic field H is given by ν (in megahertz) = 2.80 H (in gauss). The NMR frequency of a proton is given by ν (in kilohertz) = 4.258 H (in gauss). During recent years magnetic resonance has proved to be a powerful experimental technique for obtaining information about the magnetic moments of atoms and nuclei and the strengths of internal magnetic fields in solids. (See MAGNETIC RESONANCE and references 4, 5, 6 and 8 for more details.)

Resonances are also found in nuclear reactions and have proved useful in clarifying some features of nuclear structure, which in general is more complicated than atomic structure. When a particle such as a neutron, proton, deuteron, or alpha particle strikes a target nucleus a compound nucleus consisting of the target nucleus and the bombarding particle is temporarily created. This compound nucleus, the model for which was first proposed by Bohr, can exist in excited states. If the energy of the incident particle plus the energy binding it to the compound nucleus equals the energy of an excited state a resonance effect occurs. The resonance is characterized phenomenologically by a sharp increase in the rate of emission of particles or γ-rays from the target as the compound nuclei decay. From the form of the curve showing the rate of emission or the cross section for the reaction as a function of the bombarding energy the energy of the excited state and its level width can be obtained. From systematic investigations carried out over a range of bombarding energies and with different incident particles it is possible to obtain information about the lifetimes, decay modes, and spacing of the excited states. The lifetime of the state refers to the time for the compound nucleus to decay to its final nuclear state accompanied by the emission of a particle or γ-ray. It is inversely proportional to the level width. The Breit-Wigner formula, derived from quantum mechanical considerations, gives a theoretical expression for the dependence of the cross section σ on the bombarding particle energy E and the level width Γ in the vicinity of the peak resonance energy E_0. In its simplest form, σ is proportional to

$$\frac{1}{(E - E_0)^2 + \left(\frac{\Gamma}{2}\right)^2}. \qquad (15)$$

This formula has been applied with considerable success to the interpretation of data from many nuclear reactions, particularly those involving neutron bombardment at energies such that the excited states do not overlap. A narrow level width implies that the lifetime of the excited state is long, which means the rate of energy loss due to emission is smaller than for an excited state with a wider level width. The plot of σ vs. E for different Γ value is analogous to the plot of the rate of absorbed energy vs. frequency for differing Q values for the simple mechanical oscillator in the neighborhood of resonance, as shown in Fig. 1. (See references 3, 7, and 9.)

Although resonance is a phenomenon which appears in many different systems with widely ranging dimensions and configurations, its fundamental characteristic of a maximum response when the frequency or energy of a perturbing influence matches a natural frequency or energy difference is universal.

RHEOLOGY

Rheology is the study of the response of materials to an applied force. It deals with the deformation and flow of matter.

Heraclitus, a pre-Socratic metaphysician, recognized in the fifth century B.C. that *παντα ρει*, or "everything flows." Long before Heraclitus, the prophetess Deborah, fourth judge of the Israelites, had sung that "the mountains flowed before the Lord" in celebrating the victory of Barak over the Canaanites (1). Reiner (2) claims that the translation in the authorized version of the Bible that the mountains "melted" before the Lord misses the essential point of her wisdom, for Deborah recognized this early instance of a relaxation in the time scale provided by eternity; in recognition of her basic contribution to the primary literature of rheology, Reiner proposed the dimensionless quantity D (for Deborah) where

$$D = \frac{\text{time of relaxation}}{\text{time of observation}} = \frac{\tau}{t} \qquad (1)$$

The difference between solids and liquids is found in the magnitude of D. Liquids, which relax in small fractions of a second, have small D; solids, large D. A long enough time span can reduce the Deborah number of a solid to unity, and impact loading can increase D of a liquid. Viscoelastic materials are best characterized under conditions in which D lies within a few decades of unity.

Force Balance Equation When a force f is applied to a body, four things may happen. The body may be accelerated, strained, or made to flow. If these three responses are added to each other, one can write for motion in one direction

$$f = m\ddot{x} + r\dot{x} + sx \qquad (2)$$

where m is the mass, r is a damping diameter related to viscosity, and s to elasticity. Evaluation of the coefficients m, r, and s involves the measurement of displacements, x, and their time derivatives in a manner which links these kinematic variables via an equation of state such as Eq. (2) to stress, σ (force per unit area), and its time derivatives.

Scope of Rheology In contrast to the discipline of mechanics wherein the responses of bodies to unbalanced forces are of concern, rheology concerns balanced forces which do not change the center of gravity of the body. Since rheology involves deformation and flow, it is concerned primarily with the evaluation of the coefficients r and s of Eq. (2). The coefficients account for most of the energy dissipated and stored, respectively, during the process of distorting a body.

Most rheological systems lie between the two extremes of ideality: the Hookean solid and the Newtonian liquid.

Measurements of Viscosity and Elasticity in Shear *Simple Shear.* Shear viscosity η and shear elasticity G are determined by evaluating the coefficients of the variables $\dot{x}$ and x respectively, which result when the geometry of the system has been taken into account. The resulting equation of state balances stress against shear rate $\dot{\gamma}$ (reciprocal seconds) and shear strain γ (dimensionless) as the kinematic variables. For a purely elastic, or Hookean, response,

$$\sigma = G\gamma \qquad (3)$$

and for a purely viscous, or Newtonian, response

$$\sigma = \eta\dot{\gamma}\,. \qquad (4)$$

As a consequence, G can be measured from stress-strain measurements, and η from stress-shear rate measurements.

Elasticoviscous behavior is described in terms of the additivity of shear rates:

$$\dot{\gamma} = \frac{\sigma}{\eta} + \frac{\dot{\sigma}}{G} \qquad (5)$$

whereas viscoelastic behavior is characterized by the additivity of stress according to Eq. (2):

$$\sigma = G\gamma + \eta\dot{\gamma}\,\cdot \qquad (6)$$

See reference 3 for further information on rheological bodies.

Relaxation. Numerous attempts have been made to fit simplified mechanical models to the two behavior patterns described by Eqs. (5) and (6). One can picture the elastic element as a spring arrayed in a network parallel with the viscous element to give essentially a (Kelvin) solid with retarded elastic behavior, wherein

$$\frac{\eta_k}{G_k} = \lambda \text{ sec (retardation time)} \qquad (7)$$

or as a series (Maxwell) network which flows when stressed or relaxes under constant strain:

$$\frac{\eta_m}{G_m} = \tau \text{ sec (relaxation time)} \qquad (8)$$

and transient experiments may be designed to measure these parameters singly. In real systems, a single relaxation (or retardation) time fails to account for experimental results. A distribution of relaxation times exists (see RELAXATION).

Dynamic Studies. When Eq. (2) is written in the form

$$\ddot{x} + 2k\dot{x} + \omega_1{}^2x = 0 \qquad (2b)$$

the equation suggests that the variation in stress be cyclic. Rheometers are designed so that the system may oscillate in free vibration of natural resonant frequency ω_1, or else so that a cyclic shearing stress of the form $f_0 \cos \omega t$ is impressed on the sample over a frequency range which spans ω_1. In neither case is the material strained beyond its range of linearity. Equation (2b) represents a damped harmonic oscillator, providing that the coefficients are constant (i.e., providing that they do not depend on the strain magnitude). Not all systems meet this requirement in the strict sense, with the result that one of the first consistency checks which the experimenter makes is for linearity. Doubling the amplitude of oscillation should double the stress and should not change the phase relationships between the cyclic stress and the deformation.

See RESONANCE and see reference 4 for more information on dynamic studies.

Time-temperature Equivalence *Steady-state Phenomena.* The creep of a viscoelastic body or the stress relaxation of an elasticoviscous one is employed in the evaluation of η and G. In such studies, the long-time behavior of a material at low temperatures resembles the short-time response at high temperatures. A means of superposing data over a wide range of temperatures has resulted which permits the mechanical behavior of viscoelastic materials to be expressed as a master curve over a reduced time scale as large as twenty decades, or powers of ten (see references 5 through 7).

Polymeric materials generally display large G values 10^{10} dynes/cm^2 or greater) at low temperatures or at short times of measurement. As either of these variables is increased, the modulus drops, slowly at first, then attaining a steady rate of roughly one decade drop per decade increase in time. If the material possesses a yield value, this steady drop is arrested at a level of G which ranges from 10^7 downward.

Dynamic Behavior. The application of sinusoidal stress to a body leads inevitably to the complex modulus G^*, where

$$G^* = G' + iG'' = G' + i\omega\eta' \qquad (9)$$

where G' is the in-phase modulus (σ/γ) which represents the stored energy, and G'' is the out-of-phase modulus $(\sigma/\dot{\gamma})$ representing dissipated energy (as its relation to η' suggests); the variable against which G' and η' are determined is the circular frequency ω. Superposition of variable temperature data or variable frequency data provides a master curve of the type described for the steady-state parameters.

Problems in Three Dimensions *State of Stress.* The forces and stresses applied to a body may be resolved into three vectors, one normal to an arbitrarily selected element of area and two tangential. For the yz plane the stress vectors are σ_{xx}, and σ_{xy}, σ_{xz}, respectively. Six analogous stresses exist for the other orthogonal orientations, giving a total of nine quantities, of which three exist as commutative pairs $(\sigma_{rs} = \sigma_{sr})$. The state of stress, therefore, is defined by three tensile or normal components $(\sigma_{xx}, \sigma_{yy}, \sigma_{zz})$ and three shear or tangential components $(\sigma_{xy}, \sigma_{xz}, \sigma_{yz})$. The shear components are most readily applicable to the determination of η and G.

Strain Components. For each stress component σ there exists a corresponding strain component γ. Even for an ideally elastic body, however, a pure tension does not produce a pure γ_{xx} strain; γ components exist which constrict the body in the y and z directions.

The complete stress-strain relation requires the six σ's to be written in terms of the six γ components. The result is a 6×6 matrix with 36 coefficients, k_{rs}, in place of the single constant. Twenty-one of these coefficients (the diagonal elements and half of the cross elements) are needed to express the deformation of a completely anisotropic material. Only three are necessary for a cubic crystal, and two for an amorphous isotropic body. These parameters are discussed in reference 8.

Similar considerations prevail for viscous flow, in which the kinematic variable is $\dot{\gamma}$.

ROTATION—CURVILINEAR MOTION

1. Curvilinear Motion, Rotation Rotary motion such as a wheel revolving on an axel is common in physics and everyday life. The more general term *curvilinear motion* is exemplified by a satellite such as our Earth traversing its orbit about the Sun as an attracting center. The curved line followed as the satellite's path may be a circle, which is a special case, or in general a curved line of any shape. Figure 1 represents simple rotation in a circle in the plane of the page. If angle θ changes between times t_1 and t_2 from θ_1 to θ_2, the average angular speed ω_{av} of P (or r), measured usually in radians $\cdot$ sec^{-1} is

$$\omega_{av} = \frac{\theta_2 - \theta_1}{t_2 - t_1} = \frac{\Delta\theta}{\Delta t}; \tag{1}$$

and the instantaneous angular speed is

$$\omega = \frac{d\theta}{dt}, \tag{2}$$

or in vector notation

$$\boldsymbol{\omega} = \boldsymbol{\omega}_1 \frac{d\theta}{dt}, \tag{2a}$$

where $\boldsymbol{\omega}_1$ is a unit vector perpendicular to and out from the page at O.

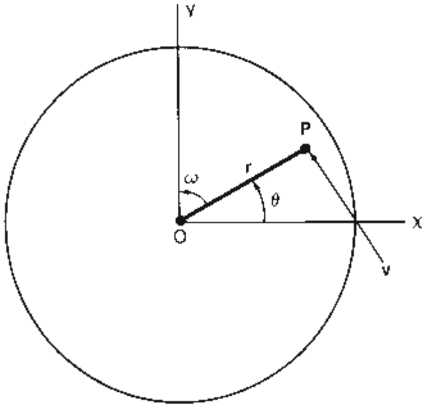

FIG. 1. Rotation of particle or body P of mass m about a fixed axis through O perpendicular to page. r, rotation radius OP; v, tangential velocity vector.

When ω is not constant but changes from ω_1 to ω_2 as t increases from t_1 to t_2, there is angular acceleration α measured usually in radians · sec^{-2} and the corresponding equations are

$$\alpha_{\text{av}} = \frac{\omega_2 - \omega_1}{t_2 - t_1} = \frac{\Delta\omega}{\Delta t}, \tag{3}$$

$$\alpha = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2}, \tag{4}$$

$$\boldsymbol{\alpha} = \frac{d\boldsymbol{\omega}}{dt} = \boldsymbol{\omega}_1 \frac{d^2\theta}{dt^2}, \tag{4a}$$

for the average, instantaneous, and vector expressions.

In *uniform* circular motion (both angular and linear tangential speeds constant) there is an acceleration different from that of Eqs. (3), (4), and (4a) which arises because the *velocity* vector, while not changing in magnitude, is continuously varying in *direction*, remaining always tangent to the circle of motion. This acceleration a_c is termed *centripetal* acceleration, since its cause is a central attractive or centripetal force directed always from the rotating point P toward the center of motion. a_c does not, however, involve a change in the length of the radius r, so it is not expressed here in terms of d^2r/dt^2.

The standard physics texts[1] show in simple derivation that

$$a_c = \omega v = \omega^2 r = v^2/r; \tag{5}$$

or vectorially, employing unit vector $\mathbf{i}_r$ along r and outward from center O,

$$\mathbf{a}_c = \mathbf{i}_r\, a_c. \tag{5a}$$

The corresponding centripetal force F_c measured in newtons is then

$$F_c = ma_c = m\omega^2 r = mv^2/r, \tag{6}$$

or vectorially

$$\mathbf{F}_c = \mathbf{i}_r F_c = \mathbf{i}_r\, ma_c = \mathbf{i}_r\, m\omega^2 r, \tag{6a}$$

where m is measured in kilograms.

Returning to Fig. 1, the linear, tangential speed v of P measured in m · sec^{-1} is

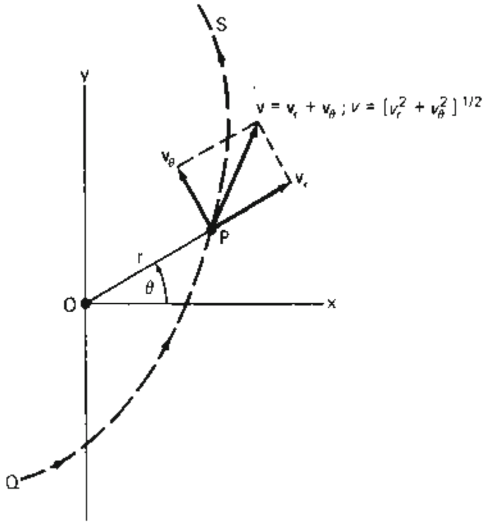
$$v = r\omega = r\frac{d\theta}{dt}, \tag{7}$$

and the vector velocity is

$$\mathbf{v} = \mathbf{i}_\theta\, v = \mathbf{i}_\theta\, r\frac{d\theta}{dt}, \tag{7a}$$

where $\mathbf{i}_\theta$ is a unit vector in the direction of $\mathbf{v}$, perpendicular to r and in the direction of increasing θ.

More generally, if the curvilinear motion of P is not circular but still in the plane of the page along the dotted path QPS (Fig. 2), there is still rotation about the fixed center O but with the important difference that the linear velocity $\mathbf{v}$ has components both tangential, $\mathbf{v}_\theta$, and radial $\mathbf{v}_r$. $\mathbf{v}_\theta$ is defined by Eq. (7a) and $\mathbf{v}_r$ by



S
Y
$\mathrm{v} = \mathrm{v}_r + \mathrm{v}_\theta\,;\ v = [v_r^2 + v_\theta^2]^{1/2}$
v_θ
v_r
P
r
θ
O
X
Q

FIG. 2. Curvilinear motion in a plane of particle or body P of mass m along dashed path QPS, showing noncircular rotation about fixed axis through O perpendicular to page. $r(= OP)$, θ are polar coordinates of P; $\mathbf{v}$, total velocity vector tangent to curve QPS at P; $\mathbf{v}_\theta$, velocity component perpendicular to r; $\mathbf{v}_r$, velocity component along r.

$$\mathbf{v}_r = \mathbf{i}_r\, v_r = \mathbf{i}_r \frac{dr}{dt}; \tag{8}$$

where $\mathbf{i}_r$ is a unit vector in the direction of $\mathbf{r}$. The corresponding linear accelerations are

$$\begin{aligned}\mathbf{a}_\theta &= \mathbf{i}_\theta\, a_\theta \\ &= \mathbf{i}_\theta\, r\frac{d^2\theta}{dt^2} = \mathbf{i}_\theta\, r\alpha,\end{aligned} \tag{9}$$

where α is as defined by Eq. (4), and

$$\mathbf{a}_r = \mathbf{i}_r\, a_r = \mathbf{i}_r \frac{d^2 r}{dt^2}. \tag{9a}$$

Truly general 3-dimensional curvilinear motion with rotation about the center O (Fig. 2) would include, in addition to $\mathbf{v}_\theta$ and $\mathbf{v}_r$, a third component $\mathbf{v}_\phi$ of the linear velocity $\mathbf{v}$, perpendicular to the page and given by

$$\mathbf{v}_\phi = \mathbf{i}_\phi\, v_\phi = \mathbf{i}_\phi\, r\cos\theta \frac{d\phi}{dt}, \tag{9b}$$

where ϕ is the angle between the plane of the page and a fixed plane (not shown by Fig. 2) passing through Oy, which should be visualized as tilted toward the reader out from the plane of the page, and $\mathbf{i}_\phi$ is a unit vector perpendicular to $\mathbf{r}$ and both perpendicular to and out of the page at P. $\mathbf{i}_r, \mathbf{i}_\theta, \mathbf{i}_\phi$ are then the three mutually orthogonal unit vectors at P, and r, θ, ϕ are the spherical coordinates of the moving point P. The total 3-dimensional translated velocity $\mathbf{v}$ is

$$\mathbf{v} = \mathbf{v}_r + \mathbf{v}_\theta + \mathbf{v}_\phi = \mathbf{i}_r\, v_r + \mathbf{i}_\theta\, v_\phi + \mathbf{i}_\phi\, v_\phi, \tag{10}$$

and the total linear speed v is

$$v = [v_r{}^2 + v_\theta{}^2 + v_\phi{}^2]^{1/2}. \tag{10a}$$

The corresponding 3-dimensional linear accelerations are a_r, a_θ, a_ϕ, or vectorially $\mathbf{i}_r a_r$, $\mathbf{i}_\theta a_\theta$, $\mathbf{i}_\phi a_\phi$, which include all linear accelerations, including centripetal and, from another viewpoint (see Section 6), the *centrifugal* and *Coriolis* accelerations corresponding to the same-named forces.

2. Momentum The basic physical quantity *momentum* is of great importance in curvilinear motion. Both *linear* and *angular* momentum, of parallel importance, are possessed simultaneously by a particle or body P of mass m moving in a curve, as in Figs. 1 and 2. The defining equations are, for linear momentum $\mathbf{M}_\ell$ measured in kg · m · sec^{-1},

$$\mathbf{M}_\ell = m\mathbf{v}, \tag{11}$$

and for angular momentum $\mathbf{M}_\omega$ measured in kg · m^2 · sec^{-1},

$$\mathbf{M}_\omega = m\,\mathbf{r} \times \mathbf{v} = I\boldsymbol{\omega}, \tag{12}$$

where I is the *moment of inertia* (defined in all physics texts) of m about its axis of rotation. Equation (12) necessarily employs vector cross-product notation, since $\mathbf{r}$ and $\mathbf{v}$ are not in general orthogonal; vector $\mathbf{M}_\omega$ is perpendicular to the plane of $\mathbf{r}$ and $\mathbf{v}$ and in Figs. 1 and 2 points vertically upward from the page. In non-vector (scalar) form Eq. (12) becomes

$$M_\omega = mrv \sin\theta, \tag{12a}$$

where θ is the angle between $\mathbf{r}$ and $\mathbf{v}$.

Both linear and angular momentum are conserved in closed (isolated) systems; this constitutes the most basic of all conversion principles. In quantum theory the "quantization" of mementa is fundamental; this means that these quantities can change by fixed amounts only.

3. Kinetic Energy As for momentum, the kinetic energy of a mass m in curvilinear motion simultaneously possesses both linear and angular kinetic energies, E_ℓ and E_ω, respectively, measured in joules, defined by

$$E_\ell = \tfrac{1}{2}\, mv^2, \tag{13}$$

and

$$E_\omega = \tfrac{1}{2}\, I\omega^2. \tag{14}$$

Both E_ℓ and E_ω are scalar quantities, so that for an aggregate of mass particles both the total linear and angular kinetic energies of the aggregation (or body) are simply the algebraic sums of the individual kinetic energies of the separate mass particles comprising the aggregate or body.

4. Planetary Motion (Central Force, Kepler's Laws, Newtonian Motion) Some real-life examples of curvilinear motion will emphasize the importance of the subject. Consider first the rotation of the planets (*natural* satellites) of our solar system about the Sun.

(1) Johannes Kepler (German astronomer, 1571–1630) had limited mathematics available to him but was a man of rare physical insight, dedicated persistence, and keen intuitive reasoning. He had no knowledge of the calculus of Gottfried von Leibnitz (1646–1716) and Isaac Newton (1642–1727), which was devised about a half-century after Kepler's death, nor of the algebra and calculus of vectors. Employing only, along with his remarkable talents, the analytic idea of the attractive *central force* (directed from the planet toward the Sun), but not knowing the central force followed an inverse-square law (Newton's discovery), he inferred the principal analytics governing planetary motion in our solar system, known as Kepler's Laws:

First Law, the Law of Orbits (1609). All planets and other bodies of the solar system must move in plane orbits which are conic sections—ellipses for the planet, with the Sun at one focus as the center of attraction.

Second Law, the Law of Areas (1609). Equal areas are swept out by the radius vector from the Sun to the planet in equal times. This means that as the planet is approaching the orbit perihelion (the point nearest the Sun) it speeds up, whereas approaching the orbit aphelion (the point farthest from the Sun, at the opposite end of the major axis of the ellipse from the perihelion) it must slow down.

Third Law, the Law of Periods (1619). The squares of the periods of the planets are proportional to the cubes of the major axes of their elliptic orbits.

Analytic details of Kepler's Three laws may be found in Joos.[2]

(2) Analytically, Kepler's central force $\mathbf{F}(r)$ is written

$$\mathbf{F}(r) = f(r)\, \mathbf{i}_r, \tag{15}$$

where $f(r)$ is a function of the polar coordinate r of the planet and $\mathbf{i}_r$ is a unit vector along $\mathbf{r}$, as used previously.

In 1671, some 40 years after Kepler's death, Isaac Newton discovered the *Law of Universal Gravitation*, which described Kepler's central force function $f(r)$ as an inverse-square dependence upon the radius vector $\mathbf{r}$; analytically, then, Eq. (15) becomes

$$\mathbf{F}(r) = f(r)\,\mathbf{i}_r = \frac{N}{r^2}\,\mathbf{i}_r, \tag{16}$$

where N is a constant negative number, the minus sign indicating that the force is attractive and hence directed in the negative $\mathbf{r}$ direction.

Using Eq. (16) Newton deduced analytically that the orbital paths of the planets are conic sections, specifically ellipses, with the Sun at one focus, thus confirming mathematically Kepler's First Law.

Comets, meteorites, and other bodies entering the solar system and therefore subject to the gravitational pull of the Sun may execute plane parabolic or hyperbolic orbits which are not closed curves. Therefore such objects may pass through and beyond the solar system never to return.

The possibility of parabolic or hyperbolic orbits which permit an object to leave the gravitational field of the Sun, or better the gravitational field of the solar system, and so "escape" from our planetary system elicits the interesting question of what is the Earth's *escape velocity*. More precisely, what is the minimum velocity, directed vertically opposite to the gravity pull at the Earth's surface, which would result in an object (e.g., a rocket-propelled spacecraft) leaving the Earth's gravitational field.

To determine this interesting number it is necessary simply to calculate the work done against the pull of gravity in moving a mass m from the Earth's surface to that distant point where its gravitational force is zero; that is, to an infinite distance away. Then, this amount of work or potential energy is equated to the kinetic energy that the same mass acquires if it were to fall from rest at that infinitely distant point and impact upon Earth (Fig. 3):

$$\int_{R_E}^{\infty} -F(r)\,dr = \tfrac{1}{2}\,mv_{\mathrm{es}}^2, \tag{17}$$

where $F(r)$ is Newton's gravitational force, defined by Eq. (16), with the minus sign now used because it is directed toward Earth in the negative radial direction, and v_{es} is the speed with which the freely falling mass m strikes Earth, which in turn is numerically equal to the "lift-off" escape speed but is oppositely directed. $F(r)$ is usually expressed in terms of the two attracting masses m and m_E, so that

$$F(r) = -\frac{N}{r^2} = -\frac{Gmm_{\mathrm{E}}}{r^2}, \tag{18}$$

where G is the gravitational constant (6.6720×10^{-11} newton $\cdot\, m^2 \cdot \mathrm{kg}^{-2}$). Using Eq. (18) in Eq. (17) yields

$$\int_{R_{\mathrm{E}}}^{\infty} -\frac{Gmm_{\mathrm{E}}}{r^2}\,dr = \tfrac{1}{2}\,mv_{\mathrm{es}}^2. \tag{19}$$

Dividing by m and integrating the left-hand side of Eq. (19) yields

$$\frac{Gm_{\mathrm{E}}}{R_{\mathrm{E}}} = \frac{v_{\mathrm{es}}^2}{2}. \tag{20}$$

Numerical values for G, m_{E}, and R_{E} could be substituted in Eq. (20) to calculate the numerical value of v_{es} but it is simpler to write Newton's law for the Earth's surface. Thus

$$\frac{Gmm_{\mathrm{E}}}{R_{\mathrm{E}}^2} = mg, \tag{21}$$

where g is the acceleration due to gravity at Earth's surface. Again dividing by m, Eq. (21), another expression for the left-hand side of Eq. (20) is obtained:

$$\frac{Gm_{\mathrm{E}}}{R_{\mathrm{E}}} = gR_{\mathrm{E}}. \tag{21a}$$

Finally, equating the right-hand sides of Eqs. (20) and (21a) yields

$$v_{\mathrm{es}} = (2gR_{\mathrm{E}})^{1/2}. \tag{22}$$

Note that employing Eq. (21) avoids use of constants G and m_{E}, replacing the two constants by a familiar single constant g.

Inserting approximate but quite accurate values for g and R_{E} in Eq. (22) yields

$$v_{\mathrm{es}} = \left[2 \times \frac{32\ \mathrm{ft}\cdot\mathrm{sec}^{-2}}{5280\ \mathrm{ft}\cdot\mathrm{m}^{-1}} \times 4000\ \mathrm{mi}\right]^{1/2}$$
$$= 6.96\ \mathrm{mi}\cdot\mathrm{sec}^{-1}, \tag{23}$$

which establishes the magnitude of Earth's escape velocity as 7 mi · sec^{-1}, very nearly.

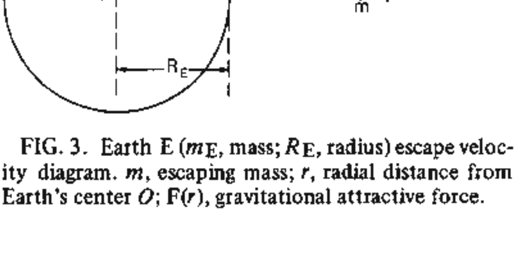


FIG. 3. Earth E (m_{E}, mass; R_{E}, radius) escape velocity diagram. m, escaping mass; r, radial distance from Earth's center O; $\mathbf{F}(r)$, gravitational attractive force.

5. Elementary Dynamics of Space Flight (Artificial Earth Satellites) A second physical example of curvilinear motion is the rotation of man-made satellites placed in stable orbits about Earth via rocket launches from Earth's surface. Such *artificial* satellites are governed, of course, by the same dynamics as the planets, which are *natural* satellites of the Sun.

(1) The tangential orbital speed v_s which must be attained by the artificial satellite to achieve a stable, fixed orbit about Earth has to be adjusted critically so that the satellite neither spirals into the Earth nor out of the solar system.

To calculate v_s, consider for simplicity a circular orbit with Earth as center. The Earth's attracting force upon the satellite or spacecraft in such a stable orbit can be expressed in two ways: by Newton's law of gravitation, Eq. (18), and by a centripetal force expression, Eq. (6). Equating the two expressions yields

$$\frac{Gm_s m_E}{{r_s}^2} = \frac{m_s {v_s}^2}{r_s}, \tag{24}$$

where m_s is the satellite mass, r_s is its radial distance, and the other symbols have the same meanings as before. Dividing both sides of Eq. (24) by m_s and solving for the critical speed v_s yields

$$v_s = \left(\frac{Gm_E}{r_2}\right)^{1/2}. \tag{25}$$

Known values could be substituted for the three quantities of the right-hand side of Eq. (24) to yield a numerical value for v_s. Again, as was done in the escape velocity calculation in Section 4, it is easier, and instructive, to express the right-hand side of Eq. (24) in terms of weight, $m_s g_s$. Thus

$$\frac{m_s {v_s}^2}{r_s} = m_s g_s, \tag{26}$$

or

$$v_s = (g_s r_s)^{1/2} \simeq (gR_E)^{1/2}, \tag{27}$$

where g_s is the acceleration due to gravity at the satellite altitude, which for artificial satellites at altitudes of 100 mi (or several hundreds of miles) can be replaced by g (gravity at Earth's surface), and r_s by R_E (Earth's radius) to good approximations. Substitution of the numerical values in Eq. (27) yields

$$v_s = \left(\frac{32 \text{ ft} \cdot \text{sec}^{-2} \times 4000 \text{ mi}}{5280 \text{ ft} \cdot \text{mi}^{-1}}\right)^{1/2}$$
$$= 4.92 \text{ mi} \cdot \text{sec}^{-1} \simeq 5 \text{ mi} \cdot \text{sec}^{-1}. \tag{28}$$

The period for such a satellite is calculated approximately, but with good accuracy, by dividing the circumference of its orbit (Earth circumference, approximately) by the round-number satellite speed from Eq. (28). Thus

$$\text{Period} = \frac{25{,}000 \text{ mi}}{5 \text{ mi} \cdot \text{sec}^{-1} \times 60 \text{ sec} \cdot \text{min}^{-1}}$$
$$= 83 \text{ min} \simeq 1\tfrac{1}{3} \text{ hr}, \tag{29}$$

which is the time to complete one revolution (one orbit) about Earth.

(2) It should be noted that an artificial satellite moving in a fixed stable circular orbit does not "fall" toward Earth but maintains a constant radial distance from the center of the Earth. This recalls the elementary physics lecture-hall demonstration (Fig. 4) which is designed to show that a ball dropped *vertically* from rest (by deenergizing magnet *M*) and a projectile fired *horizontally* from a gun at the same vertical height as the ball and at the same instant the magnet is deenergized, fall vertically together so that the projectile strikes the ball at impact point *A* after elapsed time *t*.

In view of the artificial satellite situation, where the satellite moving with horizontal speed relative to Earth's surface of about 5 mi/sec *maintains* its vertical distance above Earth, it follows that the lecture-hall demonstration appears to work only because of the short distances and times and the low speed involved. The conclusion usually stated, that an initially horizontally moving object falls to Earth with the same gravity acceleration as an object dropped from rest with zero horizontal speed from the same vertical height, is, strictly speaking, incorrect. For the horizontally moving satellite speeding at about 5 mi/sec does not "fall" at all. The correct conclusion is that the horizontal speed of the gun projectile, negligible compared to the satellite speed, results in negligible *centrifugal* force upon the projectile so that it *appears* to fall with the same gravity acceleration as an object falling from rest with zero horizontal speed. (The concept of centrifugal force is treated in detail in Section 6).

(3) It is interesting to note that Kepler's Third Law, derived in Joos[2] (pp. 92-93) for elliptic orbits, can be derived quite simply for circular orbits employing Newton's law of gravitation and algebraic manipulations only.

Thus, considering an artificial Earth satellite as appropriate in this section, the central attractive force upon the orbiting satellite can be expressed in two ways (as was done in obtaining Eq. (24) above), by Newton's law, Eq. (18),

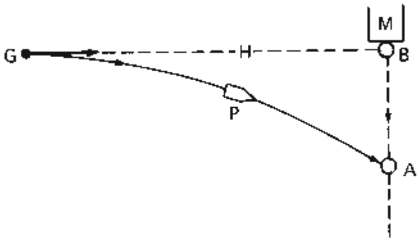

FIG. 4. Sketch of apparatus used to demonstrate "falling" of a horizontally-fired projectile and a vertically dropped ball. G, gun; H, horizontal line of fire (dashed); P, projectile; M, electromagnet; B, ball; A, impact point.

and by a centripetal force expression, Eq. (6). Equating these two expressions yields

$$\frac{Gm_s m_E}{r_s^2} = m_s \omega_s^2 r_s, \tag{30}$$

where ω_s is the angular speed of the satellite:

$$\omega_s = 2\pi/T_s, \tag{31}$$

with T_s the rotation period of the satellite about Earth. Using Eq. (31) in Eq. (30) and solving for T_s^2 yields

$$T_s^2 = \left(\frac{4\pi^2}{Gm_E}\right) r_s^3. \tag{32}$$

Since the term in parentheses in Eq. (32) is constant, this equation states Kepler's Third Law for circular orbits: The squares of the periods of satellites are proportional to the cubes of the diameters of their circular orbits (remembering that the diameter of a circle, a special case of the ellipse, is its major axis and is twice its radius).

(4) *"Stationary" Artificial Satellites.* Artificial satellites which revolve about Earth with the same period as, and in phase with, the Earth are extremely important in communications, in direct television-antenna transmission over distances far greater than horizon-limited line-of-sight TV-tower transmissions, in observations of selected areas of Earth's surface, and so on. Such 24-hr period satellites are termed *stationary* because, synchronized with Earth's turning, they remain "fixed" above the same spot upon Earth's surface.

The critical altitude (above Earth's *surface*) of a stationary satellite in circular orbit is calculated directly by Eq. (32), in which r_s and T_s may be changed to R_{st} and T_{st}, the satellite radius (measured from Earth *center*) and period, respectively, for the "stationary" orbit; or

$$R_{st}^3 = \left(\frac{Gm_E}{4\pi^2}\right) T_{st}^2. \tag{33}$$

As before, instead of using numerical values for G and m_E in Eq. (33), it is simpler to evaluate the product Gm_E using Eq. (21a). Thus

$$Gm_E = gR_E^2, \tag{33a}$$

which substituted in Eq. (33) yields

$$R_{st}^3 = \left(\frac{gR_E^2}{4\pi^2}\right) T_{st}^2. \tag{34}$$

Substituting numerical values for the constants in parentheses in the right-hand side of Eq. (34) yields

$$R_{st} = \left[\frac{\frac{32}{5280}\ \text{mi} \cdot \text{sec}^{-2}\ (4000\ \text{mi})^2\ (24 \times 3600\ \text{sec})^2}{4\pi^2}\right]^{1/3} = 2.64 \times 10^4\ \text{mi}, \tag{34a}$$

from which, substracting the radius of Earth (4000 mi, approximately), *22,400 mi, approximately* is obtained as the critical altitude of a stationary satellite; this is very roughly equivalent to Earth's circumference, 25,000 mi.

6. Forces* (Centripetal Force; Centrifugal and Coriolis Forces; Inertial and Noninertial Reference Frames) In Section 1 the radially directed attractive force upon a point or body of mass m was discussed briefly and termed *centripetal* force [Eqs. (6) and (6a)] since it is directed toward the center of motion. It should be noted here that the concept of *centripetal* force is much preferred by physicists to that of *centrifugal* force. In fact, the latter term is denied and labeled as fictitious in some treatments of the subject. However, this negative attitude may be justified only when the observer of the motion is in an *inertial frame of reference.* Centrifugal forces have a proper place in *noninertial reference frames.* This matter is discussed in detail in this section.

Centrifugal and *Coriolis forces* are considered in somewhat more sophisticated discussions of curvilinear motion. It is important to realize that the concept of *centrifugal* force, and also that of Coriolis force, can be used *instead of* the simpler centripetal force concept, provided the reference frame for the motion is changed from an inertial to a noninertial frame.

Thus far an inertial frame of reference has been implied; that is, the observer is fixed in space as a bystander watching the motion. (A simple example: a bystander watching a wheel rotating on an axle.) An alternative and equally valid way of observing motions such as the rotary motion of the mass point P in Fig. 1 is for the observer to take his position upon the radius vector OP, as though he were on a turntable, and observe the same point P. Such an observer is in a noninertial reference frame.

Both the inertial and the noninertial observations are equally correct, as is emphasized in general relativity theory, but they are separate and distinct viewpoints; either one, but not both simultaneously, can be used to describe and analyze the motion.

To clarify these two viewpoints somewhat further consider a ball tied to a string whirled in a horizontal circle and then released while whirling. A bystander in this case is essentially

*This section is a revised summary of the corresponding discussion of forces in rotary motion by Arthur G. Rouse (Saint Louis University, deceased) which appeared in the first two editions of this Encyclopedia. The present author expresses his indebtedness to that original review of the subject.

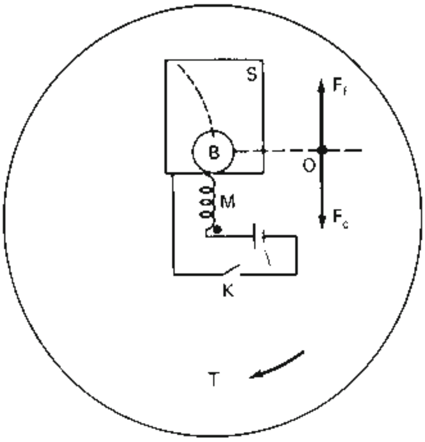

FIG. 5. Sketch of apparatus to demonstrate an "observer" in a *noninertial* frame. T, horizontal turntable; S, "magic slate," M, electromagnet energized by closing switch K to hold steel ball B; F_f and F_c, centrifugal and centripetal forces, respectively, translated for clarity from center of B to O. (Adapted from Ref. 3.)

an inertial observer and sees the ball fly off in a straight line in a tangential direction. Now consider the apparatus shown in Fig. 5. While the turntable is rotating clockwise at constant speed the steel ball can be released by deenergizing the electromagnet, causing the ball to roll on the "magic slate" and leave a trace as shown. The slate plays the role of a rotating, noninertial, observer and the trace on it is the record of the ball's path as seen by such observer. Note that the ball begins to roll in a radial direction on the slate and then curves. The inertial observer standing nearby sees a tangential motion of the ball just as it is released, whereas the noninertial observer on the turntable sees an initial radial motion.

In the example of the ball being whirled horizontally in a circle the bystander (in the inertial frame) says there is but one force acting upon the ball, the tension in the string directed toward the center of the uniform circular motion, which he terms the centripetal force. When the ball is released the centripetal force disappears, there is no horizontal force upon the ball, and so it goes off on a straight-line tangent at constant linear speed.

In contrast, the rotating observer (in the noninertial frame) on the rotating turntable says that while the ball is held by the magnet it is at rest, it has no motion and no acceleration relative to the "magic slate" and is in equilibrium (there is no net force acting on it). Hence there are two equal and opposing forces acting on the ball, the centripetal pull F_c of the magnet and the centrifugal force F_f acting radially outward. Upon release of the ball by the deenergized magnet the centripetal force disappears, the centrifugal force initially accelerates the ball radially outward, and an additional *Coriolis* force (plus the effect of conservation of angular momentum, as will be explained in Section 8) causes the ball to follow the curved path on the slate seen by the noninertial rotating observer. The Coriolis force appears when the ball acquires velocity $\mathbf{v}$ with respect to the rotating observer and it turns out to be always perpendicular to $\mathbf{v}$, while $\mathbf{v}$ in this experiment is always perpendicular to the angular velocity $\boldsymbol{\omega}$ of the rotating reference frame. (Remembering, as noted in Section 1, that $\boldsymbol{\omega}$ is perpendicular to the plane of the rotary motion.) Note that it is the rotating observer only, in his noninertial reference frame, who employs the concepts of centrifugal and Coriolis force. The discussion of Coriolis force is continued and expanded in the next section.

(NOTE: An observer at rest upon Earth is strictly not an inertial observer—one at rest with respect to the fixed stars—since Earth is rotating on its axis and traversing its orbit about the Sun at the same time. However, the motion of Earth in space may be neglected in the examples considered in this section, so that a bystander at rest upon Earth is essentially an inertial observer.)

7. **Rotation of Earth; Some Effects of Centrifugal, Gravitational, and Coriolis Forces** Simple yet adequate and correct discussions of the Coriolis force [named for G. G. Coriolis (1792–1843) a French scientist who first published an analysis in 1835] are not found in elementary physics texts and also are difficult to locate in the literature. An adequate discussion should include the concurrent centrifugal force and other related forces. Hence it is attempted here to supply such a treatment.

Our Earth in continuous rotation about its axis furnishes striking and convincing evidence of the reality and importance of the Coriolis force in combination with the other related forces, centrifugal and gravitational. An observer upon eastward rotating, Earth is a noninertial observer on a rotating plane disk (the circle of radius CP in Fig. 6) parallel to the equatorial plane and perpendicular to Earth's North-South axis, who plays the role of the "magic-slate observer" on the revolving turntable of Fig. 5.

Figure 6 illustrates the Earth rotating eastward with constant angular velocity $\boldsymbol{\omega}_E$ (counterclockwise, looking down the axis) about its axis, and shows the three forces F_G, F_f, and F_{cor} acting on a body freely falling from rest at P near Earth's surface in the Northern hemisphere. It should be noted that the *gravitational* force F_G which is not affected by Earth's rotation is directed toward Earth's center C, whereas the force of gravity F_g (the vector resultant of F_G and F_f) points toward O' on Earth's axis but "below" O in the Northern hemisphere.

The standard theoretical physics texts[4] derive the following expression for $\mathbf{F}_{cor}$:

$$\mathbf{F}_{cor} = -2m(\boldsymbol{\omega} \times \mathbf{v}) = -2m(\boldsymbol{\omega}_E \times \mathbf{v}), \quad (35)$$

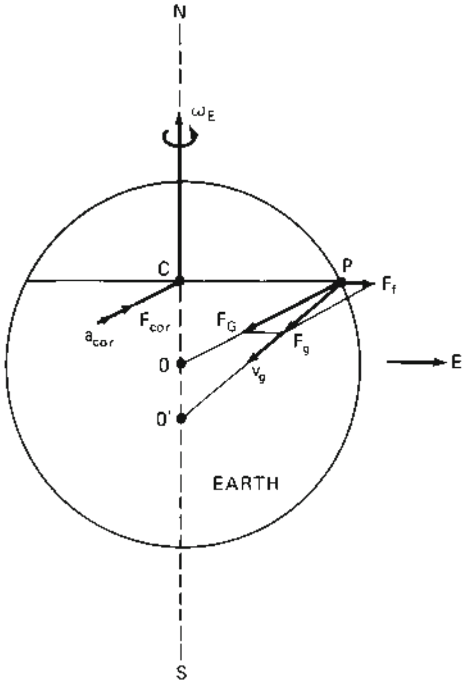

FIG. 6. Forces seen by *noninertial* observer upon a freely falling body at P near Earth rotating about geographic axis N-S (cross-sectional view through axis) with angular velocity ω_E. Ff, centrifugal force; F_G, gravitational force; F_g, gravity force (vector resultant of F_g and Ff); F_{cor}, a_{cor} Coriolis force and acceleration, initial directions (translated for clarity from P to C). C, center of plane circle of latitude through P parallel to equatorial plane.

where $\mathbf{v}$ is the instantaneous velocity, initially $\mathbf{v}_g$, of mass m at P. The corresponding Coriolis acceleration $\mathbf{a}_{cor}$ then is given by

$$\mathbf{a}_{cor} = -2(\boldsymbol{\omega} \times \mathbf{v}) = -2(\boldsymbol{\omega}_E \times \mathbf{v}). \qquad (35a)$$

The vector cross-products in Eqs. (35) and (35a) establish that both $\mathbf{F}_{cor}$ and $\mathbf{a}_{cor}$ are perpendicular to v (and to ω also) as stated in Section 6 and shown by Fig. 6.

8. Examples of Coriolis Force Although as indicated the Coriolis force is not known or understood widely, vivid examples exist for us who dwell upon a rotating platform, the planet Earth, and these follow.

(1) Figure 6 illustrates the effect of centrifugal force $\mathbf{F}_f$, in vector combination with mass attraction $\mathbf{F}_G$, in causing a plumbline's deviation from the direction PO toward Earth's center to the "vertical" $\mathbf{F}_g$ direction PO' away from Earth's center.

(2) If a downward motion is introduced, say in allowing lead balls to fall freely in the $\mathbf{F}_g$ plumbline direction by dropping them in a deep mine shaft drilled in the same vertical direction, the balls would strike the *East* side of the shaft before reaching the bottom. Such an experiment was in fact performed in northern Michigan some years ago, the balls being dropped from the exact center of an 8-ft-square, mile-deep shaft. None of the balls ever reached the bottom; instead they were found imbedded in the East side of the shaft, i.e., the balls in falling drifted some 4 ft *eastward* with respect to the bottom of the shaft before striking the side. This eastward drift of freely falling bodies (neglecting air resistance) in the Northern hemisphere is the effect of the Coriolis force arising from the combination of the Earth's rotational velocity $\boldsymbol{\omega}_E$ and the linear velocity $\mathbf{v}$, as shown by Fig. 6 and explained above.

Also involved in the mine-shaft experiment is the principle of conservation of angular momentum (see Section 2), which must be included with the Coriolis force to account for the observed eastward drift of the falling balls. Because the angular momentum of the closed system (Earth and the falling ball) must remain unchanged, the original eastward horizontal velocity of the ball, which is the same as the Earth's eastward surface velocity at the drop point, remains essentially constant while the ball is dropping. Hence the ball, dropped from "rest" relative to Earth, catches up to the East side of the shaft as it falls. It is essential to realize that the bottom of the shaft has a smaller eastward horizontal velocity than the top due to its shorter radial distance from Earth's axis through COO' (Fig. 6). Here Eq. (7), $v = r\omega$, applies; since ω_E is constant, v for the mine shaft bottom is lower because r has decreased, whereas the falling ball, conserving angular momentum, continues eastward with the same horizontal velocity as at the top of the shaft.

(3) Another everyday example of the action of the Coriolis force is available to everyone in the draining of water from his bathroom washbowl (a hemispherical, symmetric bowl best shows the effect). If the drain plug of the water-filled bowl is opened carefully when the water has quieted to a still surface, the discharging water will usually be seen to swirl into a rotating (counterclockwise in the Northern, clockwise in the Southern hemisphere) hollow whirlpool as it goes down the drain. This effect occurs because the central core of the draining water drops faster down toward and into the drain than the water near the side of the bowl, so that a central hollow is formed, which is turn causes the water immediately around the hollow to slide down the hill of the vortex cavity, thus resulting in a downward-slanted velocity $\mathbf{v}_g$ due to gravity, much as in Fig. 6. The vector combination of $\mathbf{v}_g$ with $\boldsymbol{\omega}_E$ produces the Coriolis force [Eq. (35)] upon the downward-draining water, causing it to swirl as observed. The Coriolis force, and its consequent acceleration and velocity, turn out to be

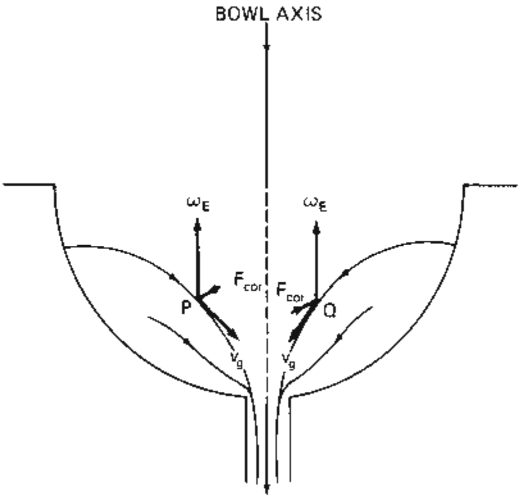

FIG. 7. Diagram to explain effect of Coriolis force inducing counterclockwise vortex motion of water draining from washbowl (vertical cross-sectional view. Northern hemisphere, ω_E, angular velocity of Earth due to eastward rotation about N-S axis; v_g, velocity due to gravity of small volumes of water at typical locations *P* and *Q*; F_{cor}, perpendicular to page (out from page at *P*, into page at *Q*). $\boldsymbol{\omega}_E$ and $\mathbf{v}_g$, in plane of page (see text for note on more precise directions).

directed all around the hollow vortex of the draining water in a counterclockwise direction (looking down upon the water) in the Northern hemisphere, as should be clear from Fig. 7. (Actually, in Fig. 7 $\boldsymbol{\omega}_E$ is pointed parallel to Earth's North-South axis, which is tilted relative to the "bowl axis" shown in the plane of the page so that the $\boldsymbol{\omega}_E$ and $\mathbf{F}_{cor}$ vectors shown are really the components of those two vectors in and perpendicular to the plane of the page, respectively.)

This analysis is somewhat simplified. For example, it is evident that any small volume of water in the draining washbowl considered as the "body" in motion is not isolated, as is the lead ball falling in the mine shaft, but interacts continually with other surrounding small volumes or bodies of water. So it appears that the centrifugal force on any such small volume would be counteracted in part at least by the resisting forces of the next radially outward small volume because of liquid incompressibility and other liquid (viscous) forces. Further, once the draining washbowl water is in circular motion due to the Coriolis force effect, conservation of angular momentum acts to increase the swirling counterclockwise motion of the water as it moves *inward* from the outer edges of the whirlpool toward and down into the central drain, because, by Eq. (12), as the radius **r** of swirling decreases, the speed **v** must increase to keep the momentum **M** constant.

S

SCHRÖDINGER EQUATION

The Schrödinger equation, first obtained in 1926[1], was an extension of de Broglie's hypothesis, proposed two years earlier,[2] that each material particle has associated with it a wavelength λ related to the linear momentum p of the particle by the equation

$$\lambda = \frac{h}{p} \tag{1}$$

where h is Planck's constant. Since any sinusoidally varying wave motion of amplitude ψ and wavelength λ satisfies the differential equation*

$$\nabla^2 \psi + \frac{4\pi^2}{\lambda^2} \psi = 0 \tag{2}$$

matter waves would obey the equation

$$\nabla^2 \psi + \frac{4\pi^2}{h^2} p^2 \psi = 0 \tag{3}$$

In particular, a particle of mass m with no forces acting on it has energy $E = \frac{1}{2}mv^2 = p^2/2m$, or $p^2 = 2mE$. Equation (3) may thus be written

$$\nabla^2 \psi + \frac{8\pi^2 m}{h^2} E\psi = 0 \tag{4}$$

This is the Schrödinger equation for a free particle. Of greater importance is the equation for a bound particle for which the binding force can be related to a potential energy V. In this case, the total energy of the particle is equal to the sum of the kinetic and potential energies, i.e., $E = p^2/2m + V$, or $p^2 = 2m(E - V)$. Equation (3) thus becomes

$$\nabla^2 \psi + \frac{8\pi^2 m}{h^2} (E - V)\psi = 0 \tag{5}$$

This is known as the time-independent Schrödinger equation. Its great utility lies in the fact that it enables one to calculate energy levels, or eigenvalues, of the energy E (see QUANTUM THEORY). The remarkable agreement of the results of the equation with experimental fact has led to its being regarded as one of the fundamental equations of physics.

The more advanced formulation of the Schrödinger equation is based on the operator concept of quantum theory together with the Hamiltonian methods of classical mechanics. Specifically, to each dynamical variable q_i, there is a conjugate momentum p_i. The fundamental postulate of quantum mechanics states that for each pair (q_i, p_i), the equation

$$p_i\psi = -i\hbar \frac{\partial \psi}{\partial q_i} \tag{6}$$

holds, where $\hbar = h/2\pi$. That is, $-i\hbar\partial/\partial q_i$ is an operator, which, when applied to the wave function ψ, is equivalent to multiplying by p_i. In the Hamiltonian function $H(p_i, q_i)$, each p_i is replaced by its corresponding operator. The result is the Hamiltonian operator $H(-i\hbar\partial/\partial q_i, q_i)$, which, when it operates on the wave function, is equivalent to multiplying by the energy E, viz.,

$$H(-i\hbar\partial/\partial q_i, q_i)\psi = E\psi \tag{7}$$

This is the generalized form of the time-independent Schrödinger equation. It reduces to Eq. (5) when applied to a single particle, but it has the advantage that the application to systems of many particles can be carried out in a straightforward manner.

The time-dependent form of the Schrödinger equation is obtained by replacing E by its operator $E \rightarrow i\hbar\partial/\partial t$, so that

$$H\left(-i\hbar \frac{\partial}{\partial q_i}, q_i\right)\psi = i\hbar \frac{\partial}{\partial t} \psi \tag{8}$$

For applications of the various forms of the Schrödinger equation, the reader should consult the article on WAVE MECHANICS and references therein.

SECONDARY EMISSION

Secondary electron emission is the emission of electrons from a surface as the result of bombardment of the surface by incident "primary" particles. The primary particles can be electrons, ions, or neutral atoms. Unless otherwise specified, secondary electron emission is generally taken to refer to electron emission as the result of impinging primary electrons. The phenomenon of secondary emission is the basis for a wide range of practical applications. In the last decade, secondary emission has been extensively used as a method of surface atom identification (Auger electron spectroscopy). Secondary emission is important in most vacuum systems, because insulating or electrically floating surfaces in the presence of charged particles assume a potential that is determined in large part by the secondary emission properties of the material.

Secondary electrons have energies ranging from zero up to the primary electron energy (Fig. 1). The energy distribution curve peaks between 1 and 10 eV, drops down to a low value above 30 eV, and may rise again near the primary electron energy. Superimposed on this curve are discrete energy peaks, described below.

The secondary electron emission ratio or yield δ is the number of secondary electrons emitted on average per incident primary electron. This ratio is a function of the energy of the incident primary electron and of its angle of incidence (Fig. 2). For a given material, surface conditions are important, and small amounts of contamination or oxidation can alter the secondary emission ratio. Different crystalline faces of the same crystal may have different work functions and secondary emission yields.

The emission of low energy secondary electrons is a complicated multiple process. The primary electron loses its energy in one or more inelastic collisions. Some of this energy may be imparted to other electrons in a cascading process. Electrons arriving at the surface from within the solid with energy and direction enabling them to traverse the surface barrier emerge as secondary electrons. Factors tending to increase the secondary emission yield are: a long mean free path inside the solid for the cascading low energy secondary electrons, and a low surface barrier or work function. If the primary electron makes a small angle of incidence (nonperpendicular) with the surface, the yield is enhanced because relatively more secondary electrons originate close to the surface. As the primary electron energy is increases, many of the secondaries are formed too far from the surface to be able to reach it with sufficient energy to escape, and the secondary emission yield drops with primary electron energy.

Metals generally have a maximum yield between 1 and 2. This low yield is mostly a consequence of the large number of free electrons in the metal that interact with the secondaries, causing short mean free paths and short escape depths.[1] In insulators, low energy secondary electrons may have relatively long mean free paths because of the absence of nearly free electrons with which to interact. The secondaries lose energy to phonons, as can be shown by a decrease in yield with increasing temperature. The yields of insulators are generally higher than yields of metals. See Table 1.

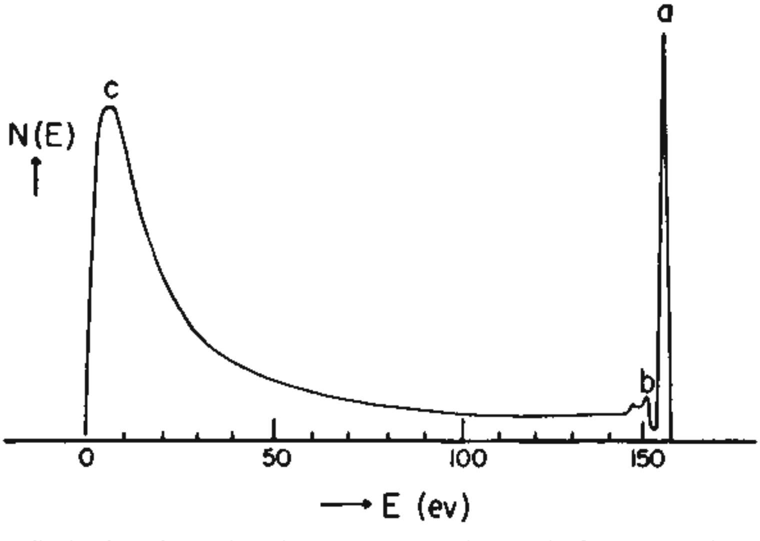

FIG. 1. Energy distribution of secondary electrons, showing a large peak of low energy electrons, a sharp peak of elastically reflected electrons at the primary electron energy, and some energy loss peaks. [E. Rudberg, Phs. Rev. 50, 138 (1937)]

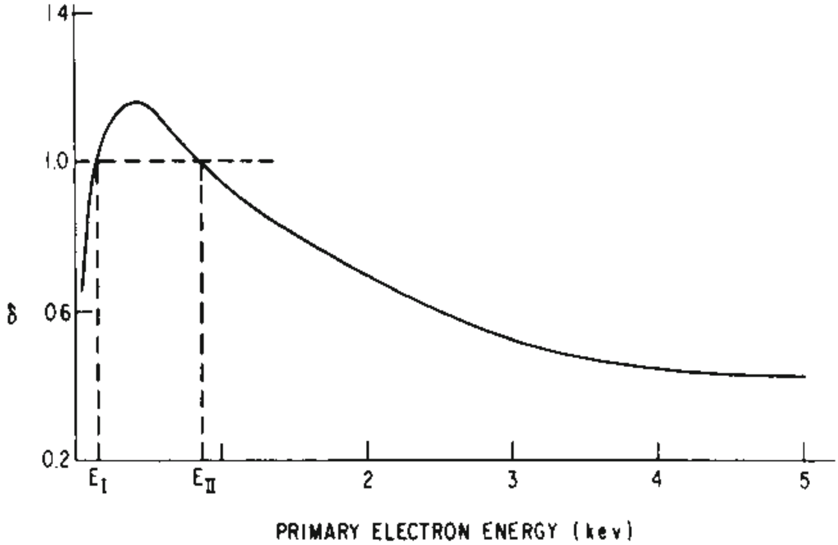

FIG. 2. The secondary emission yield of germanium as a function of primary electron energy. The first and second crossovers where the yield is unity are given by E_{I} and E_{II}. [J. B. Johnson and K. G. McKay, Phys. Rev. 93, 668 (1954)]

Backscattered Electrons Whereas most secondary electrons have lost all but a few eV of energy in emerging from the solid, some energetic secondaries have energies all the way up to the primary electron energy. By convention, backscattered electrons are denoted as those with energy of 50 eV or more. The backscattered fraction or ratio is the average number of backscattered electrons per primary electron. Figure 3 presents the backscattered fraction for a number of elements. For low atomic number materials ($Z < 30$), the backscattered fraction is relatively constant with primary electron energy, and increases with increasing atomic number. At higher atomic numbers, the backscattered fraction increases with primary electron energy.

Elastically Reflected Electrons A number of

TABLE 1. SECONDARY ELECTRON EMISSION YIELDS OF SOME REPRESENTATIVE MATERIALS.
($\delta_{\max}$ is the maximum secondary emission yield at energy $E_{p\ \max}$. E_{I} and E_{II} are the first and secondary crossovers. For a more complete list, see Ref. 5.)

Material	$\delta_{\max}$	$E_{p\ \max}$ (eV)	E_{I} (eV)	E_{II} (eV)
Ag	1.5	800	200	>2000
Al	1.0	300	300	300
Au	1.4	800	150	>2000
Be	0.5	200	none	none
C (graphite)	1.0	300	300	300
C (soot)	0.45	500	none	none
Cu	1.3	600	200	1500
Fe	1.3	400	120	1400
Mg	0.95	300	none	none
Pt	1.8	700	350	3000
Si	1.1	250	125	500
Si (cesiated)	900	20,000	125	–
W	1.4	650	250	>1500
NaCl (crystal)	14	1200		
NaI (crystal)	19	1300		
MgO (crystal)	25	1500		
MgO (layer)	3-15	400-1500		
BeO	3.4	2000		

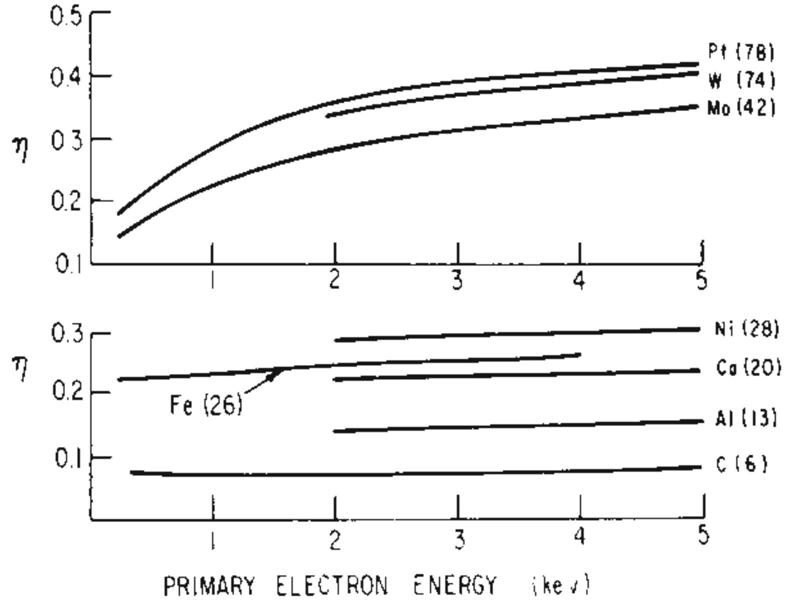

FIG. 3. The backscattered fraction as a function of primary electron energy. {E. J. Sternglass, Phys. Rev. 95, 345 (1954), P. Palluel, Compt. Rend. 224, 1492 (1947)

processes give rise to electrons with discrete amounts of energy. To retain this precise energy, these processes must occur close to the surface to reduce the chance of further inelastic losses. Electrons that are elastically scattered back out of the surface give rise to a peak with the full primary electron energy.

Energy Loss Electrons Reflected electrons may excite surface or volume plasma excitations of the electrons in the solid before leaving the surface. Vibrational modes of individual atoms may also be excited.[2] The emerging secondary electrons have the full primary energy minus the excitation energy. These energy losses cause a series of peaks in the yield curve just below the primary electron energy. Measurement of these losses is termed *electron energy loss spectroscopy*, and is used to study the vibrational properties of atoms and ordered overlayers on surfaces.

Auger Electrons Auger electrons have energies related to transition levels within the atom in the solid where they originate. This energy is independent of the primary electron energy, in contrast to plasma loss electrons that have the primary energy minus the loss energy. Auger electrons originate in processes where an inner shell electron is ejected from an atom by a bombarding particle. A vacancy is created that is filled by a higher energy level electron. The difference in energy levels may be either given to an outer shell electron or emitted as an x-ray. If such a process occurs near the surface with an electron receiving the energy, and if the electron suffers no further energy loss, it will have the Auger electron energy for that atom. Atoms with many transition levels have a series of Auger electron energies. (See Fig. 4.)

High Yield Materials Considered as a group, insulators have higher secondary emission yield maxima than conductors, although there are exceptions. Some high yield materials are MgO, with a yield as high as 25 for a good single crystal, and NaBr, with 24. In insulators, an excited electron in the conduction band may have insufficient energy to interact with electrons in the valence band. Its main energy loss mechanism may be through interactions with lattice vibrations, with a small loss of energy per interaction. Hence the diffusion path lengths can be long, and excited electrons formed deep within the insulator may be able to reach the surface.

Interesting high yield materials can be made with negative electron affinity semiconductors. Examples of these are cesiated GaP and Cs-activated silicon.[4] Electrons at the bottom of the conduction band at the surface are able to emerge as secondaries because of the absence of a surface barrier. The electron may originate at a long distance from the surface. In cesiated silicon, a yield of 900 has been reported at a primary energy near 20 keV.

In practical high yield devices, such as electron multipliers, the emitting material is usually in thin film form on a suitable conductor, so that electrical leakage or breakdown through the film prevents the surface potential from differing appreciably from that of the substrate. An alloy of magnesium and silver is frequently used, containing a few percent magnesium. When heated in an oxidizing at-

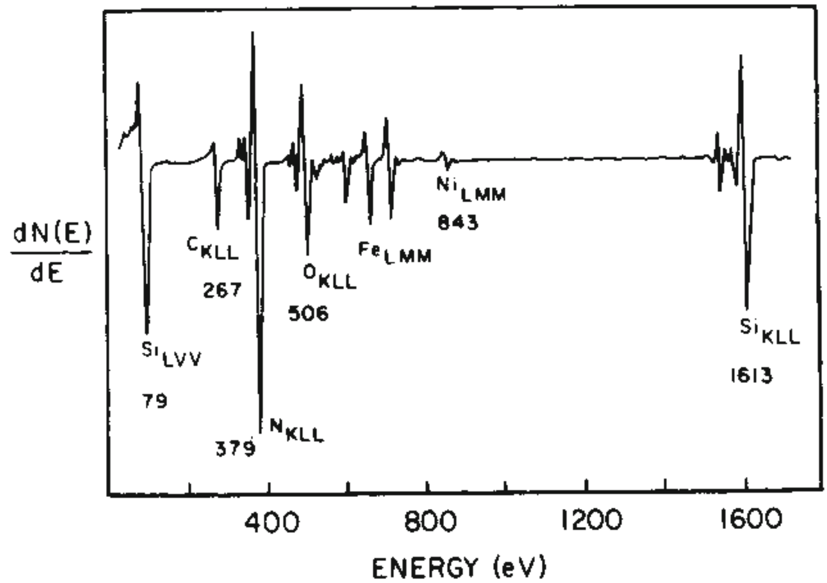

FIG. 4. Auger Spectrum from the surface of Si_3N_4. Note that the derivative of the yield is measured, enhancing the structure in the curve. The various Auger electron peaks and the corresponding transition are labeled. (Ref. 3)

mosphere, a high yield magnesium oxide film forms on the surface. Cesium or cesium oxide are sometimes introduced to lower the electron affinity of the film. Yields of thin film MgO range from 3 to 15, depending on how the film was handled. An alternative material is an oxidized Be-Cu alloy containing a few percent Be, with beryllium oxide at the surface.

Thick porous oxide films occasionally exhibit field-enhanced emission. Positive charges near the surface create strong local fields, enhancing the emission of electrons. This type of emission is known as the Malter effect. It is usually unstable and nonreproducible.

Low Yield Surfaces It is frequently necessary to minimize the secondary emission yield of a surface. A roughened or porous surface often helps to do this, because many secondaries are intercepted by other surfaces before exiting the solid. Carbon in the form of soot is commonly used for this purpose.

First and Second Crossovers The potential which an insulating or floating surface attains in the presence of charged particles may depend on its secondary emission properties. The first and second crossovers of a material are the primary energies at which its secondary emission is unity (Fig. 2). If the primary energy is less than the first crossover, the surface will charge negatively toward the electron source potential. If the primary energy is between the first and second crossovers, the yield is greater than unity. The surface will then charge positively toward the second crossover provided there is a positive surface that attracts or collects the secondaries. If the primary energy is greater than the second crossover, the yield is less than unity, and the surface will charge negatively toward the second crossover.

Applications Secondary emission is always present when charged particles strike surfaces. Many devices make use of this property. Secondary emission multipliers use a series of secondary emission surfaces to multiply the number of electrons—gains of a million or more are readily achieved. Scanning electron microscopes can monitor the secondary emission yield of the surface being scanned by the primary beam—with changes in the secondary emission current showing the boundaries of each material. Auger electron spectroscopy (and scanning Auger microscopes) use the discrete energies of Auger electrons to identify surface atoms with great sensitivity. Channel plate multipliers consist of fine capillary tubes through a glass plate. The conductivity and secondary emission are such that an incident focused optical image produces photoelectrons which are multiplied in the channel plate capillaries to give proportionate electron currents at the exit side.

Historical Secondary emission was discovered by Austin and Starke in 1902. In their experiment, a primary electron beam was incident on metal targets at different angles of incident. As the incidence angle went from perpendicular to nearly grazing, they observed that the total current to the target decreased to zero and went negative. They concluded that not only are some primaries reflected, but secondaries formed in the metal also leave the surface, exceeding the primary electron current. The phenomenon was observed to be strictly proportional to the primary electron current.

SEISMOLOGY

Most of our detailed knowledge of the interior of the Earth and Moon and the most precise geophysical explorations of the Earth's crust come from seismology. In a narrow sense, seismology is the study of earthquakes and their effects, but knowledge of seismic waves has been applied in many fields. Not only does seismology provide information on Earth structure, but it also relates to fundamental problems of economic and social importance. Earthquakes are destructive over wide areas of the world and, with the growth of industrialization and the spread of population, the consequences of strong ground shaking can be catastropic. Thus, seismologists provide engineers with risk maps which are the basis for national building codes, as well as estimates of strong ground motions for the earthquake-resistant design of large critical facilities, such as nuclear reactors, hospitals, dams, and bridges.

The first advance in quantitative seismology took place at the turn of the century, when instruments called *seismographs* were installed in various parts of the world to measure earthquake ground motion. The availability of seismograms that show the actual ground motion in earthquakes provided the basis for physical interpretations. As the century advanced, seismological studies led to the understanding of interior Earth structure and the tectonics of the crust and played a crucial role in exploration for minerals, oil, and other energy resources. In addition, in the last two decades, seismograph networks and analysis of seismic waves have provided vital information in the attempt to attain a comprehensive treaty to ban underground nuclear tests.

Most earthquakes are caused by the sudden release of elastic energy that occurs during rupture of a few km/sec along geological faults in the Earth's upper layers. Some earthquakes are caused by motion of magma under volcanoes, massive landslides, rock bursts in mines, and similar phenomena. Most significant earthquakes, called *tectonic earthquakes*, are produced, however, by fault slip. Their mechanism became clear after studies of faulting and strain of the crust associated with the great 1906 San Francisco earthquake along the San Andreas fault. A definitive study by H. F. Reid modeled the earthquake source as rapid elastic rebound of the rock on both sides of the fault after slow accumulation of elastic strain in the region. In detail, the physical processes involved are complicated, involving opening and closing of microfractures in the rock, percolation of ground water, and the distribution of strain between compression and shear. Dilatancy of the rock seems to occur before the major fault rupture; this involves an increase in the volume of the strained rocks due to various elastic and nonelastic changes. In a strained area, there may be minor percursory slip on faults producing *foreshocks*. After the main or principal earthquake the readjustment of strain around the ruptured fault often produces smaller slips that are observed as an *aftershock* sequence.

The place where slip begins on a fault is called the *hypocenter* or *focus* and the point on the Earth's surface above the focus is the *epicenter*. The main activity at the several hundred seismographic observatories around the world is to determine the location of such foci, using seismic waves that radiate outward at known speeds from the fault rupture through the Earth's interior. The amplitude of the seismic waves is also measured to give the magnitude or the seismic moment of the earthquake. A common measurement of earthquake size is the *Richter magnitude*, although there are other magnitude scales in use which depend on measurements of various parts of the seismic wave train. The magnitude scale is a logarithmic one that can range from negative values to values above 8. The largest shocks have been found to have magnitudes in excess of $8\frac{1}{2}$. The *seismic moment* is equal to the rigidity of the strained rock times the area of faulting times the amount of fault-slip. The largest earthquakes have moments in excess of 10^{26} dyne cm. Neither magnitude nor moment is a direct measure of the energy released in an earthquake. Such measurements are difficult because of energy loss by friction and other causes along the slipping fault and the damping of the waves as they travel through the Earth. An empirical relation between surface wave magnitude M and the energy E (in ergs) is $\log E = 11.8 + 1.5M$. Earthquakes of largest size probably release as much as 10^{25} ergs in the form of seismic wave energy, and the average annual seismic energy released from all earthquakes is also about 10^{25} ergs.

Earthquake waves consist predominantly of three types. Two types, called *P waves* and *S waves*, travel through the body of Earth while the third type, called *surface waves*, travel around the Earth's surface. The fastest is the P wave, involving compression and dilation of the rock. The slower body wave is the S wave, which shears the rock as it propagates. It follows that there are no S waves in liquid media. The speed of seismic waves depends on the elastic properties of the rocks through which they pass. The P wave velocity is given by $V_{\rm P} = \sqrt{k + \frac{4}{3}\mu}$, and the S wave velocity is $V_{\rm s} = \sqrt{\mu/\rho}$, where k and μ are elastic moduli and ρ is the density. The velocities of P waves range from about 5 km/sec in crustal rocks to a maximum of 13 km/sec (see Fig. 1). The shear wave velocities range from about 3 to 8 km/sec. Surface waves are of two main kinds, namely, *Rayleigh waves*, in which particle motions are in a vertical plane aligned with the direction of wave propagation, and *Love waves*, in which motions are horizontal at right angles to the propagation direction. Various physical complexities in the Earth, such as heterogeneity and anisotropy, couple these simple wave types to a minor extent. Seismic waves contain a wide range of frequencies (see Fig. 2). The highest frequencies recorded from near earthquakes are of the order of 10 Hz (0.1 sec period) and periods of 1–20 seconds predominate in the recordings of most distant earthquakes. The longest periods in seismic motion range up to 53 minutes which corresponds to the greatest free oscillation of the whole Earth.

A major observational improvement was the establishment of the World-Wide Standardized Seismograph Network (WWSSN) in the 1960s. By 1969, about 120 of these special stations were distributed in 60 countries. The immediate consequence was the more complete and precise coverage of the location of earthquakes around the globe. The network is being upgraded in the 1980s with more modern seismographs that record digitally over a wider range of frequencies. Global seismicity recorded by the WWSSN concentrates along the mid-oceanic ridges, island arcs, and deep oceanic trenches. Most foci are situated at shallow depths (less

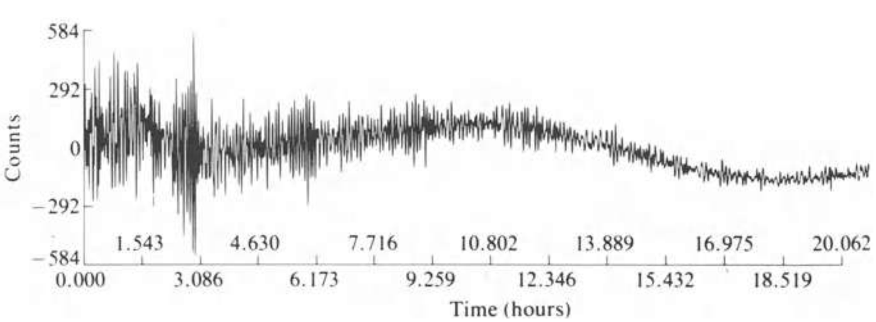

FIG. 2. A seismogram showing the vertical ground motion at Whiskeytown Station of the University of California, Berkeley, in the great Indonesia earthquake of August 19, 1977 (magnitude 7.9). The Earth tide with period of about 12 hrs can also be seen.

than 30 km), but in regions associated with deep oceanic trenches (such as western Central and South America, Alaska, Japan, the Caribbean Antilles, the Aegean Sea, Tonga, and Indonesia), earthquake foci dip to depths of up to 700 km. Typically, the zones of deep earthquakes, named after H. Benioff, dip at 30–60° toward the land. Other deep earthquakes are located in regions without trenches, such as the Hindu Kush and Romania.

A recent explanation of the strong patterns of seismically active belts surrounding largely aseismic areas is the *plate tectonic theory*. The theory describes the lithosphere of the Earth as consisting of about 10 large, and some smaller, stable regions or *plates*. Each plate extends to about 80 km depth and moves horizontally relative to neighboring plates. At plate edges, large strains form, producing earthquakes. Along the mid-oceanic ridges, the plates spread away from each other, and along the Benioff zones the lithosphere subducts downward into the Earth's interior. The mechanisms of earthquake sources are found to agree generally with this description, with normal faulting predominating along ocean ridges and thrust faulting dominating along subduction zones.

Tens of thousands of recorded seismic waves from natural earthquakes and underground nuclear explosions have given a detailed picture of the structure of the Earth's interior (see Fig. 1). It consists of a crustal shell about 5 km thick under oceans and 30–40 km thick under continents; this is the upper part of the 80-km-thick lithosphere. There is a solid but layered mantle extending to about 2900 km depth. Below the mantle is a 2259-km-thick outer core with properties resembling a liquid (no S waves) and at the center of the planet is a separate solid inner core of radius 1216 km. Present research is aimed at elucidating the interior fine structure, including the properties of transition shells and the mapping of regions of large-scale heterogeneity.

Seismograms have been obtained from both the Moon and Mars. The lunar Apollo seismograms gave preliminary information on Moon structure, detecting between 600 and 3000 moonquakes during every year of operation, although most have magnitudes less than 2.0. The lunar interior has a crust 60–100 km thick overlying a two-layered mantle with a transition zone near 450–480 km. A seismograph on Viking II operated on Mars for 546 Martian days. Although background seismic noise (microseisms) was generally high, the indication was that seismicity is very low.

Exploration of the Earth's interior represents a clear example of mathematical inverse problems. Measurements on the surface must be used to infer deep structure. Seismological applications have stimulated the development of inverse theory, particularly in the use of the free oscillations (eigenvibrations) of the Earth (see Fig. 2). The largest earthquakes vibrate the whole planet, and interference between traveling seismic waves produces two classes of eigenvibration, *spheroidal*, ${}_nS_l$, and *torsional*, ${}_nT_l$ (see Fig. 3). The subscripts n and l refer to interior and surface nodal surfaces, respectively. The fundamental spheroidal oscillations ${}_0S_2$ has the longest period, approximately 3,233 seconds, while the fundamental torsional ${}_0T_2$ has a period of 2,638 seconds. The ellipticity, rotation, and heterogeneity of the Earth split the eigenspectra into multiplets. These hyperfine spectra are now being intensively studied with a view to their inversion to finer Earth structure. Observations of the damping of both traveling and standing seismic waves give information on the rheology of the Earth's interior. The average value of the damping parameter Q for ${}_0S_2$ is 620 and that for ${}_0T_2$ is 350.

Emphasis has recently been placed on earthquake prediction. Forecasting the time and place of great earthquakes would provide many social benefits in countries where construction is generally not earthquake-resistant, such as China. Although the theoretical basis for prediction is still weak, rock mechanics experiments suggest that variations in rock properties occur before a large fault slip. These effects produce ground uplift and tilting, increased concentrations of radon emission from ground water, changes in electrical resistivity, and changes in microseismicity. Field programs with special instruments searching for such precursory effects in various countries have given conflicting results to date. Well documented claims for specific short-term earthquake predictions are few, the most important being a 24-hour prediction of a damaging earthquake on February 4, 1975, in Liaoning province, China. That evening, an earthquake, magnitude 7.3, occurred in the Haicheng-Yingkow region. Previous evacuation of the populace ensured few casualties from the damaged structures.

The second type of prediction is the specification of strong ground motion likely to occur at a particular site should a large earthquake occur. Seismic risk maps are produced that give the probabilities of exceeding specified amplitudes of seismic waves in a specified number of years. Mathematical models of fault rupture have led to plausible synthetic records that predict the pattern of seismic waves at points near and far from the seismic source. Such calculations must be scaled to the actual levels of ground acceleration, velocity, and displacement by using records from strong-motion accelerometers of moderate and large earthquakes. Accelerations up to $1.2g$ have been recorded horizontally and vertically. Because few strong-motion accelerograms have as yet been obtained, most estimates of the distribution of ground motion rely heavily on reported seismic intensity. The intensity scale is not instrumental, but describes human responses, earthquake damage to structures, etc.

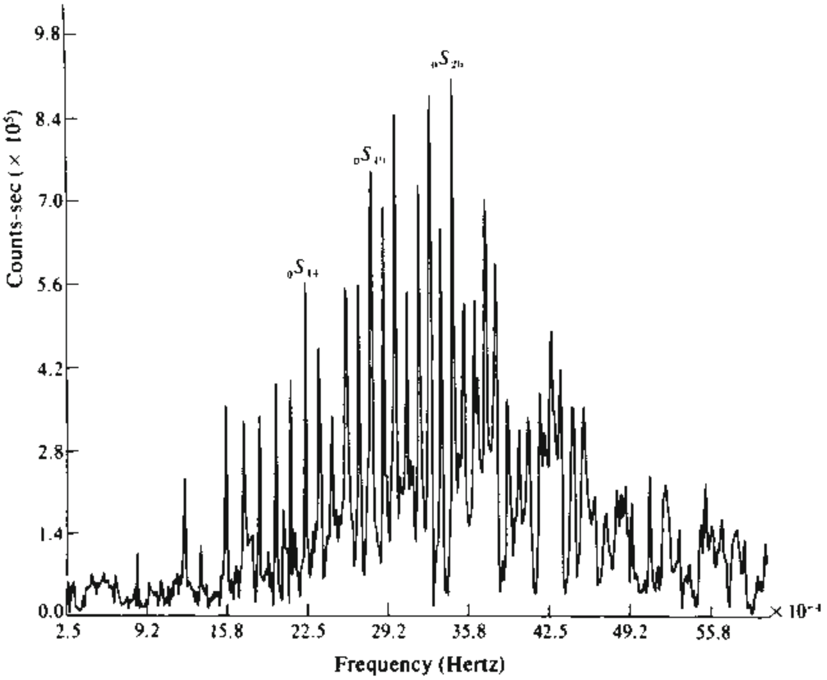

FIG. 3. Spectral peaks of free oscillations of the Earth after the 1977 Indonesia earthquake from an analysis of the motion in Fig. 2. Three peaks have been identified as spheroidal type $_nS_l$.

The most common Western scale is the *Modified Mercalli intensity*, with divisions from I to XII. Correlations have now been made between intensities and seismic magnitudes and moments and recorded ground accelerations for various soil and rock conditions and types of earthquake mechanism (strike-slip, dip-slip, etc.).

Specially designed groups of accelerometers, called *strong-motion arrays*, are now being installed in highly seismic parts of the world. The first large-scale array with digital accelerometers began operation in Taiwan in 1980. Building codes have been adopted in some earthquake areas to minimize the damage from shaking. Studies of strong-motion records and building collapse and failure mechanisms in large earthquakes have lead to code revisions.

SEMICONDUCTOR

Semiconductors are distinguished from other classes of materials by their characteristic electrical conductivity σ. The electrical conductivities of materials vary by many orders of magnitude, and consequently can be classified into the following categories: (1) the perfectly conducting superconductors, (2) the highly conducting metals ($\sigma \sim 10^6$ mho/cm), (3) the somewhat less conducting semimetals ($\sigma \sim 10^4$ mho/cm), (4) the semiconductors covering a wide range of conductivities ($10^3 \gtrsim \sigma \gtrsim 10^{-7}$ mho/cm), (5) the insulators also covering a wide range ($10^{-10} \gtrsim \sigma \gtrsim 10^{-20}$ mho/cm).

The low-conductivity semiconductors are characterized by the great sensitivity of their electrical conductivities to sample purity, crystal perfection, and external parameters such as temperature, pressure, and frequency of the applied electric field. For example, the addition of less than 0.01 per cent of a particular type of impurity can increase the electrical conductivity of a typical semiconductor like silicon and germanium by six or seven orders of magnitude. In contrast, the addition of impurities to typical metals and semimetals tends to decrease the electrical conductivity, but this decrease is usually small. Furthermore, the conductivity of semiconductors and insulators characteristically *decreases* by many orders of magnitude as the temperature is lowered from room temperature to 1 K. On the other hand, the conductivity of metals and semimetals characteristically *increases* in going to low temperatures and the relative magnitude of this increase is much smaller than are the characteristic changes for semiconductors. The principal conduction mechanism in metals, semimetals, and semiconductors is electronic, whereas both electrons and the heavier charged ions may participate in the conduction process of insulators. (See CONDUCTIVITY, ELECTRICAL.)

It is customary to classify a semiconductor according to the sign of the majority of its charged carriers, so that a semiconductor with an excess of negatively charged carriers is termed *n*-type, and an excess of positively charged carriers is called *p*-type, while a material with no excess of charged carriers is considered to be perfectly compensated. Many of the important semiconductor devices depend on fabricating a sharp discontinuity between the *n*- and *p*-type materials, the discontinuity being called a *p-n* junction. (See SEMICONDUCTOR DEVICES, TRANSISTORS.)

Most semiconductors exhibit a metallic luster upon visual inspection; nevertheless, the visual appearance of materials does not provide an adequate criterion for the classification of materials, since the electrical conductivity of all materials is frequency-dependent. Visual inspection tends to be sensitive to the conductivity properties at visible frequencies ($\sim 10^{15}$ Hz). Although materials with a high optical reflectivity tend also to exhibit high dc conductivity, these two properties are not necessarily correlated in all semiconductors and metals. An example of a metal without metallic luster is ReO_3, a semitransparent reddish solid. On the other hand, most of the common semiconductors do exhibit metallic luster primarily because electronic excitation across their fundamental energy gaps can be achieved at infrared frequencies. At low frequencies, the principal conduction mechanism is free carrier conduction, which is important in metals and is present to some extent in semiconductors which contain impurities or are found at elevated temperatures. On the other hand, interband transitions dominate the conduction process at very high frequencies. Interband transitions contribute to the conductivity by about the same order of magnitude in semiconductors, metals, and insulators.

Since the dc conductivity due to free carriers is characteristically low in semiconductors and insulators, the generation of free carriers by exposure to light at infrared, visible, and ultraviolet frequencies can lead to a large increase in the dc conductivity. This photoconductive effect, which is not observed in metals or semimetals, can be enormous in low-conductivity semiconductors (an increase in the dc conductivity of CdS by eight orders of magnitude is observed). (See PHOTOCONDUCTIVITY.)

Because of the extreme sensitivity of semiconductors to impurities, temperature, pressure, light exposure, etc., these materials can be exploited in the fabrication of useful devices, such as the crystal diode, the transistor, integrated circuits, photodetectors, and light switches. Semiconductor devices do, in fact, date back to the infancy of the electronics industry .when crystal sets were used for radio reception. With the development of reliable and efficient vacuum tubes, the interest in semiconductor devices waned for several decades. Renewed interest in crystal rectifiers was stimulated by the needs of the radar technology which developed during the World War II period at the M.I.T. Radiation Laboratory and at other laboratories. During this period and the immediate post-war years, intensive activity developed in the fabrication of very pure semiconducting materials as well as in the basic understanding of the energy level schemes and of the charged carrier transport in silicon and germanium. This intense activity culminated in the discovery of the transistor by Shockley, Bardeen, and Brattain in 1947, for which they were awarded the Nobel Prize in Physics (1956). With the invention of the transistor, the electronics industry rapidly incorporated semiconductor devices, and since the mid-1960s, solid-state components have largely replaced vacuum tubes in many technological applications, from the transistor radio to components for high-speed electronic computers and microprocessors.

The most common semiconductors are the elemental semiconductors silicon and germanium. Other common elemental semiconductors are diamond (carbon), gray tin, tellurium, selenium, and boron. Closely related to the group IV semiconductors diamond, silicon, germanium, and gray tin are the III-V compounds formed from elements in the third and fifth columns of the periodic table, such as InSb, InAs, GaAs, GaP, and GaSb. Another important class of inorganic semiconductors is the II-VI compounds, formed from elements in the second and sixth columns of the periodic table such as CdS, CdSe, CdTe, ZnS, ZnSe, ZnTe, HgS, HgSe, and HgTe. Many other varieties of compound semiconductors are found, some of the more common varieties being the IV-IV compound SiC, the IV-VI compounds PbS, PbSe, PbTe, SnSe, SnTe, $Pb_xSn_{1-x}Te$, $Pb_xSn_{1-x}Se$, GeTe and the oxides MnO, NiO, SiO_2, SnO_2, GeO_2. Another class of semiconductors is the organic semiconductors, common examples being anthracene, tetracene, free radicals such as α α-diphenyl-β-picryl hydrazyl, biologically interesting materials such as the phthalocyanines, and various organic dyes.

Certain classes of semiconductors also possess other interesting properties. For example, the europium chalcogenides form a family of magnetic semiconductors, with EuO, EuS, and EuSe undergoing a ferromagnetic phase transition, while EuTe becomes antiferromagnetic below a Néel temperature of 9.8 K. Magnetic semiconductors are of particular interest because of the close coupling between the electrical and magnetic properties, such as electrical conductivity and the magnetic susceptibility. Some semiconductors have also been found to undergo a superconducting phase transition, as for example GeTe and SnTe for carrier concentrations of $\sim 10^{21}/cm^3$ and transition temperatures below 0.3K. More recently, semimagnetic semiconductors have been prepared by doping II-IV compounts with substitutional magnetic cations, e.g., Mn. These materials are of interest because of their intriguing magnetic and magneto-optical properties.

Although most of the common semiconductor devices utilize crystalline materials, semiconductors are also found in the liquid and amorphous states. Of special interest is the fact that the electrical conductivity of an amorphous semiconductor tends to be much lower than that of its crystalline counterpart; the opposite situation prevails for amorphous and crystalline metals. Common semiconductors like silicon and germanium have been prepared in the amorphous state, although the major emphasis in recent years has been given to the amorphous chalcogenide glasses containing tellurium and selenium along with a host of other elements; these glasses have been utilized for switching and memory devices.

Semiconductors tend to be hard and brittle and become ductile only at high temperatures. The hardness of semiconductors like diamond and SiC is utilized in the manufacture of industrial abrasives. Because of this hardness, high-quality optical surfaces on semiconductors can be achieved using lapping and etching techniques.

Because of the industrial demands for the fabrication of high-quality, high-purity semiconductors, a great deal of attention has been given to the development of a sophisticated semiconductor technology. To illustrate the present state of the art, it is now possible to grow single crystals of germanium with uncompensated impurity concentrations of $2 \times 10^{10}/cm^3$, which corresponds to less than one charged impurity in 10^{12} germanium atoms; this is probably the purest and most perfect crystalline material of any type that is now available.

A number of techniques have been employed in growing single crystals of semiconductors. To produce single crystals of large size, it is common to pull the crystal from the melt by the Czochralski technique. These large boules are then cut up into wafers and appropriate impurities are diffused into the material to produce the desired device structures.

For some specific applications, it is necessary to achieve greater control in the carrier concentration than is possible with diffusion techniques, as, for example, in the production of heterojunction devices. In such cases, liquid-phase epitaxial growth is employed, using as a substrate either the same semiconductor or another material of similar lattice constant and thermal expansion coefficient. For example, in the fabrication of sharp *p-n* junctions in GaP for light-emitting-diode applications, a wafer of GaP grown by the Czochralski technique is used as a substrate and epitaxial layers of *n*- and *p*-type GaP are then sequentially deposited by liquid-phase epitaxy.

To produce crystals of the highest purity and crystalline perfection, the method of chemical vapor deposition is often employed. For certain semiconductors, such as SiC and SnO_2, single crystals can be prepared only by chemical vapor deposition. Although the growth rate by this technique is slow, chemical vapor deposition has been utilized in the fabrication of specific microcircuits in order to exploit the flexibility that this technique provides for varying the type and concentration of dopants which are introduced. Furthermore, chemical vapor deposition can be utilized in the growth of certain mixed compound semiconductors. For example, $GaAs_{.6}P_{.4}$, which is a desirable light-emitting-diode material, is difficult to prepare by conventional means but can be prepared using as a substrate a wafer of GaP, which can be grown easily by the Czochralski technique: on this substrate a graded growth of $GaP_{1-x}As_x$ proceeds by chemical vapor deposition until the desired composition is achieved. (See CRYSTALLIZATION.)

To develop an understanding of the electrical conduction in semiconductors, it is necessary to examine the conduction mechanisms appropriate to these materials. The flow of electric current depends on the acceleration of charges by the externally applied electric field. Only those charges that resist collisions or scattering events are effective in the conduction process. Because of collisions, charged particles in a solid are not accelerated indefinitely by the applied field, but rather, after every scattering event, the velocity of a charged particle tends to be randomized. Thus, the acceleration process must start anew after each scattering event and charged particles achieve only a finite velocity along the electric field **E**, the average value of this velocity being denoted by $\mathbf{v}_D$, the drift velocity. The effectiveness of the charge transport by a particular charged particle is expressed by the mobility μ which is defined as $\mu = v_D/E$. The mobility of a particle with charge e and mass m can be related directly to the mean time between scattering events τ (also called the relaxation time) by the expression $\mu = e\tau/m$. The electrical conductivity σ depends on the mobility of the charged carriers as well as on their concentration n, and is simply written as $\sigma = ne\mu$ where e is the charge of the carriers. The advantage of expressing the conductivity in this form is the explicit separation into a factor n which is highly sensitive to external parameters such as temperature, pressure, optical excitation, irradiation, and into another factor μ which depends characteristically on scattering mechanisms and on the electronic structure of the semiconductor.

The classical theory for electronic conduction in solids was developed by Drude in 1900. This theory has since been reinterpreted to explain why all contributions to the conductivity are made by electrons which can be excited into unoccupied states (Pauli principle) and why electrons moving through a perfectly periodic lattice are not scattered (wave-particle duality in quantum mechanics). Because of the wavelike character of an electron in quantum mechanics, the electron is subject to diffraction by the periodic array, yielding diffraction maxima in certain crystalline directions and diffraction minima in other directions (See DIFFRACTION BY MATTER.) Although the periodic lattice does not scatter the electrons, it nevertheless modifies the mobility of the electrons through introduction of an effective mass m^* so that $\mu = e\tau/m^*$. A sensitive technique for the measurement of the effective mass and its anisotropy is the cyclotron resonance technique. (See CYCLOTRON RESONANCE.) In terms of the effective mass approximation, which provides a good description for the transport properties of many common semiconductors, the effect of a periodic potential on a conduction electron can be approximately taken into account by considering the electron to move with an effective mass m^* and in a medium with dielectric constant ϵ. For many of the common semiconductors, the effective mass of the carriers is characteristically lighter than the free electron mass m_0, though low-mobility semiconductors containing transition metal atoms (d-bands) tend to have carriers with large effective masses, often larger than m_0. (See SOLID-STATE PHYSICS.)

Although the perfectly periodic lattice does not scatter electrons, an electron in a solid does, in fact, experience scattering events through a variety of mechanisms. At room temperature and above, the principal scattering mechanism is due to lattice vibrations, which arise from the thermal motion of the lattice. Lattice vibrations cause a displacement of the atoms from their equilibrium positions, thereby destroying the perfect periodicity of the lattice.

The effectiveness of lattice vibrations (or phonons) in scattering electrons depends to some extent on the *type* of phonon which is involved in the scattering event. Phonons are classified as either *acoustic* (atoms on adjacent sites vibrate *in* phase) or *optical* (atoms on adjacent sites vibrate *out of* phase). Materials with only one atom/unit cell have only acoustic branches, three in number, while materials with multiple atoms/unit cell have, in addition to the three acoustic branches, three optical branches for every additional atom/unit cell. Every acoustic and optical phonon branch is further classified according to whether the lattice vibrations are along the direction of propagation of the lattice mode (longitudinal) or perpendicular to this direction (transverse). Phonons exhibit dispersion relations whereby the phonon frequency ω_q depends on the wave vector **q** for the lattice mode. Of particular interest are those ranges of **q** where ω_q varies slowly with q, thereby producing a high density of phonon states. Those phonons which have a high density of states (such as acoustic phonons near the Brillouin zone boundary, and the optical phonons) are most effective in scattering electrons. Since less thermal energy is required to excite an acoustic phonon than an optical phonon, it is the acoustic phonons which play a leading role in the scattering process at intermediate temperatures. At very low temperatures, the thermal energy is too small to excite significant numbers of phonons of any sort, so electron scattering is dominated by mechanisms involving crystalline imperfections such as lattice vacancies, interstitial atoms, impurity atoms, and crystal boundaries; these crystalline imperfection mechanisms do not contribute significantly to electron scattering at room temperature in solids which have a high degree of crystalline perfection and purity. On the other hand, for amorphous semiconductors, these imperfection scattering mechanisms are relatively important, even at temperatures where there are a significant number of thermally excited phonons. (See PHONONS.)

In considering the mobility of carriers in the vicinity of room temperature, it is clear that the increased probability of exciting phonons with increasing temperature T results in more frequent electron scattering events with increasing T, and consequently a decline in the electron mobility with increasing T. However, this decrease in mobility varies relatively slowly with T, having a power law dependence on T.

On the other hand, the temperature dependence of the carrier density in semiconductors is a strongly increasing function of temperature, which is closely related to the existence of a thermal activation energy E_t, or energy barrier which restricts potential carriers to bound, nonconducting states. This energy barrier can be overcome by the thermal or optical excitation of carriers, and the carrier density, n, excited at a given temperature is given by a Boltzmann factor $n = n_0 \exp(-E_t/2kT)$, where n_0 is the density of available bound carriers and k is Boltzmann's constant. With $E_t \sim 1$ eV for typical semiconductors, it is evident that $E_t >> 2kT$ at room temperature, so the carrier density is a rapidly increasing function of temperature. On the other hand, the carrier density of metals and semimetals is essentially independent of T, so the entire temperature dependence of the electrical conductivity is related to the mobility through the temperature-dependent scattering time τ.

The origin of the energy barrier for carrier generation is directly connected with the energy levels for electrons in a solid. Considering electrons in a solid from a tight-binding point of view, the discrete energy levels of the free atom broaden in the solid to form energy bands. For materials which are well described by the tight-binding approximation, the width of the energy bands is sufficiently small so that an energy gap between the energy bands is formed; in the forbidden energy gap there are no bound states. Of particular importance to the conduction properties of a solid is the fact that *all* of the available states in each band would be filled if each atom were to contribute exactly two electrons, thereby causing every solid with an odd number of electrons per atom to be metallic, while solids with an even number of electrons per atom would be insulating or semiconducting. The occurrence of energy bandgaps is also a consequence of the weak binding approximation, whereby the periodic potential itself is responsible for creating bandgaps through the mixing of states separated by a reciprocal lattice vector. (See ENERGY LEVELS.)

The solution of Schrödinger's equation to obtain the electronic energy levels of a semiconductor can be carried out in an approximate way by exploiting the translational symmetry of the perfectly periodic lattice. Through the translational symmetry, phase factors of the form $e^{i\mathbf{k}\cdot\mathbf{R}_n}$ are introduced as eigenvalues of the operator for translation by a lattice vector $\mathbf{R}_n$, where the wave vector $\mathbf{k}$ assumes the role of the quantum number labeling the various translational states. Since the Hamiltonian for an electron in a periodic solid is invariant under translations by a lattice vector, the energy eigenvalues of Schrödinger's equation are also labeled by the quantum number $\mathbf{k}$. In fact, a knowledge of the dispersion relation for electrons in a solid $E(\mathbf{k})$ uniquely determines the conduction properties of the solid; for this reason, a great deal of attention has been given to the detailed study of the energy band structure of semiconductors.

Semiconductors are classified according to whether they are direct- or indirect-gap semiconductors. For a direct-gap semiconductor, the maximum energy of the occupied valence band occurs at the same value of $\mathbf{k}$ as the minimum energy of the unoccupied conduction band. Typical direct-gap semiconductors are InSb and GaAs; these materials have their energy extrema at $k = 0$. On the other hand, for indirect-gap semiconductors, the conduction band minima and the valence band maxima occur at different wave vectors. Typical indirect gap semiconductors are silicon and germanium. Both of these semiconductors have valence band maxima at $k = 0$, but the conduction band minima for germanium are located at the Brillouin zone boundary along a (111) direction and for silicon are located along a (100) direction about 85 per cent of the distance out to the zone boundary.

Whereas the minimum energy gap is the threshold for thermal excitation in the case of both direct- and indirect-gap semiconductors, the response to optical excitation is different for the two types of semiconductors. Optical transitions involve only a very small change in k because the wavelength of light is very large compared with atomic spacings in a solid. Since optical transitions are direct (essentially k-conserving), it is necessary to either absorb or emit a phonon with wave vector $(\mathbf{k}_c - \mathbf{k}_v)$ to excite carriers optically in an indirect-gap semiconductor, where $\mathbf{k}_c$ and $\mathbf{k}_v$ correspond to the wave vectors for the conduction and valence band extrema, respectively. Measurement of the threshold for phonon-assisted absorption provided one of the earliest determinations of the phonon frequencies in a semiconductor. More accurate measurements of phonon frequencies in semiductors are now made using the techniques of phonon-assisted tunneling, Raman scattering, and inelastic neutron scattering. (See TUNNELING, RAMAN EFFECT.)

The different response of the optical carrier excitation process can be utilized in the identification of an energy gap as direct or indirect. For a direct-gap semiconductor, the onset of optically induced interband transitions across an energy gap E_g is marked by a photon energy dependence of the optical absorption coefficient α, which is $\sim(\hbar\omega - E_g)^{1/2}$. On the other hand, the threshold for interband transitions in an indirect-gap semiconductor has a characteristic photon energy dependence $\alpha \sim (\hbar\omega - E_t \pm \hbar\omega_q)^2$ in which E_t represents the indirect energy gap; for indirect transitions, the threshold occurs at a lower photon energy when a phonon of energy $\hbar\omega_q$ is absorbed than when it is emitted. Furthermore, the magnitude of the absorption coefficient for a direct-gap semiconductor is as much as two or three orders of magnitude larger than for an indirect-gap semiconductor at the threshold for the optical excitation of carriers. In the optical excitation process, electrons are introduced into the conduction band and empty states (holes) are left behind in the valence band. Both electrons and holes contribute to the electrical conductivity. Furthermore, the electron is attracted to the hole it left behind often forming a bound exciton state.

The actual calculation for the energy bands of solids is complicated by the band degeneracies which occur at high symmetry points in the Brillouin zone because of the rotational point symmetry of the crystal structure. These band degeneracies are evident in the $E(\mathbf{k})$ diagram for germanium shown in Fig. 1. Of particular interest is the band degeneracy of the valence band at $\mathbf{k} = 0$, which is typical of semiconductors which crystallize in the diamond and zincblende crystal structures. Further complications arise because these semiconductors contain two atoms per unit cell; as a result, the covalently bonded electrons form filled bonding states in the valence band, leaving the higher-lying antibonding states in the conduction band unoccupied. The basic difference between the energy band structure for a semiconductor as contrasted with a semimetal or metal is the existence of a forbidden energy gap for all **k** values. In a semimetal or metal, the maximum energy for a valence band state is larger than the minimum energy for a conduction band state, so band overlaps can occur. In a semimetal, the number of holes is equal to the number of electrons, but this need not be the case in a metal.

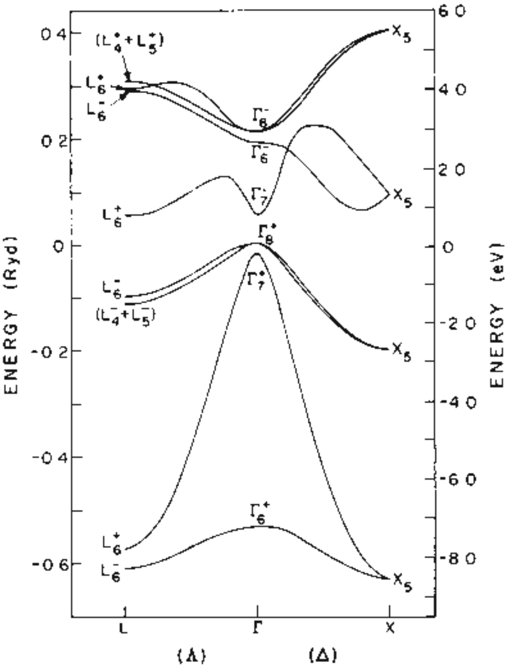

FIG. 1. Electronic band structure for Ge. The zero of energy is taken at the highest point in the valence band (Γ_8^+). The lowest level in the conduction band occurs at the Brillouin zone boundary (L_6^+).

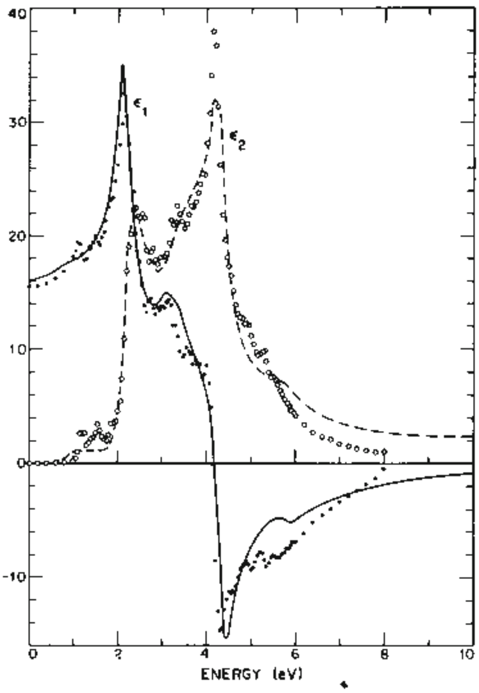

FIG. 2. The frequency-dependent complex dielectric constant ($\epsilon_1 + i\epsilon_2$). The curves are experimental results and the points represent a numerical calculation based on the energy bands shown in Fig. 1.

The figure of merit for a given energy band calculation can be determined by calculation of the frequency-dependent dielectric constant which these bands imply. The good agreement shown in Fig. 2 between the calculated (points) and experimental (curves) dielectric constants indicates confidence in the major features of the energy band structure given in Fig. 1.

It is of interest to observe that the crystal structure affects the electrical properties of a material, insofar as solids formed from a particular atomic species may be conducting or semiconducting, depending on the crystal structure. Trigonally bonded carbon forms graphite, which is highly conducting in the layer planes, while tetrahedrally bonded carbon forms the semiconductor, diamond.

The electronic energy levels of a semiconductor may be examined with profit from the chemical-bonding point of view. The elemental semiconductors, silicon, germanium, gray tin, and diamond, all crystallize in the diamond structure, in which identical atoms are located at the center and corners of a regular tetrahedron. Each group IV atom contains four valence electrons, thereby occupying exactly eight of the valence states having about equal energy. Through covalent bonding, each atom achieves a filled valence shell by sharing one electron with each of its four neighboring atoms at the corners of the tetrahedron. This strong covalent bonding is responsible for the mechanical hardness of these semiconductors. In diamond, the valence electrons are in the $n = 2$ shell, in silicon in the $n = 3$ shell, in germanium in the $n = 4$ shell, in gray tin in the $n = 5$ shell. Less energy is required to break a bond as we move down the periodic table from diamond to gray tin. The breaking of bonds freeing carriers for electronic conduction can be conveniently accomplished by thermal or optical excitation. The semiconducting properties of some amorphous materials can be most easily understood in terms of chemical bonding.

The introduction of impurities from group V (or group III) of the periodic table into the diamond structure leads to carrier generation for electrical conduction. For example, antimony has 5 valence electrons, which is one more than is necessary to satisfy the covalent bonding requirements of the diamond structure. Thus, only a small amount of energy is necessary for the liberation of this weakly bound electron from the positively charged Sb^+ ion. Impurities which contribute electrons to the conduction process are called donors and usually result in an excess of negatively charged carriers, thereby yielding an n-type semiconductor. The presence of impurities destroys the perfect periodicity of the lattice and produces energy states within the energy gap between the normally occupied valence band and the normally unoccupied conduction band. The weakly bound donor electrons occupy states close to the conduction band minima and can be treated with considerable success within the effective mass approximation by a hydrogenic model for the Coulombic attraction of the donor electron to the positively charged donor ion. In this approximation, the energy levels of the donor states are given by the bound hydrogenic states $E_n = - m^*e^4/2\hbar^2n^2\epsilon^2$, where $n = 1,2, \cdots, \epsilon$ is the static dielectric constant of the semiconductor, and the donor levels are measured relative to the lowest-lying conduction band states. Ionization of this bound donor to the conduction band by thermal or optical excitation results in electronic conduction. Since the effective masses for such donors tends to be small (group V donors in germanium have $m^* \simeq 0.1m_0$) and the dielectric constant large (in germanium $\epsilon \simeq 16$), the hydrogenic donor levels are shallow (within $\sim 6 \times 10^{-3}$ eV from the conduction band minima). Furthermore, the small effective masses and large dielectric constant result in a large effective Bohr radius $r_B = \hbar^2\epsilon/m^*e^2$, so the donor electrons are not localized within the unit cell of the donor ion, but rather extend over many unit cells.

Introduction of group III impurities, such as indium into silicon, results in a p-type semiconductor since the group III impurities have a deficiency of one electron for the fulfillment of the bonding requirement. Since the covalent bonding in these semiconductors is strong, an electron deficiency at an impurity site results in the acquisition of an electron from a covalent bond elsewhere in the material. The covalent bond with an electron deficiency represents an effective positive charge (or acceptor state) which can hop from one covalent bond to another, thereby representing the flow of positive charge, which is characteristic of p-type semiconductors. Acceptor states, like donor states, tend to lie within the forbidden semiconducting energy gap; and weakly bound acceptors characteristically have energy levels which lie just slightly above the valence band maximum energy.

Since impurity atoms in typical semiconducting crystals tend to be relatively isolated from each other, the degree of ionization of the impurity atoms and hence the concentration of n- and p-type carriers can be determined from the law of mass action:

$$np = 4\left(\frac{kT}{2\pi\hbar^2}\right)^3 (m_e m_h)^{3/2}\ e^{-E_t/kT}$$

where n and p are the concentration of electrons and holes and m_e and m_h are the corresponding effective masses. This relation is generally valid whether the carriers are produced exclusively by thermal excitation (an *intrinsic* semiconductor) or by the introduction of impurities (an *extrinsic* semiconductor). If the semiconductor is intrinsic, then $n = p$ and the Fermi level or chemical potential is determined by

$$E_F = \tfrac{1}{2} E_t + \tfrac{3}{4} kT \ln (m_h/m_e).$$

In these relations, the appropriate energy gap is the thermal energy gap E_t, which is smaller than the direct-band gap E_g, for indirect-gap semiconductors such as silicon and germanium. For extrinsic semiconductors, the Fermi level may be pinned to an impurity band of donors or acceptors within the band gap or may even lie in the valence or conduction bands, in which case the semiconductor is called *degenerate*.

In practice most semiconducting crystals contain measurable concentrations of impurities, whether or not these impurities are introduced intentionally. At high temperatures, the thermally excited carriers tend to dominate the conduction process and the semiconductor behaves as an intrinsic semiconductor; however, at low temperatures the impurity conduction mechanism is dominant and the semiconductor behaves as an extrinsic semiconductor. The passage between intrinsic and extrinsic

behavior is illustrated in the plot of ln σ vs reciprocal temperature shown in Fig. 3 for germanium. At low temperatures, conduction proceeds via impurity states, often employing a thermally activated hopping mechanism.

To separate the temperature dependence of the mobility from the temperature dependence of the carrier concentration, studies of the Hall mobility are carried out. (See HALL EFFECT.) If conduction proceeds primarily by one type of carrier, the Hall mobility μ_H is related to the conductivity by the Hall constant R_H, which is determined by Hall effect measurements, such that $\mu_H = c|R_H|\sigma$ where c is the speed of light. On the other hand, if two carriers participate in the conduction process, then the Hall constant is related to

$$R_H = \frac{1}{ec}\frac{(p\mu_h{}^2 - n\mu_e{}^2)}{(p\mu_h + n\mu_e)^2}$$

and the conductivity is given by

$$\sigma = e(n\mu_e + p\mu_h).$$

By studying the temperature dependence of the Hall constant and of the electrical conductivity, the carrier densities and mobilities of the two types of carriers can be determined. A summary of the relevant parameters for some of the more common semiconductors is given in Table 1.

SEMICONDUCTOR DEVICES

1. **Introduction** Since the invention of the bipolar transistor in 1947, the transistor and related semiconductor devices have had an unprecedented impact on our society in general and on the electronic industry in particular.[1] Semiconductor devices are compact, reliable, and inexpensive. They can be operated at ultrahigh speed with low power consumption. They lend themselves to integration into complex but readily manufacturable microelectronic circuits. The semiconductor devices are key elements, for example, in high-speed computers, in space vehicles, in communication and transportation systems, in medical equipments, and in industrial control systems.

Semiconductor devices[2] are intimately related to the energy band structures and transport properties of semiconductors, and can be affected by electric field, magnetic field, temperature, pressure, and radiation. We shall be concerned mainly with devices associated with the electric effect in which the electrical conductivity of a semiconductor device is modulated by external electrical signals. We shall divide the semiconductor devices into four groups and consider a few important devices in each group. The first group, discussed in Section 2, is bipolar devices, in which both electrons and holes are involved in the transport process. Section 3 considers the unipolar devices in which only one type of carriers predominantly participate in the conduction mechanism. Section 4 considers some special microwave devices. Most of the bipolar and unipolar devices considered in Sections 2 and 3 can be operated in the microwave region (1 to 100 GHz with corresponding wavelength from 30 to 0.3 cm). In this section we shall consider two microwave devices which are based on novel transport phenomena. Section 5 deals with photonic devices in which the basic particle of light—the photon—plays a major role.

2. **Bipolar Devices** *Bipolar Transistor*. A schematic diagram of an *n-p-n* bipolar transistor is shown in Fig. 1(a). The device consists of two closely coupled *p-n* junctions. The energy band diagram under normal operating condition is shown in Fig. 1(b). The emitter-base junction is forward-biased. The emitter current consists of two components—the electron component injected from the emitter into the base, and the hole component injected from the base into the emitter region. The collector-base junction is reverse-biased. The collector current also consists of the electron and hole components. The current-voltage characteristics for common-emitter configuration is shown in Fig. 1(c). For a given base current I_B the collector current I_C increases initially with the biasing voltage V_{CE}, then reaches a saturated value. For a given V_{CE} a small increase in the base current can result in a large increase of the collector current. The bipolar transistor is one of the most important devices for switching, power, and microwave applications. The device is extensively used in integrated circuits, and is capable of generating over 1 W power at 10 GHz (10^{10} Hz).

Thyristor. A schematic diagram of the thyristor is shown in Fig. 2(a). The four-layer *p-n-p-n* structure is intimately related to the bipolar transistor in which both electrons and holes are involved in the transport processes. The energy band diagrams for the forward "off" condition and the forward "on" condition are shown in Fig. 2(b) and (c), respectively. In the "off" condition most of the voltage drop is across the center junction, while in the "on condition all three junctions are forward-biased. The current-voltage characteristics of the forward and the reverse regions are shown in Fig. 2(d) for three different gate currents.[3] The

"forward" characteristic can be explained using the method of two-transistor analog. As the voltage increases from zero, the current will increase. This in turn will cause the current gains of both the *p-n-p* and *n-p-n* transistors to increase. Because of the regenerative nature of these processes, switching eventually occurs and the device is in its "on" state. As the gate current increases, one can reduce the threshold voltage at which switching occurs. Because of its two stable states (on and off) and the low power dissipation in these two states, the thyristor has found unique usefulness in applications ranging from speed control in home appliances to switching and power inversion in high-voltage transmission lines. Thyristors are now available with current ratings from a few milliamperes to over 5,000 A and voltage ratings extending above 10,000 V.

3. Unipolar Devices *Metal-Semiconductor (Schottky) Diode*. The metal-semiconductor diode, Fig. 3(a), is one of the earliest semiconductor devices (it was first investigated in 1874). In 1938, Schottky suggested that the potential barrier could arise from stable charges in the semiconductor. The model is known as the *Schottky barrier*, and the energy band diagram at thermal equilibrium is shown in Fig. 3(b). When a forward bias is applied (i.e., the metal electrode is positive with respect to the *n*-type semiconductor) electrons will be injected thermionically from the semiconductor into the metal, as shown in Fig. 3(c). Under reverse bias, Fig. 3(d), the current is small and is limited by the barrier height $q\phi_B$. The general *I-V* characteristic of a Schottky diode is very similar to that of a *p-n* junction. The main difference is that in usual Schottky diodes the current is due to majority carriers (e.g., electrons in an *n*-type semiconductor) so that the storage time associated with minority carriers is neglibibly small. This property makes Schottky diodes useful as microwave mixer and detector diodes as well as high-speed switching devices.

MESFET. The metal-semiconductor field-effect transistor (MESFET) is a device based on an entirely different physical principle from the bipolar transistor. While the bipolar transistor operates through the transport of injected carriers across the base, the MESFET is basically a voltage-controlled resistor, and its resistance can be varied by varying the width of the depletion layers extending into the channel. See Fig. 4(a). The device consists of a conductive channel provided with two ohmic contacts, one acting as a cathode (source) and the other as the anode (drain). The third electrode, the *gate*, forms a rectifying Schottky barrier with the channel. The gate voltage controls the width of the depletion region, and therefore varies the conductance of the channel. A typical *I-V* characteristic is shown in Fig. 4(b). We note that for a given V_G, the current increases initially with the drain voltage and then reaches a saturated value.

The GaAs MESFET is one of the most important power microwave devices. Power out-

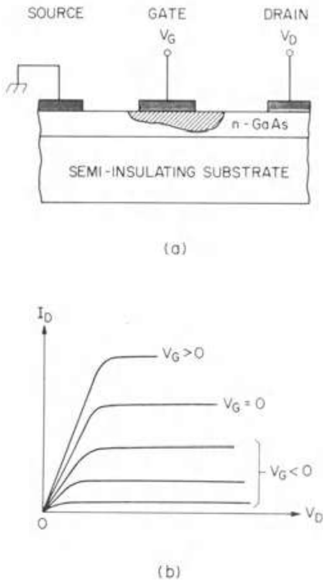

FIG. 4. (a) MESFET. (b) Typical current-voltage characteristics.

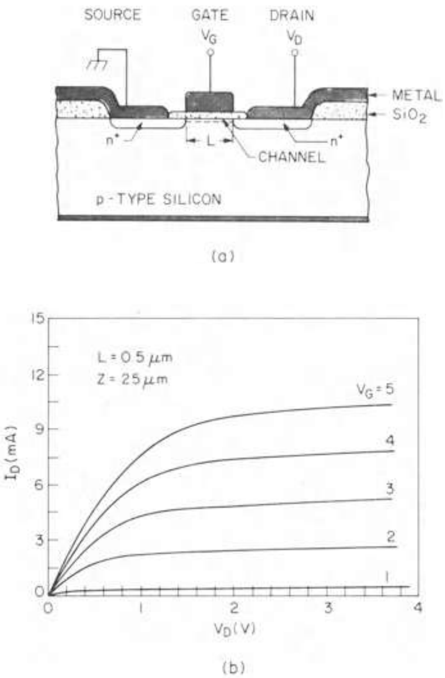

FIG. 5. (a) MOSFET. (b) Measured current-voltage characteristics for a MOSFET with 0.5-μm channel length. The channel width is 25 μm.

put up to 10 W at 10 GHz has been obtained with a noise figure less than 1 dB. The operation of a junction field-effect transistor (JFET) is identical to that of a MESFET. In the JFET, however, a *p-n* junction instead of a Schottky barrier is used for the gate electrode. Both devices offer many attractive features for applications in switching, microwave amplifications, and integrated circuits.

MOSFET. The basic structure of a metal-oxide-semiconductor field-effect transistor (MOSFET) is shown in Fig. 5(a). The device consists of a *p*-type semiconductor substrate into which two n^+ regions, the *source* and the *drain*, are formed. The metal contact on the insulator is called the *gate electrode*. When there is no voltage applied to the gate the source-to-drain electrodes correspond to two *p-n* junctions connected back to back. Therefore there is practically no current flowing from source to drain. When a sufficiently large negative voltage is applied to the gate such that a surface inversion layer is formed between the two n^+ regions, the source and the drain are connected by a conducting-surface *n* channel through which a large current can flow. The conductance of this channel can be modulated by varying the gate voltage. One may readily extend the discussion to a *p*-channel device by exchanging *p* for *n* and reversing the polarity of the voltage. A current-voltage characteristic of a MOSFET with 0.5 μm channel length is shown in Fig. 5(b). Note that as the gate voltage increases, the drain current increases accordingly; and the general behavior is quite similar to that of a MESFET.

MOSFET is the most important device for very-large-scale integrated (VLSI) circuits such as microprocessors and semiconductor memories. Figure 6(a) shows the reduction of the minimum device dimension since the beginning of the integrated circuit era in 1959. Figure 6(a) also shows that the minimum dimension will shrink continuously; the 1-μm barrier for commercial devices will be overcome by 1990. The reduction of device dimensions is driven by the requirement that integrated circuits of high complexity be fabricated.[4] The number of components per integrated-circuit chip has grown exponentially since 1959 [Fig. 6(b)]. The rate of growth is expected to slow down because of a lack of product definition and design. However, a complexity of 1 million or more devices per chip will be available before 1990 using 1-μm or submicron device geometries.

Charge-Coupled Device (CCD). In CCD, minority carriers are transferred from under one electrode to a closely adjacent electrode on the same semiconductor substrate when appropriate voltages are applied to the electrodes. Figure 7(a) shows a CCD in a situation wherein a sufficiently large negative bias has been applied to all the electrodes to produce surface depletion, and the center electrode has a slightly larger applied bias such that the center MOS structure is under greater depletion. If minor-

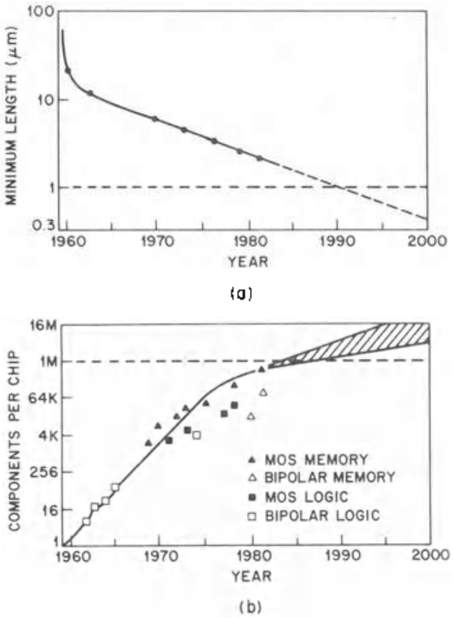

FIG. 6. (a) Minimum device dimension in an integrated circuit as a function of the year for commercial devices. (b) Complexity of integrated circuits as a function of the year.

ity carriers are introduced, they will collect at the surface in the potential minimum defined by the excess potential on the central electrode. If now the potential of the right-hand electrode is increased to exceed that of the central electrode, one obtains the potential distribution as shown in Fig. 7(b). In this case, the minority carriers will be transferred from the central to the right-hand electrode. Subsequently, the potential on the electrodes can be readjusted so that the quiescent storage site is located at the right-hand electrode. By continuing the above process, one can successively transfer the carriers along a linear array. Using this basic mechanism, CCD can perform a wide range of electronic functions including image sensing and signal processing.

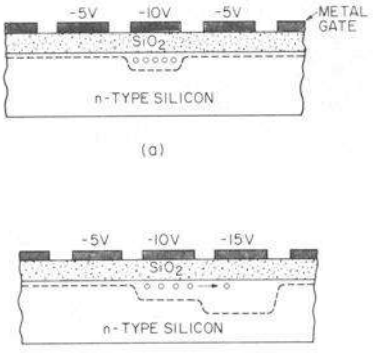

FIG. 7. (a) Charge-coupled device (CCD) with central electrode under depletion condition. (b) CCD under charge transfer operation.

4. Special Microwave Devices *IMPATT Diode.* IMPATT stands for *im*pact ionization *a*valanche *t*ransit *t*ime. IMPATT diodes employ impact-ionization and transit-time properties of semiconductor structures to produce negative resistance at microwave frequencies. A basic IMPATT diode is a *p-n* junction as shown in Fig. 8(a), where it is biased into reverse avalanche breakdown. There is a high-field avalanche region at the p^+n junction where electron-hole pairs are generated. The generated holes quickly enter the p^+ region; the generated electrons are injected into the drift region, Fig. 8(b). As the electric field changes periodically with time around an average value [Fig. 8(c)], the impact ionization rate per carrier follows the field change nearly instantaneously. However, the carrier density does not follow the field change in unison, because carrier generation depends also on the number already present. Even after the field has passed its maximum value, the carrier density keeps increasing because the carrier generation rate is still above the average value. The maximum carrier density is reached approximately when the field has decreased from the peak to the average value. Thus the ac variation of the carrier density lags the ionization rate by about 90°. The above situation is illustrated as the "injected" current in Fig. 8(d). The peak value of ac field (or volt-

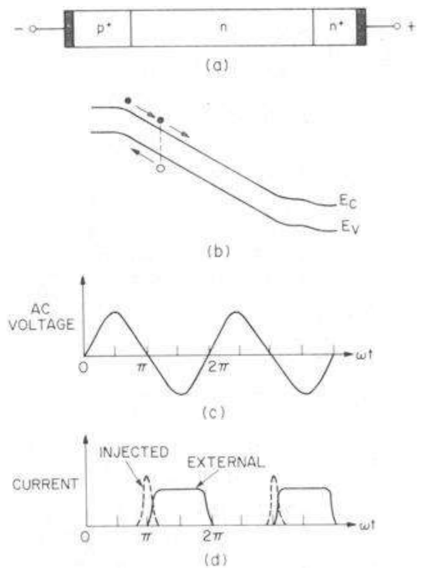

FIG. 8. (a) IMPATT diode. (b) Band diagram under avalanche condition. (c) AC voltage. (d) Injected and external current waveforms.

age) occurs at $\theta = \pi/2$, but the peak of the injected carrier density occurs at $\theta = \pi$. The injected electrons then enter the drift region, which they traverse at the saturation velocity. The induced external current is also shown in Fig. 8(d). From comparison of the ac field and the external current it is clear that the diode exhibits a negative resistance at its terminals.

IMPATT diodes are among the most powerful solid-state sources of microwave power. Up to 10 W at 10 GHz and 100 mW at 200 GHz have been obtained.

Transferred-Electron Device (TED). In GaAs, InP, and some other compound semiconductors, the energy band consists of a high-mobility low-energy valley and an adjacent low-mobility high-energy valley [inset of Fig. 9(a)]. When an electric field is applied, the electrons can gain energy and be transferred from the lower valley to the upper valley. In doing so, because of the reduction of mobility, the current is reduced as the field increases giving rise to a differential negative resistance as shown in Fig. 9(a).

The TED can be operated in various modes. One of the modes, called the ***transit-time dipole-layer mode***, is shown in Fig. 9(b). When the diode is biased above the threshold E_T, periodic space-charge dipolar layers are launched at the negative terminal and propagate through the active region. A series of current pulses results, each spaced in time by the length of the active layer divided by the drift velocity. For a 10 μm sample, the frequency of oscillation is about 10 GHz. About 3 W power output at 10 GHz and over 50 mW at 100 GHz have been obtained.

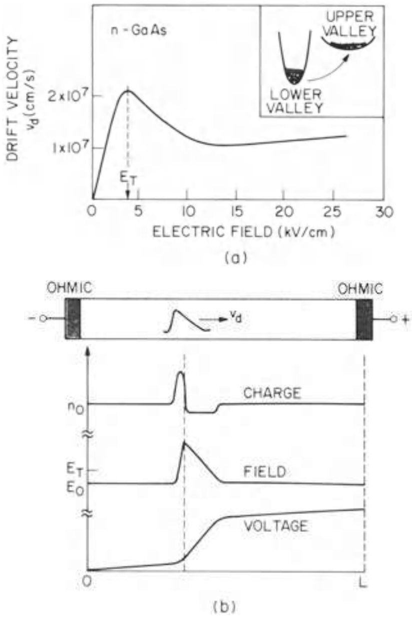

FIG. 9. (a) Drift velocity versus electric field in GaAs; insert shows electron transfer from lower valley to upper valley in the conduction band. (b) Schematic diagram of a TED, charge distributions (dipole layer), field profile, and voltage variation along the active device length.

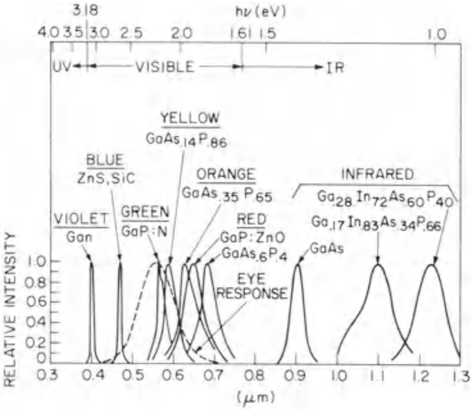

FIG. 10. Relative intensity versus wavelength of various LEDs.

In addition to the above devices, there are many other two-terminal microwave devices including tunnel diode and BARITT diode.

5. Photonic Devices *Light Emitter Diode (LED).* The LED belongs to the electroluminescent device family. Electroluminescence is the generation of light by an electrical current passed through a material under an applied electric field. The basic operation of a LED is a *p-n* junction under forward bias; holes and electrons are diffused across the depletion region where radiative recombinations take place. Figure 10 shows the relative intensity of optical radiation versus wavelength for various LEDs from ultraviolet to infrared. The visible LEDs are useful as indication lamps and for alphanumeric displays. The infrared LEDs are useful for opto-isolators and are potentially very important as sources in optical-fiber communication systems.

Laser. The *p-n* junction laser (*l*ight *a*mplification by *s*timulated *e*mission of *r*adiation) also belongs to the electroluminescent device family. The laser light has spatial and temporal coherence, and is nearly perfectly monochromatic (0.1 to 1 Å) as compared to a much broader spectrum (100 to 500 Å) in a LED. Using *double heterojunction structure*[5] as shown in Fig. 11(a) and (b), the laser can be operated continuously at or above room temperature. (A heterojunction is a junction formed between two semiconductors having different energy band gaps.) The heterostructure can confine the carriers in the active region (the central *p*-GaAs layer) by the potential barriers, and can confine the light intensity within the active region by

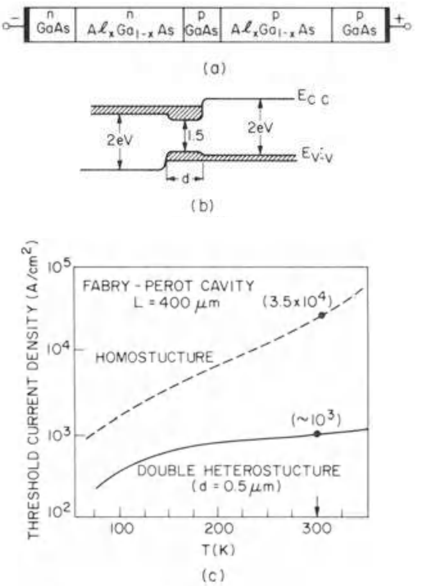

FIG. 11. (a) Double heterostructure laser. (b) Band diagrams under forward bias. (c) Comparison of threshold current density for homostructure (ordinary *p-n* junction) and double heterostructure laser.

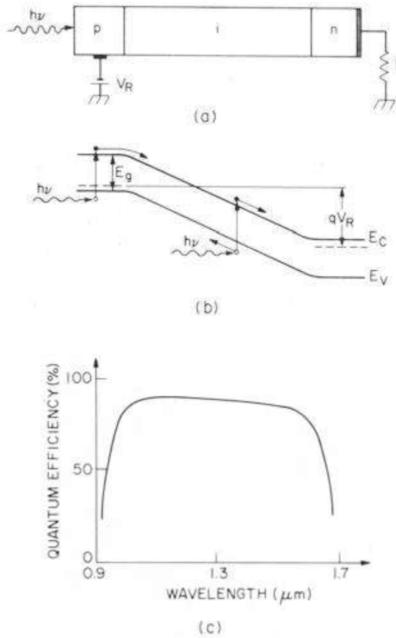

FIG. 12. (a) *p-i-n* photodetector. (b) Band diagram under reverse-biased operating condition. (c) Quantum efficiency versus wavelength for a *p-i-n* photodetector.

the sudden reduction of the refractive index outside the active region. These confinements will enhance the population inversion and provide significant quantum amplification in the active region; therefore, the threshold current density (i.e., the minimum current density to initiate lasing) is considerably lower than that required for a homostructure, as shown in Fig. 11(c). The wavelength of coherent radiation has been extended from the near ultraviolet into the visible and then out to the far-infrared region (0.3 to 30 μm). The diode laser is considered one of the most important light sources for optical-fiber communication systems. It is also important for applications in many areas of basic research and technology, such as high-resolution gas spectroscopy and atmospheric pollution monitoring.

Photodetector. Photodetectors are semiconductor devices that can detect optical signals through electronic processes. They convert the optical variations into electrical variations that are subsequently amplified and further processed. One of the most important photodetectors for optical-fiber communication systems is the *p-i-n* diode. Figure 12(a) shows a schematic representation of a *p-i-n* diode. The corresponding energy-band diagram under reverse-bias condition is shown in Fig. 12(b). Light absorption in the semiconductor ($h\nu > E_g$) produces electron-hole pairs. Pairs produced in the depletion region or within a diffusion length of it will be separated by the electric field, leading to current flow in the external circuit as carriers drift across the depletion layer. A typical plot of quantum efficiency versus wavelength for a ternary compound ($Ga_xIn_{1-x}As$) *p-i-n* photodetector is shown in Fig. 12(c). The quantum efficiency is the number of electron-hole pairs generated per incident photon. The quantum efficiency for this photodetector is almost constant over the spectral range from 1.0 to 1.5 μm. In addition to the *p-i-n* diode, there are many other photodetectors including photoconductors, Schottky photodiodes, avalanche photodiodes, and phototransistors.

Solar Cell. Solar cells at present furnish the most important long-duration power supply for satellites and space vehicles. As worldwide energy demand increases, conventional energy resources, such as fossile fuels, will be exhausted in the not-too-distant future. Therefore, we must develop and use alternative energy resources, especially our only long-term natural resource, the sun. The solar cell is considered a major candidate for obtaining energy from the sun, because it can convert sunlight directly to electricity with high conversion efficiency, can provide nearly permanent power at low operating cost, and is virtually free from pollution.[6] A representative solar cell is diagrammed in Fig. 13(a). It consists of a shallow *p-n* junction formed on the surface, a front ohmic contact stripe and figures, a back ohmic contact that covers the entire back surface, and an antireflection coating on the front surface. The current-voltage characteristics under solar ra-

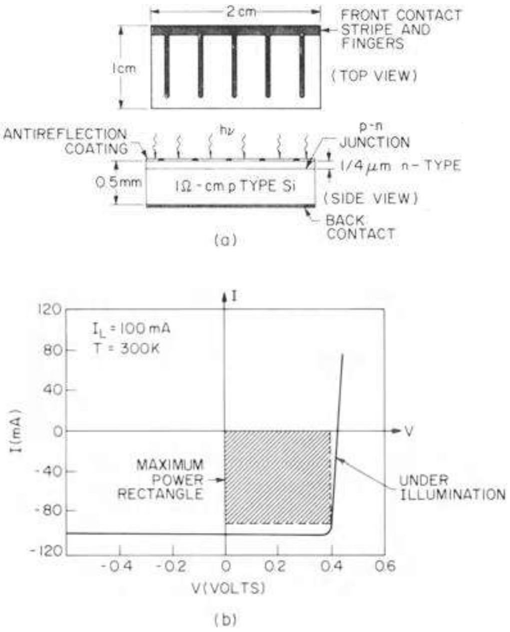

FIG. 13. (a) Schematic representation of the silicon *p-n* junction solar cell. (b) Current-voltage characteristics of a solar cell under illuminaton.

diation are shown in Fig. 13(b). The curve passes through the fourth quadrant and, therefore, power can be extracted from the device. Recently, development of low-cost thin-film solar cells, flat-panel solar cells, and concentrator systems has quickened. Typical solar-to-electrical conversion efficiencies are 5–10% for thin-film devices, 10–15% for flat-panel cells and 20–30% for concentrator systems.

6. Summary We have briefly described some of the major semiconductor devices. We expect that the semiconductor-device development in the 1980s will be vigorous, with continued breakthroughs in device concept and performance.

SERVOMECHANISMS

Definition–A servomechanism is a feedback control system in which the difference between a reference input $r(t)$ and some function of a controlled output $c(t)$ is used to supply an actuating signal $e(t)$ to a controller and a controlled system. The actuating signal is amplified in the controller and is used to vary the output of the controlled system in such a manner that the difference between input and output is reduced to zero. A simple block diagram representation of a servomechanism is shown in Fig. 1.

The controlled system may consist of a mechanical structure, a chemical process, a heating system, an electric supply or any system in which a variable can be measured and controlled. The reference input may be a reference level, a sinusoidal or a polynomial function of time, or a discrete, sampled, or programmed set of values. The difference detector is usually matched to the form of the output and input signals. The controller contains signal amplifiers and may also contain power amplifiers which furnish power to an actuating device from an external power source. Actuating devices vary with the controlled system. Actuating devices to position or move mechanical structures may be electromechanical, hydraulic, or pneumatic.

The controller is designed to control a system with known dynamic properties to respond to a specified type of input signal with a specified steady-state and transient performance. The controller may be digital or analog and may be designed for nonlinear or linear operation or may have a linear operating region of actuating signals and a nonlinear saturation zone. Nonlinear systems can be designed with better performance characteristics than linear systems, but linear systems are easier to analyze. A simple linear system with unity feedback will be described.

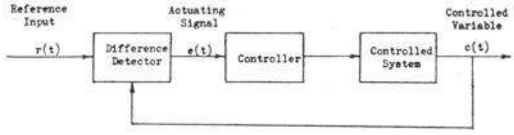

FIG. 1. Block diagram of a servomechanism with unity feedback.

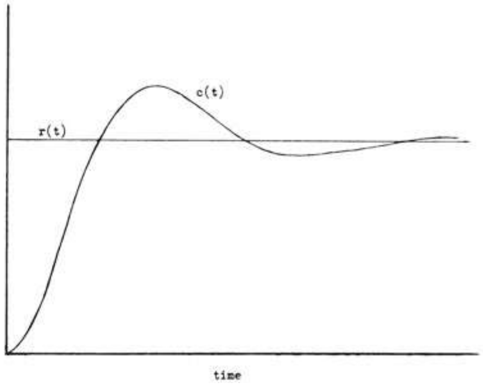

FIG. 2. Transient response of a type I servomechanism to a step input.

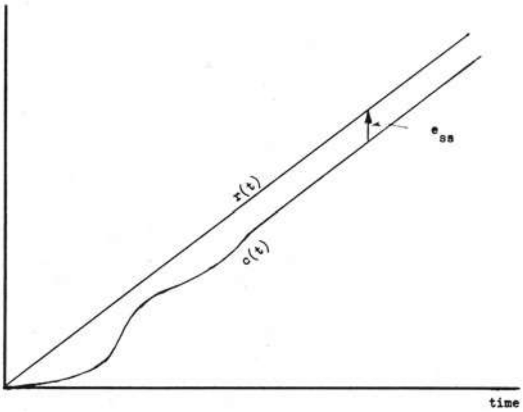

FIG. 3. Response of type I servomechanism to a ramp input.

Linear servomechanisms are analyzed in terms of their transfer function, which can be obtained by taking the Laplace transform of the differential equations of the open loop system with zero initial energy storage. The transfer function is the ratio of the Laplace transform of the output to the Laplace transform of the actuating signal.

$$G(s) = \frac{C(s)}{E(s)}.$$

In most cases, $G(s)$ is or can be approximated as a rational algebraic function and can be expressed in the following form.

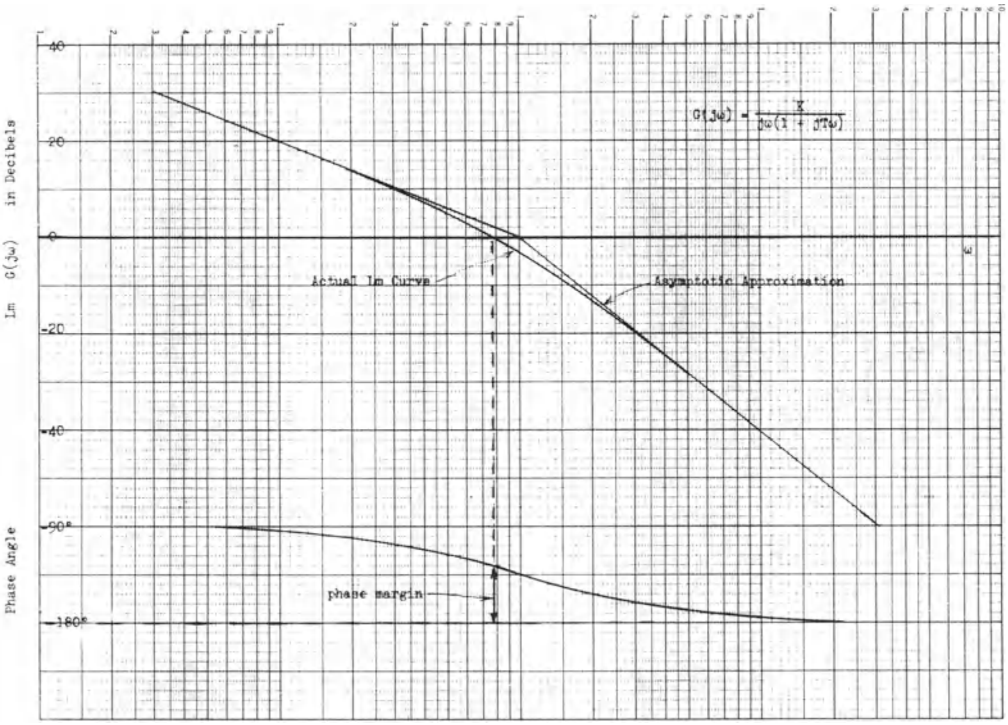

FIG. 4. Bode plots of simple type I servomechanism.

$$G(s)=\frac{K_n(T_1s+1)(T_2s+1)\cdots\left[\dfrac{s^2}{\omega_1{}^2}+\dfrac{2\zeta_1}{\omega_1}s+1\right]\left[\dfrac{s^2}{\omega_2{}^2}+\dfrac{2\zeta_2}{\omega_2}s+1\right]\cdots}{s^n(T_as+1)(T_bs+1)\cdots\left[\dfrac{s^2}{\omega_a{}^2}+\dfrac{2\zeta_a}{\omega_a}s+1\right]\left[\dfrac{s^2}{\omega_b{}^2}+\dfrac{2\zeta_b}{\omega_b}s+1\right]\cdots}$$

The value of the exponent n is used to classify the type of servomechanism. For $n = 0$ (a type 0 servomechanism), the system is often called a regulator or governor, rather than a servomechanism, the distinction being that a servomechanism must contain integration in its transfer function ($n \geqq 1$) in order to be able to reduce its steady-state error for a position input to zero.

The control ratio is the closed-loop counterpart of the transfer function.

$$\frac{C(s)}{R(s)}=\frac{G(s)}{1+G(s)}.$$

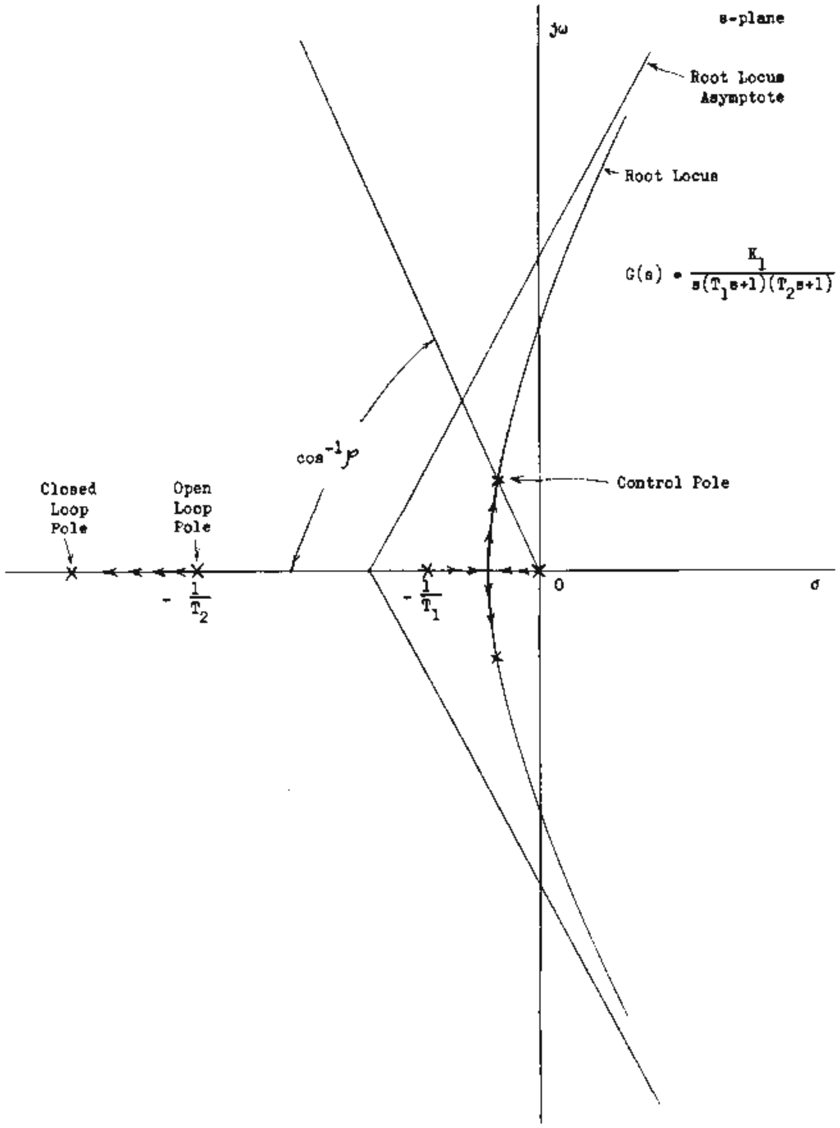

FIG. 5. Root locus plot of typical type I servomechanism.

The ratio of error (or actuating signal) transform to the input signal transform is given by

$$\frac{E(s)}{R(s)} = \frac{1}{1 + G(s)}.$$

The characteristic equation for the closed loop system is given by

$$1 + G(s) = 0.$$

For a stable system, there must not be any roots of the characteristic equation in the right half of the complex s plane. A stable system usually has a pair of complex roots much closer to the imaginary axis than any of the other roots. These roots, known as the control poles, are largely responsible for the transient performance of the servomechanism. The controller may contain compensating networks which introduce zeros to cancel undesirable poles and substitute desirable poles.

Transient performance is often given in terms of the output response to a unit step input—the response frequency, overshoot, and settling time being specified. A value of $\zeta = 0.4$ in the control poles usually limits the transient overshoot to 25 per cent.

Steady-state performance may be specified in terms of the steady-state error during a steady ramp input.

$$r(t) = \omega_i t.$$

For a type I servomechanism ($n = 1$)

$$e_{ss} = \lim_{s \to 0} sE(s) = \frac{\omega_i}{K_1}.$$

For a type II servomechanism ($n = 2$), the steady-state error for a steady ramp input is theoretically zero.

Servomechanisms can be complicated systems with multiple loops, feedback functions, nonlinear or time-varying components, adaptive elements, and undesired random-variable inputs. Special design techniques have been developed to handle these systems.

A very widely used design technique for linear servomechanisms is the Bode plot. The log modulus of the transfer function,

$$\mathrm{Lm}\,[G(j\omega)] = 20 \log_{10} |G(j\omega)|$$

and the corresponding phase angle of $G(j\omega)$ are plotted vs frequency on semilog paper. Straight-line asymptotic approximations for the log modulus plots are usually sufficiently accurate. The phase margin, defined as the amount of phase lag less than 180° of $G(j\omega)$ when $\mathrm{Lm}[G(j\omega)] = 0$ decibels, is the basic design quantity. A phase margin of 45° corresponds to control poles with a $\zeta = 0.4$ and a 25 per cent transient overshoot.

A useful tool in the design and analysis of servomechanisms is the root locus plot. The loci of the roots of the closed loop characteristic equation are plotted as the gain is varied. The gain is adjusted until the control poles have a value of ζ corresponding to the desired transient response.

SHOCK WAVES*

Shock waves arise from a rapid release of chemical, nuclear, electrical, or mechanical energy in a small region. Although the end result of a shock wave experiment may appear to be caused by a violent and disorderly process, the shock process is quite orderly and amenable to mathematical analysis by the laws of physics. Shock waves do, however, subject matter to extraordinary conditions and, therefore, provide a stringent test of our understanding of the fundamental physical processes. The book by Glass (1974) provides a broad discussion of natural and man-made shock waves.

*The preparation of this article was supported by the Office of Naval Research under contract number N00014-81-K-0840.

The practical uses of shock waves date back to the invention of gun powder. Scientific work in this field started in the late nineteenth century and early contributions to the theoretical work were made by Poisson, Stokes, Riemann, Earnshaw, Hugoniot, and Rayleigh. Pioneering experiments on large amplitude stress waves were done by Vieille in gases, and by John and Bertram Hopkinson in solids. As with many other areas of physics, however, active research in shock waves started during the Second World War and has grown steadily since that time. Despite the many developments over the last four decades, there does not exist an in-depth understanding of fundamental mechanisms associated with the effects of shock propagation in condensed matter. Questions concerning atomic and molecular processes of interest to physicists and chemists are only now being addressed. There remain outstanding problems for those who enjoy challenges.

A shock wave is a large amplitude disturbance, propagating at a supersonic speed, across which the pressure, density, temperature, and related physical properties change in a near-discontinuous manner. Although mathematical discontinuities do not occur in real materials, the jump shown in Fig. 1 is used to approximate the very short rise time disturbances observed in experiments. Unlike acoustic waves, shock waves are nonlinear waves characterized by amplitude-dependent wave velocity.

The present discussion, like most shock wave studies, will be restricted to one-dimensional problems, that is, the material properties vary with respect to only one spatial coordinate and time. Two- and three-dimensional problems have received considerably less scientific attention due to the complexity in experiments and analysis. The nonlinear nature of shock problems has also stimulated vast amounts of numerical studies and developments and these will also not be addressed here.

Shock wave studies can be conveniently divided into two areas: shocks in gases and shocks in condensed matter. In gases, the interatomic (or intermolecular) forces are weak and large compressions can be achieved at modest pressures. Temperature changes are, however, large; temperatures of the order of 10^7 °K have been produced by strong shocks (tens of atmospheres) in gaseous plasmas. In the condensed state, the interatomic (or intermolecular) forces are strong and large pressures are required for even modest compressions (a few percent). Accordingly, temperature changes are small. At the very highest pressures (on the order of 10^7 atmosphere or 10 Mbar) reported in condensed materials, the compressions are large (approaching a factor of 2) and temperature changes are also significant (of the order of 5×10^4 °K). Thus, at very high pressures the solid starts behaving like a gas. The contributions to pressure from the thermal motion of the atoms and electrons become significant.

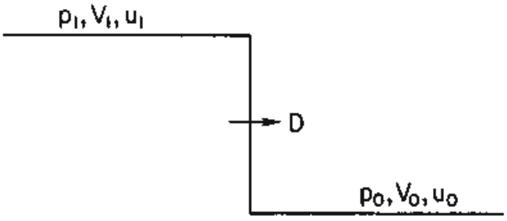

FIG. 1. Discontinuous shock front propagating at a velocity D and connecting two uniform states. The discontinuity is an idealization and actual shocks have finite widths.

Recent interest in thermonuclear research has generated considerable interest in shock waves in plasmas. (See articles by Gross and Krokhin in "Physics of High Energy Density," 1971.) Another area related to shock wave studies that will not be addressed here is the study of detonations (see Fickett and Davis, 1979).

The formation of a shock wave can be qualitatively understood by considering the wave motion due to a piston moving into a compressible material. The piston motion and the resulting compression can be divided into a large number of smaller successive steps. The propagation velocity of each step can be written as $c + u$, where c represents the acoustic velocity corresponding to a given compression and u represents the velocity of the material at the end of the previous step. Because this local acoustic velocity is higher for each successive step, the wave motion due to the piston compression steepens into a shock front traveling supersonically into the undisturbed material. This approximate example illustrates shock formation due to compression in most materials. The above arguments can be used to show that wave motion due to unloading (rarefaction waves) spreads out with propagation. The remarks about shock formation assume a particular, though common, material response to be discussed later.

The conservation equations for mass, momentum, and energy for continuous one-dimensional planar flows, independent of material properties, in the absence of heat conduction are

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho u)}{\partial x} = 0 \qquad (1)$$

$$\rho \frac{du}{dt} + \frac{\partial p}{\partial x} = 0 \qquad (2)$$

$$\frac{dE}{dt} + p \frac{dV}{dt} = 0 \qquad (3)$$

where ρ is density, u is particle or mass velocity, p is the compressive stress in the x-direction and includes viscosity and other time-dependent contributions, E is the specific internal energy; and $V = 1/\rho$ is the specific volume. The choice of spatial (or Eulerian) coordinates is preferred for fluids. For solids, the material (or Lagrangian) description is preferable. The above equations represent a restricted type of planar flow, that is, uniaxial strain deformation. Although this is the most commonly studied problem, the more general one-dimensional flow includes shear deformations.

For stress waves traveling without a change in shape, that is, discontinuous or steady shocks, the above equations can be integrated to give the Rankine-Hugoniot jump conditions:

$$\rho_0(D - u_0) = \rho_1(D - u_1) \quad (4)$$

$$p_1 - p_0 = \rho_0(D - u_0)(u_1 - u_0) \quad (5)$$

$$E_1 - E_0 = \tfrac{1}{2}(p_1 + p_0)(V_0 - V) \quad (6)$$

where D is the shock velocity. Equations (4)–(6) relate the states on the two sides of the shock front. Hence, p in the jump conditions represents the equilibrium stress, unlike the p in the conservation equations. Within the shock front itself, deviations from thermodynamic equilibrium can be appreciable.

The locus of end states achieved through a shock transition [Eqs. (4)–(6)], shown in Fig. 2, is referred to as the *Rankine-Hugoniot (R-H) curve* or merely the *Hugoniot* or *shock adiabat*. The chord connecting the two end states is called the *Rayleigh line*. The slope of this line is a measure of the shock velocity and increases with shock amplitude. Strictly speaking, the Hugoniot curve represents only those states for which the jump conditions are applicable, that is, uniform states connected by a steady shock. However, in the literature the term "Hugoniot" is often used to denote states that are achieved under rapid loading but may not be uniform or may not be connected by a steady shock.

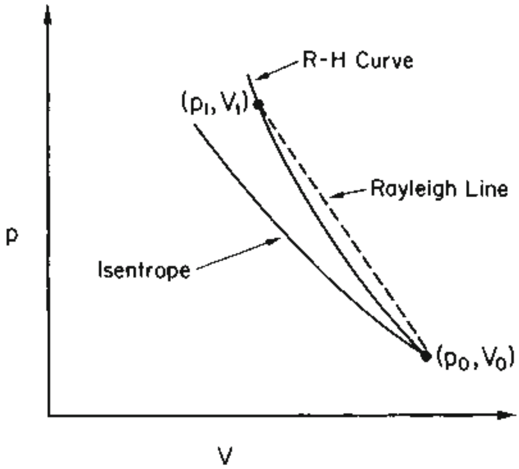

FIG. 2. R-H curve centered at p_0, V_0. The Rayleigh line and an isentrope through p_0, V_0 are also shown. The isentrope and the R-H curve have a second-order contact at p_0, V_0.

Although the jump conditions are valid for both fluids and solids, the following thermodynamic discussion will be limited to fluids. The energy jump condition refers only to thermodynamic quantities and can be combined with an equation of state of the material to provide the Rankine-Hugoniot curve (locus of p-V states). For gases, at least in many simple systems, the E-p-V relation is known and the R-H curve can be easily calculated. For condensed matter, the pressure changes are large and the needed thermodynamic data are not available. Consequently, most of the effort in these materials has focused on the converse problem: how to obtain thermodynamic information from shock wave experiments. By determining two of the variables in Eqs. (4)–(6) from experiments, the equations can be completely solved. Generally the shock velocity D and one other variable, either p or u, are measured. A knowledge of the Hugoniot curve provides the p, V, and E values at each point of the curve. To construct the E-p-V surface requires additional information and/or assumptions. Analysis of the Hugoniot data to provide more complete thermodynamic information for condensed materials is an active area of shock wave research. (See papers by Duvall, and Royce and Keeler in "Physics of High Energy Density," 1971.) Despite the limited thermodynamic nature of the shock data, these experiments provide the principal means for obtaining information at very high pressures and temperature. Hence, these data have proved valuable both in fundamental and applied studies.

The shock transition is an irreversible process giving rise to entropy production. The entropy change can be written most easily for weak shocks by expanding the entropy in a Taylor series along the Hugoniot. The resulting expression is

$$S_1 - S_0 = \frac{1}{12T_0}\left(\frac{\partial^2 p}{\partial V^2}\right)_{S_0, V_0}(V_0 - V_1)^3 + \cdots . \quad (7)$$

Equation (7) shows that the entropy change is third order in compression and $(\partial^2 p/\partial V^2)_S$ has to be positive for a positive entropy change. The p-V relations for most fluids are indeed concave upward (Fig. 2) as required. For materials satisfying this restriction, shocks are restricted to compressive waves based on hydrodynamic and thermodynamic considerations. For many problems in condensed matter, the volume compression is quite small (a few percent) and the entropy change is negligible.

It is interesting to note that the magnitude of the entropy jump across a shock is independent of the dissipative mechanisms like viscosity and thermal conductivity. The magnitude of these mechanisms determines the thickness of the shock front. Because these mechanisms can never be completely absent in a real material, the concept of a shock discontinuity (Fig. 1) is an idealization. The formation of a steady shock, with finite thickness, results from a balancing of the dissipative processes tending to diffuse the shock front and the curvature of the p-V curve which tends to steepen the shock. (See discussion about shock fronts in Chapters I and VII in the book by Zeldovich and Raizer, 1966.)

In many problems of scientific interest, deviations occur from the "normal" Hugoniot shown in Fig. 2. Thus, the question of shock stability is of considerable interest for both theoretical and experimental problems. The general theory of shock stability is complicated (see paper by Fowles in "Shock Waves in Condensed Matter," 1981). However, in nonreactive materials the stability condition can be written as

$$D - u_1 < C_1 \tag{8}$$

where C_1 is the sound speed in the shocked state. Physically, this condition implies that the shock front is subsonic with respect to the material behind it. Hence a disturbance (e.g., rarefaction) behind the shock front catches up with the front. The above condition has been analyzed by Duvall to obtain the condition on the p-V relation cited after Eq. (7).

Another area of considerable theoretical interest is the study of wave interactions involving both shock and rarefaction waves. These interactions arise from reflections, transmission, and diffraction of shock waves from material boundaries. Wave interaction problems in one dimension are useful in analyzing laboratory experiments and are important in developing an intuitive understanding of shock wave problems. Two- and three-dimensional problems, though quite complicated, are important in applications involving gas dynamics and in aeronautics. The book of Courant and Friedrichs (1948) provides a comprehensive discussion of wave interaction problems. Problems of contemporary interest may be seen in the proceedings of the symposium on shock tube research ("Shock Tube and Shock Wave Research," 1978).

Shock waves are produced by a rapid deposition of energy, as stated at the beginning. The most common technique for producing shock waves in gases is the use of a shock tube. A long cylindrical tube is divided in two sections by means of a diaphragm. One section of the tube contains the high pressure or driver gas and the other section contains the low pressure or sample gas. Upon rupture of the diaphragm, a compression wave propagates into the low pressure side and a rarefaction wave propagates into the high pressure side. Because the gas is constrained laterally, the flow is one dimensional. Deviations from the idealized one-dimensional situation occur because of diaphragm effects and viscous forces at the wall boundary. Well designed shock tubes minimize these perturbations. The use of light driver gases, explosives, and electromagnetically driven shock tubes can produce higher compressions. In addition, the implosion techniques have been utilized to provide even larger compressions and higher temperatures. Temperatures of the order of 20,000°K are generated in these experiments.

Shock tube measurements generally consist of measuring the shock velocity and one or more of the following shock properties: density, pressure, temperature, and chemical composition. The need for minimal interference and high time resolution from the measurement technique has resulted in the wide use of optical methods. Techniques employed consist of optical interferometry, Schlieren and shadow photography, visible, ultraviolet, and infrared spectroscopy, and x-ray absorption. Spectroscopy measurements have been used for the determination of chemical composition. Developments in laser technology are rapidly expanding the realm of spectroscopy measurements. At very high temperatures, the luminosity behind the shock front is used for studying the shock front and the processes behind the shock front. The nonoptical methods consist of piezoelectric and ionization gauge measurements. Further details may be found in the references (Bradley, 1962; Glass, 1974; "Shock Tube and Shock Wave Research," 1977).

Shock wave studies in gases are of considerable interest to the fields of gas dynamics and aeronautics related to flow past high speed aircraft and reentry vehicles. Shock studies are also used in the study of chemical kinetics to probe relaxation processes involving chemical reactions, electronic vibration and rotation excitations, and even dissociation at high temperatures.

In shock studies of condensed matter, a wide variety of experimental methods have been used, including radiation deposition. In comparison to shock propagation in gases, the compressions and temperatures achieved in condensed materials are smaller, but the pressures are much higher. Deviations from idealized shock response are also more common in condensed matter. Using laser driven shocks, pressures to 35 Mbar (10 times the pressure at the center of the earth) have been reported. The two most common techniques used are in-contact explosives and colliding flyer plates. Stresses ranging from 0.1 GPa (1 kbar) to approximately 1 TPa (10 Mbar) have been achieved using these techniques. At very high stresses, temperatures approach tens of thousands of Kelvin. Time durations for the experiments range from a nanosecond to several microseconds. The development of gas guns that use projectiles driven by compressed gas have permitted very precise impact experiments. Shock production can be understood by examining the collision of flat plates shown in Fig. 3(a). The stress and particle velocity states (p, u) achieved in the experiment can be determined by imposing the condition of continuity of p and u at an interface and transforming the R-H curve to the p-u plane. In Fig. 3(b), the intersection of the p-u curves for the impactor and the target plates are shown. The slopes and positioning of the curves indicate the direction of shock propagation in each plate and the initial particle velocity of the plates, respectively. Prior to the time of arrival of rarefactions from the edges (the useful time of the experiment), the sample is exactly in a state of uniaxial strain. Hence, the one-dimensional equations indicated earlier are rigorously applicable.

Unlike the work in gases, the experiments in condensed matter have mostly consisted of measuring continuum variables like stress, particle velocity, and shock velocity. Earlier measurements concentrated on time of wave arrival (shock velocity measurements) and free surface velocity measurements (these provide particle velocity data) using optical and capacitor techniques. Recent developments using electromagnetic gauges, laser interferometry, piezoelectric, and piezoresistance gauges have given continuous time-resolved, in-material measurements of the wave profiles. These data are noteworthy in their ability to better characterize the shock front and the states behind the shock front. Time resolution to one nanosecond has been achieved. In contrast to the measurement of continuum variables, attempts to study electrical, magnetic, and optical properties of condensed materials have been minimal. These measurements will be discussed in subsequent paragraphs.

The ability to study the response of solids under one-dimensional combined compression and shear loading is an important recent development. In this experiment, the colliding plates are parallel but inclined to the direction of the impactor plate. The motion upon impact can be resolved into a compression and a shear motion which propagate at the appropriate wave velocities. Particle velocity profiles can be measured using electromagnetic velocity gauges. This experimental technique has the ability to measure the shear response of the material behind the shock and to examine the change in other material properties due to shear loading. The use of this technique to study solids and viscous fluids is just starting and the full significance of this development will not be known for some time.

The majority of the studies in condensed matter have been on the mechanical properties. The very high pressure data obtained for a number of materials are particularly noteworthy. The pressure range of these data are well beyond the range of static high pressure measurements and have made significant contributions to the fields of geophysics (quantifying material response at pressures in the interior of the earth) and solid state physics. At large compressions, the shock data permit an evaluation of the interatomic potentials.

One aspect of the dynamic high pressure work involves the study of polymorphic phase transitions in solids. Initially, it was believed that such transitions could not occur on the microsecond time scale available in the shock wave experiments. The experimental data have provided results to the contrary. The conversion of graphite to diamonds in shock wave experiments

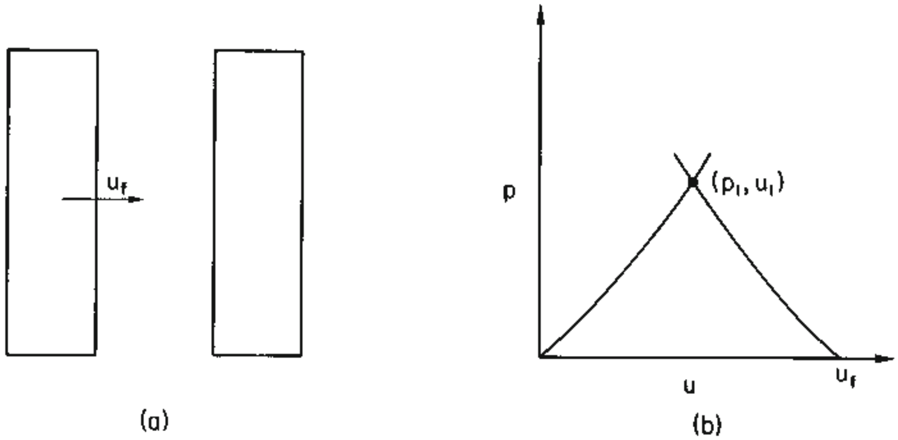

FIG. 3. (a) Schematic view of the impact of two parallel plates. The target plate is at rest and the flyer plate is moving with velocity u_f. (b) The stress and particle velocity (p_1, u_1) achieved upon impact are determined by the intersection of the R-H curves in the p-u plane. The sign of the slope indicates the direction of wave propagation.

by DeCarli and Jamieson is a noteworthy example. Despite studies of shock-induced phase transition in many materials (analysis of wave-profiles), a quantitative understanding of the mechanisms has not been achieved. An understanding of the kinetics of the transition and the role of shear strength and deformation are necessary before correlations can be confidently made with static high pressure data.

The phase change studies are a subclass of an old problem receiving considerable attention in recent years: Do shock waves merely simulate the effects of superposing the mechanical stress or pressure and temperature, or are there effects that are unique to shock waves? This question has received considerable attention in the Soviet Union in the studies of chemical reaction under shock loading. The results suggest that shock waves produce unique changes in materials. Unequivocal resolution of this question will require considerable work involving improved time-resolved measurements.

Dynamic yielding is another aspect of mechanical studies that has received considerable attention in the past two decades. Since the late 1950s it has been recognized that the use of the fluid approximation at stresses below 10–20 GPa (100–200 kbar) was incorrect. Recent work suggests that strength effects may be important even at stresses in excess of several hundred kilobars. Although considerable progress has been made in relating the observed wave structure in metals to continuum aspects of deformation, the atomic or microscopic mechanisms are not well understood. For nonmetals even the continuum response, because of a lack of knowledge of the complete stress tensor, is not well understood. Shock wave interactions have also been used to study fracture on microsecond time scales. Fracture strength shows appreciable rate dependence.

Among the thermodynamic and continuum measurements, the two big uncertainties in existing shock data are temperature and shear stresses. As indicated earlier, some progress has been made toward measurement of the latter. Temperature measurement remains a challenging problem and is perhaps the biggest limitation of shock work. Previous attempts have used optical radiation from shocked solids and thermoelectric measurements. No reliable techniques have emerged to date. The difficulty is that the techniques used to monitor temperature in other branches of physics cannot be easily extended because of the coupling between stress, loading rate, and temperature in shock experiments.

Electrical, magnetic, optical, and x-ray measurements that are commonly used in other fields of condensed matter physics and chemistry have not been extensively used in shock wave studies. The most common of these measurements have been electrical conductivity data in insulators, semiconductors, and metals. Some studies of piezoelectric and ferroelectric materials have also been carried out. However, the mechanisms responsible for shock-induced conductivity changes, polarization, and depoling of ferroelectric materials are not well understood.

Although optical measurements of various kinds including luminescence, refractive index changes, and absorption spectroscopy have been attempted in the past, they have not lead to any comprehensive understanding. Recently, a concentrated effort on shock wave spectroscopy has started at several laboratories. These studies should lead to a better understanding of the molecular processes important under shock loading in condensed materials.

Finally, mention should be made of the x-ray diffraction work under shock loading by Johnson and Mitchell at Lawrence Livermore Laboratory. This one set of experiments confirmed the existence of crystalline order behind the shock front in two materials on time scales of the order of tens of nanoseconds. The confirmation of this important but commonly made assumption is very gratifying. Further work in this area would be beneficial to a basic understanding of shock effects.

The lack of optical and x-ray data in condensed matter studies is caused by the difficulty and costs of the experiments. In contrast to shock tube experiments, condensed matter samples cannot be probed through the sides because of edge effects. This not only makes the experimental geometry difficult, but severely limits the time available for recording. The review by Davison and Graham (1979) provides a very comprehensive list of references for shock waves in solids.

In conclusion, shock waves in condensed matter have contributed greatly to mechanical and thermodynamic information at extreme loading conditions. The use of shock waves as a tool to probe the atomic and molecular states of matter at extraordinary conditions remains a challenging problem both experimentally and theoretically. The single-event nature of the experiments and the need to make deductions from incomplete measurements in a single experiment require considerable experimental skills and theoretical innovation.

Ongoing research in shock waves in gases is published in the proceedings of the symposia on shock tube research held every two years. Contemporary problems in shock waves in condensed matter are published in the proceedings of the AIP topical conferences held every two years.

SIMPLE MACHINES

A machine is a device used to change the magnitude and or direction of a force or torque. This enables man to perform laborious work. Basically there are three types of machines: Type A, the *lever*, including simple levers, pulleys, and wheel and axle; Type B, the *inclined plane*, including the simple inclined planes, wedges, and screws; and Type C, the *hydraulic press*, which is not discussed here. All machines, however complicated, are combinations of these simple machines.

Mechanical Advantage and Efficiency Let us consider a simple machine in which an input force F_i is applied through a distance d_i so that the input work is $W_i = F_i d_i$; while the output force F_o is applied through a distance d_o, so that the output work is $W_o = F_o d_o$. In addition, the work done against friction by the machine is W_f. From the conservation of work-energy principle (see WORK, POWER AND ENERGY) $W_i = W_o + W_f$, that is,

$$F_i d_i = F_o d_o + W_f. \tag{1}$$

The actual mechanical advantage (AMA) is defined as the ratio of the output force to the input force, that is,

$$\text{AMA} = F_o/F_i. \tag{2}$$

Usually F_o is greater than F_i (while d_o is less than d_i) and hence AMA is greater than 1. There are situations in which it is desirable to have F_o less than F_i, but d_o greater than d_i, as in the case of scissors.

For an ideal machine, $W_f = 0$, and hence from Eq. (1), $F_i d_i = F_o d_o$. We define the *theoretical mechanical advantage* (TMA) (or ideal mechanical advantage) as

$$\text{TMA} = d_i/d_o. \tag{3}$$

Note that when there is no friction ($W_f = 0$), $\text{TMA} = \text{AMA} = F_o/F_i = d_i/d_o$.

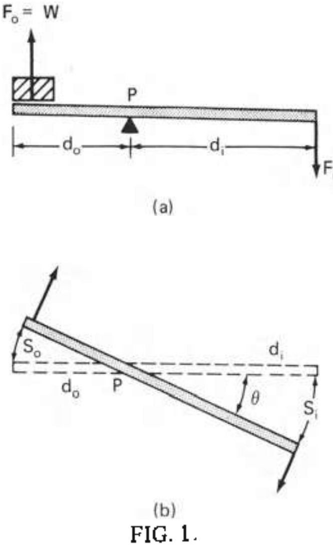
We define the *efficiency* η of a simple machine as the ratio of the output work to the input work, that is,

$$\eta = \frac{\text{work output}}{\text{work input}} = \frac{F_o d_o}{F_i d_i} = \frac{F_o/F_i}{d_i/d_o} = \frac{\text{AMA}}{\text{TMA}}. \tag{4}$$

η is usually expressed as a percentage and represents the part of the input work changed into useful work by the machine. The efficiencies of simple and complex machines vary between ~5% and ~95%.

The efficiency can also be calculated by applying the equilibrium principle instead of the work energy principle as discussed above.

Levers A *simple lever* consists of a nearly rigid rod pivoted about a certain point P called the *fulcrum*. A most common type is shown in Fig. 1(a) with point P between the load $W = F_o$ and the applied force F_i. By applying a small



(a)

(b)

FIG. 1.

force F_i, a large load W can be lifted. Applying the condition of equilibrium that the input torque is equal to the output torque, we get $F_i d_i = F_o d_o$ (neglecting a very small friction that may be present at the pivot point). Therefore AMA = TMA, and

$$\text{TMA} = \frac{d_i}{d_o} = \frac{F_o}{F_i}. \qquad (5)$$

We can obtain the same result from work considerations. As shown in Fig. 1(b), when F_i moves through a distance s_i, the force F_o moves through a distance s_o. Since the two arcs s_i and s_o subtend the same angle θ at P, we may write

$$\theta = \frac{s_i}{d_i} = \frac{s_o}{d_o}. \qquad (6)$$

Therefore

$$\text{TMA} = \frac{s_i}{s_o} = \frac{d_i}{d_o}. \qquad (7)$$

The above type of lever in which the fulcrum point is between the load and the applied force is called the Class I lever. In the Class II lever, the load is between the fulcrum and the applied force, as in the case of a wheelbarrow. In the Class III lever, the applied force is between the load and the fulcrum, as in the case of the human forearm held horizontally with a load in the hand.

The simple lever has a limitation in that it can operate only through a small angle. This limitation is overcome by using a continuous rotation of the lever arm as in the case of the *wheel and axle*. It consists of a wheel of radius R fixed to a shaft or axle of radius r with the same axis of rotation, as shown in Fig. 2. A force F_i applied tangentially to the edge of a wheel lifts the load W (= F_o) by means of a rope wrapped around the axle. Thus when the wheel is rotated through one full rotation, the work done is $F_i d_i = F_i(2\pi R)$, the axle will rotate through one rotation doing work equal to $F_o d_o = W(2\pi r)$. We may equate these two or apply the equilibrium principle by taking torques about point P, that is,

$$F_i r = F_o R.$$

Thus, we get

$$\text{TMA} = \frac{d_i}{d_o} = \frac{R}{r}. \qquad (8)$$

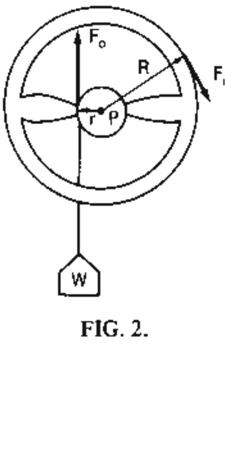


FIG. 2.

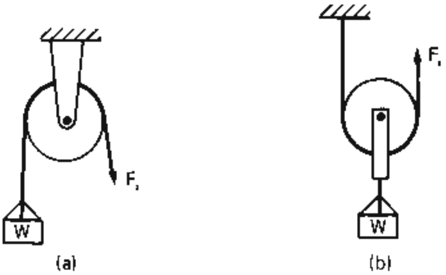

FIG. 3.

This principle is used in almost every motor-driven machine. In trucks which may be equipped with power steering, $R \gg r$. Also we use the same principle every time we use a doorknob to open a door.

The Pulley. A pulley is a wheel or disk with a groove on the circumference edge. A pulley is a continuous lever in which forces are transmitted by ropes. A single fixed pulley, as shown in Fig. 3(a), is a lever with equal moment arms ($d_i = d_o$), and hence TMA = $d_i/d_o = F_o/F_i = 1$. The only purpose this single pulley serves is to change the direction of the applied force F_i. Instead, if we have a single movable pulley as shown in Fig. 3(b), TMA = 2. In order to lift the weight W through a height h (= d_o), each of the two vertical ropes must be raised through a height h, that is, F_i must be applied through a distance $2h$ (= d_i). Thus TMA = d_i/d_o = $2h/h = 2$.

A system of pulleys, called a *block and tackle*, as shown in Fig. 4, may be considered equivalent to a lever with arms of different lengths. For example, consider the block and tackle systems shown in Fig. 4(a), where there are 4 ropes supporting the movable block, hence TMA = 4, and in Fig. 4(b) (which is the system of Fig. 4(a) inverted) where the TMA = 5, because there are five ropes supporting the movable system of block and pulleys. Hence

$$\text{TMA} = \text{Number of strands of rope supporting movable block of block and tackle.} \qquad (9)$$

The chain hoist or *differential pulley* is based on the combination of the block and tackle and the wheel and axle. As shown in Fig. 5, it consists of two pulleys of radii R and r attached to each other and rotating about a common axle. An endless chain connects the dual pulley to another free pulley wheel, as shown. The chain

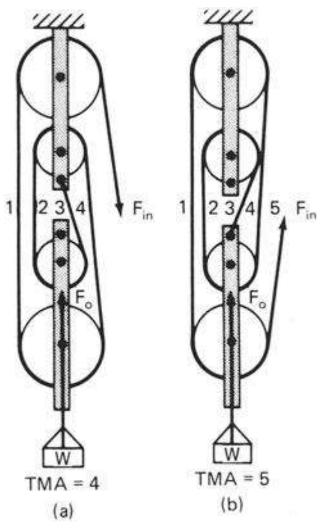

FIG. 4.

and the corresponding teeth on the dual pulleys prevents slipping between the chain and the pulleys. In one complete revolution, the input force F_i acts through a distance $d_i = 2\pi R$. The chain around the movable pulley results in shortening by $2\pi R$ and lengthening by $2\pi r$, thereby, raising the weight W (= F_o) by a height $d_o = 2\pi R - 2\pi r$. Thus,

$$\text{TMA} = \frac{d_i}{d_o} = \frac{2\pi R}{2\pi R - 2\pi r} = \frac{R}{R - r}. \qquad (10)$$

Thus, the closer the values of R and r, the larger the TMA.

The Inclined Plane Ramps and staircases are two simple examples of *inclined planes*. Large loads can be moved by applying small forces. As shown in Fig. 6, when a force F_i is applied through a distance d_i (= L), the load $W = F_o$ is lifted through a height h. Thus work input = work output, that is, $F_iL = Wh$, and hence, if there were no friction,

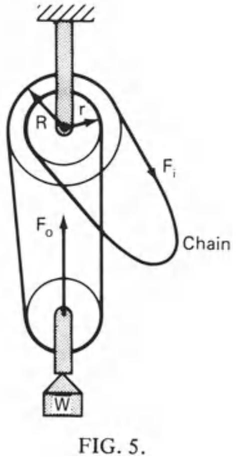

FIG. 5.

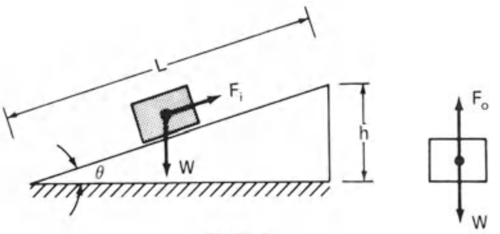

FIG. 6.

$$\text{TMA} = \frac{W}{F_i} = \frac{L}{h} = \frac{1}{\sin\theta}. \qquad (11)$$

The *wedge* is a single or double movable inclined plane, as shown in Fig. 7. For a double wedge TMA = L/t. Wedges, besides being used for splitting logs or holding doors, find their application in knives, chisels, and other cutting tools. A rotary wedge called a *cam* is used to lift valves held by heavy springs in internal combustion engines.

A *screw* is essentially an inclined plane wrapped around a cylindrical shaft to form a continuous helix. The corrugations of a screw are called *threads*. The distance between the two adjacent threads is called the *pitch* of the screw, p. A typical example of screw is a *screw jack* shown in Fig. 8. When an applied force F_i is moved through one complete revolution d_i = $2\pi R$, the weight $W = F_o$ is raised through a distance p. Thus

$$\text{TAM} = \frac{d_i}{d_o} = \frac{2\pi R}{p}. \qquad (12)$$

Because of friction, the AMA of a screw jack is much less than the TMA. But the presence of friction happens to be an advantage in this case, because it holds the load in place while no input force is being applied, as in the case of lifting an automobile by using a screw jack.

Power and Torque Transmission Power P is defined as $P = Fv$ or $P = \tau\omega$, where v, ω and τ are velocity, angular velocity, and torque respectively. Power and torque may be transmitted by using mechanical devices such as

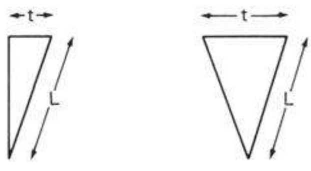

FIG. 7.

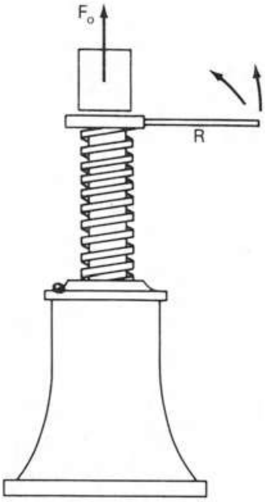

FIG. 8.

belts, shafts and gears. Figure 9(a) shows pulleys joined by a belt. The belt has a V-shaped cross section so that it cannot slide sideways, and furthermore it has a large area in contact with the pulleys thereby preventing slipping. Basically it has the same principle as a wheel and axle. A pair of step pulleys, as shown in Fig. 9(b), allows one to change shaft speeds by shifting the belt. Note that the driving pulley and the output pulley rotate in the same direction.

The mechanical advantage of a system shown in Fig. 9(a) is the ratio of the torques between the output pulley and the driving pulley, that is,

$$\text{TMA} = \frac{\tau_o}{\tau_i} = \frac{F_o r_o}{F_i r_i}.$$

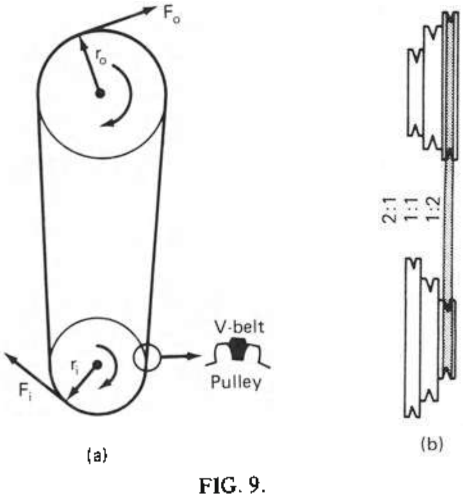

FIG. 9.

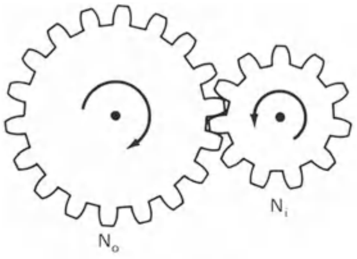

FIG. 10.

For no slipping between the belts and the pulleys ($F_i = F_o$),

$$\text{TMA} = \frac{r_o}{r_i} = \frac{D_o}{D_i}$$

where D_o and D_i are the diameters. Also input power = output power, that is,

$$\tau_i \omega_i = \tau_o \omega_o.$$

From the above two equations, if there is no friction,

$$\text{TMA} = \frac{\tau_o}{\tau_i} = \frac{\omega_i}{\omega_o} = \frac{D_o}{D_i}, \qquad (13)$$

while the *speed ratio* SR = ω_o/ω_i = 1/TMA. Thus by adjusting the diameters of the input and the output pulleys, the speed ratio and τ_o/τ_i may be adjusted. If TMA = 4, the input pulley must rotate four times as fast as output pulley, which can be achieved by having the diameter of the output pulley four times the diameter of the input pulley.

A *gear* is a notched wheel. When two gears whose notches or teeth are of the same size are meshed together, it is possible to transfer torque from one gear to the other. Gear drives are capable of transmitting very high torques without causing slipping. A typical *spur gear* is shown in Fig. 10. Note that the two gears rotate in opposite directions. Let N_i and N_o be the number of teeth on the input and the output gear respectively. As in the belt drive system, for gears

$$\text{TMA} = \frac{D_o}{D_i} = \frac{\omega_i}{\omega_o} = \frac{N_o}{N_i}. \qquad (14)$$

There are five common types of gears. *Spur gears*, Fig. 10, are those which have their teeth cut parallel to the axis of rotation. *Bevel gears* are used when the axes of rotation intersect; their teeth are cut on conical surfaces with a common apex at the point of intersection of the axes. Bevel gears are used to change the direction of rotation by 90° with or without a change of speed. In *helical gears*, the teeth are curved and cut in a spiral pattern. Helical gears operate very smoothly. In *planetary gears*, the teeth are cut inside one wheel instead of outside. When a screw meshes with a cogged wheel, it is known as a worm and worm wheel or *worm gear*. Lastly, *gear trains* consists of more than two gear wheels.

SKIN EFFECT

For a steady unidirectional current through a homogeneous conductor, the current distribution over the cross section is uniform. However, for an alternating current, the current is not uniformly distributed over the cross section but is displaced more and more to the surface as the frequency increases. For high frequencies, practically the entire current is concentrated in a thin layer at the surface or "skin" of the conductor. This phenomenon has commonly come to be called the "skin effect."

For a physical explanation of this phenomenon, consider a cylindrical conductor that is carrying a steady unidirectional current. The current distribution over the cross section is uniform. A magnetic field is set up by the current in which the magnetic flux lines within and around the conductor are symmetrical to the conductor axis, i.e., they are in concentric circles. Consider the conductor to be composed of very small circular filaments of equal area which carry equal fractions of the total current. Consider a filament A near the axis of the conductor and another filament B near the surface. The flux linking A is greater than that linking B. If the steady unidirectional current is changed to an alternating current, the magnetic field which is set up by the current must reverse itself periodically with the result that the flux linkages change with time. Self-induced electromotive forces (emf's) are created within the conductor due to these flux changes. These emf's tend to generate currents (eddy currents) which oppose the main current. Because the emf created in filament A is greater than that in B due to a greater flux linkage, the net or resulting current in A becomes less than in B. The current in the conductor is no longer uniform but is displaced toward the surface. The current density becomes greater at the surface and decreases toward the center. This current displacement becomes more pronounced the higher the rate of change of flux.

The total resistance offered by the conductor to alternating current is greater than to a steady unidirectional current because of skin effect. When the current is displaced from the center of the conductor and crowded into the area near the surface, the effective cross section of the conductor is reduced, thereby increasing its resistance. The resistance of the conductor increases with frequency

The equations which mathematically describe skin effect can be derived from Maxwells' equations for electrodynamic problems. However, exact solutions have been obtained for only a few simple shapes of conductor. Shapes which have been amenable to analysis include the cylindrical conductor, tubular conductor, flat conductor, surface plated flat, cylindrical and tubular conductor, and coaxial conductor. Even then it is necessary to consider conductors whose material properties do not change with time or temperature. More complex shapes must be treated numerically.

The first theoretical explanation of skin effect for wires of circular cross section was given by Lord Kelvin in 1887. Early investigators were Kennelly, Laws, and Pierce,[2] who conducted comprehensive experiments on skin effect, and Dwight[3] who obtained solutions for skin effect in tubular and flat conductors. Many other investigations have been made since that time.

The solution to the skin effect equation for a flat or plane conductor carrying a sinusoidal alternating current shows that the current density is maximum at the surface and decreases exponentially in magnitude with distance from the surface into the conductor. Also, as the distance from the surface increases, the current lags in time-phase further and further behind the current at the surface. A quantity $\delta = (2/\omega\mu\sigma)^{1/2}$ is often called the "skin thickness" since it corresponds to the distance from the surface in which the current density drops to $1/e$ of its value at the surface. In this equation, σ is the conductivity, μ is the permeability of the material, ω is the angular frequency. The resistance and internal reactance of the plane conductor are equal at any frequency. Also, the ac resistance of the conductor is exactly the same as the dc resistance of a plane conductor of thickness δ.

In copper, the skin thickness δ at 60 Hz is about 8.5 mm. At 1 GHz, δ decreases to about 2×10^{-6} m.

For a cylindrical conductor carrying a sinusoidal alternating current, the solution to the skin effect equation is found in terms of the zero-order Bessel function of the first kind. If the frequency is quite high, the exact formulation in terms of Bessel functions reduces to the simple exponential solution for flat or plane conductors. A useful engineering approximation for the ratio of ac to dc resistance is $R_{ac}/R_{dc} = a/2\delta$ where a is the radius of the conductor and $\delta \leqslant 0.1a$. The exact ratio in terms of Bessel functions must be used to obtain a solution for low frequencies or small conductors where $0.1a < \delta < a$. At radio frequencies, there is practically no magnetic field inside the conductor, so the reactance is negligible.

The solution to the skin effect equation for tubular conductors is expressed in terms of Bessel functions of the first and second kind. Since the interior portion of a cylindrical conductor carries very little current at high frequencies, thin tubular conductors are often used with a corresponding saving in material. At these frequencies, the tube acts like a solid conductor and effectively serves as an electromagnetic shield.

Conductors are often surface plated for specific applications. Since silver has high conductivity, resonant cavities and wave guides which operate at very high frequencies are silver plated to reduce I^2R loss since most of the current is concentrated at the surface. Analyses have been made of a number of surface plating combinations to determine what effect such coatings have on the over-all resistance.

The skin effect phenomenon has a very practical application in induction heating. Since the current is concentrated near the surface, a highly selective heating source is created in the surface itself. Advantage is taken of this phenomenon and electromagnetic induction to create a heating method which requires no external heat source and no physical contact with the energy source, the induction coil.

Consider an induction coil carrying alternating current which is wound uniformly around a metal cylinder. Eddy currents are induced in the metal and tend to concentrate near the surface. The problem is similar to that of the cylindrical conductor previously described except that the induced currents are in concentric circles at right angles to the axis of the cylinder instead of being in the axial direction. The solution of the skin effect equation is in terms of the first-order Bessel function instead of the previous zero-order function.

With the advent of high-speed digital computers, numerical methods have replaced analytical techniques in solving skin effect problems. Analytical methods, even approximate ones, are quite limited. Numerical methods tend to be more flexible and can be used for analysis of systems of more than one conductor and of conductors having a wide variety of cross sections. Numerical solutions such as finite difference schemes, finite elements, and integral equations have gained currency. At present, the finite-element method can be considered to be the fastest-growing technique for solving practical electrical engineering problems with complicated geometries.[11-15]

Up to this point, the concepts of classical skin effect have been discussed. However, at sufficiently high frequencies or conductivities, the properties of the individual conduction electrons must be considered. In simple electron theory, σ is proportional to the mean free path ℓ of conduction electrons. As σ or ω increases, at some point δ becomes smaller than ℓ. Incident electromagnetic radiation is now more strongly absorbed than would be calculated from classical skin effect theory. This situation is referred to as an *anomalous skin effect*. As ω increases, other effects may become significant, namely, relaxation effects due to the inertia of the electrons. An incident wave now "sees" a layer of virtually free electrons which results in almost total reflection. This situation is referred to as *anomalous reflection*. If ω is increased still further, the *plasma frequency* of the metal is reached. Above this frequency, the metal becomes transparent to the incident radiation. Transmission takes place and skin effect no longer exists.[16]

In metals that are in a superconducting state, skin effect exists but is independent of frequency. Theory suggests that superconducting electrons are responsible for the screening (or skin) effect, even at zero frequency, while normal electrons in the skin layer thus formed are responsible for absorption that occurs only at nonzero frequency. An application of this aspect of superconductivity, in which the field penetration is limited to a skin layer, is to be found in the fabrication of high-Q resonant cavities.[17]

SOLAR CONCENTRATOR DESIGN, OPTICS OF

The concentration factor of a solar collector is the ratio of the solar flux reaching a receiver surface to the solar flux crossing the aperture of the concentrator. The geometrically simplest and least expensive concentrator would be composed of flat surfaces and as few of those as possible.

The flat-sided rectilinear trough is a simple design whose properties have been studied in detail.[1] Figure 1 illustrates how a trough reflector can be designed for one reflection before reaching the base, or two reflections by truncating the reflector at D_1 or D_2, and so on. It is desirable to keep the number of reflections small, since energy is lost at each reflection. The concentration factor is a function of α, half the apex angle formed by the extended sides of the trough. Assuming no loss at each reflection the concentration factor for normal incidence at the aperture and n reflections is given by

$$C = \frac{D}{D_0} = \frac{\sin(2n+1)\,\alpha}{\sin\alpha}$$

where D is aperture width and D_0 base width.

One must also consider performance when the sunlight is not normal to the aperture. It is also desirable to keep the length of the sides as small as possible in order to minimize material requirements. All these factors are studied in Ref. 1. In general it appears that commercial flat-sided trough concentrators are limited to a concentration factor of 2–3 or so. The corresponding L/D_0 ratio is about 5. L is the length of one side. It is possible to increase the concentration factor by forming each side of the trough from two or more flat surfaces; or by shaping the sides and extending their lengths.

Much higher concentration factors can be obtained from truncated flat sided pyramidal or hexagonal cones. A concentration factor of about 10 can be achieved with an apex angle α of 15° and a value of $L/D_0 = 4$ or 5 where L is the length of side and D_0 is the base width. A concentration factor of 15 or so can be achieved by decreasing α to 10° and increasing L/D_0 to 10. In all cases the distribution of energy over the base is remarkably uniform. For a detailed study of the effect of all parameter variations see Ref. 2.

It has been shown by Winston[3] that the maximum geometrical concentration factor possible for a given acceptance angle θ_m is

$$C \leqslant 1/\sin(\theta_m/2) \quad \text{(2-dimensional case)}$$

$$C \leqslant 1/\sin^2(\theta_m/2) \quad \text{(3-dimensional case).}$$

$\theta_m/2$ is the angle of incidence with respect to the plane or line of symmetry at the entrance aperture. For another discussion of this subject see R. E. Jones.[4] One may not always be interested in the maximum concentration but rather in achieving a certain distribution of sunlight over the receiver surface. For example, in heating solar cells it is desirable to avoid hot spots. In the next section we describe the principles involved in designing for a given distribution of energy. Often this will still allow one to achieve close to optimum average concentration factor. The same considerations apply when designing reflectors for illumination purposes.[5] See also the book by W. B. Elmer.[6] A specified distribution can be achieved only for one direction of solar incidence, usually but not always for normal incidence at the aperture. In order to monitor deviations from the initial specified distribution as the sun's rays change direction one may employ the method for irradiance calculation described in the article IRRADIANCE (ILLUMINANCE) CALCULATION.

It is possible to shape a reflecting surface to achieve any desired distribution and concentration of solar energy, except for a theoretical upper limit which does not concern us here. We will describe the steps to be followed to design such a surface and illustrate their application to both an axially symmetric forward lighted reflector surface; and a rectilinear trough with curved sides.[7] The same procedure applies to unsymmetric configurations and also to the more general problem of changing an arbitrary distribution of incident radiation to a specified output. For example, Rhodes and Shealy[8] have designed a two-lens system that will convert a collimated laser beam of arbitrary incident irradiance profile to a uniform expanded irradiance profile. The principles involved are the same as those described

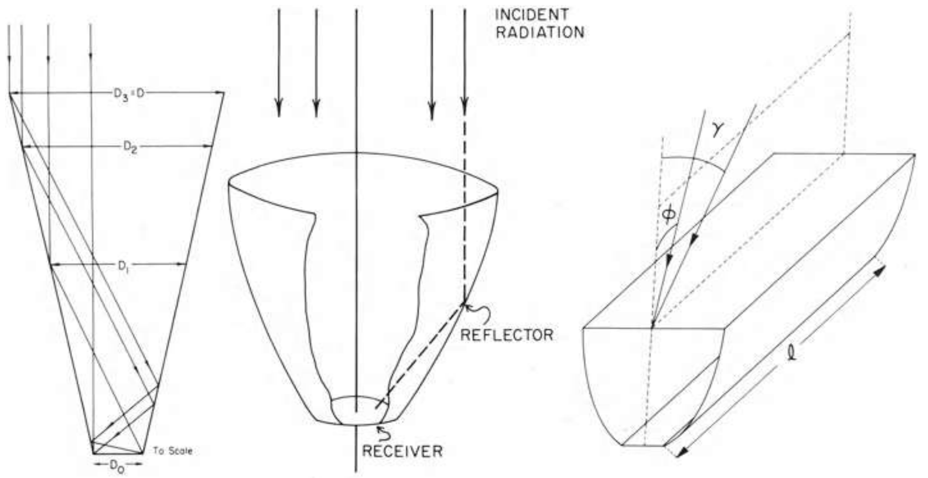

FIG. 1. Cross section of a flat-sided rectilinear trough concentrator. Axially symmetric conical concentrator. Rectilinear trough concentrator with curved sides. ϕ is an angle of incidence oblique to the length of the trough. γ is an angle of incidence with respect to the symmetry plane of the trough.

herein, except for one additional requirement, namely, that the existing beam profile be uniform not simply over a fixed receiver plane but also along the complete range of the exiting beam. They achieve this through the use of a second refracting surface, a second lens, and require that the optical path length be the same for all rays over an existing wave front that is normal to the optical axis of the system. In the latter case, the same reshaping has been achieved by means of computer generated hologram filters that replace the aspheric lenses.[9]

Axially Symmetric Geometry We first consider the rotationally symmetric geometry shown in Fig. 1. Solar energy is incident along the z-axis, left to right, upon reflector surface S_1 described by the equation $z = z(x)$. x and X are radial distances from the z-axis. The receiver surface S_2 is described by the equation $Z = Z(X)$. Let σ be the incident solar energy per unit area per unit time. The solar flux incident upon a circular ring of area about the z-axis is $2\pi\ x\ dx$. This flux is reflected to a circular ring of width dL_2 on S_2 whose area is $2\pi X\ dL_2$. The flux density at dL_2 is $\sigma x\ dx/X\ dL_2$. Since $dL_2 = [1 + (dZ/dX)^2]^{1/2}\ dX$, we have the energy balance equation

$$EX[1 + (dZ/dX)^2]^{1/2}\ dX = \sigma x\ dx. \qquad (1)$$

When the receiver surface equation $Z = Z(X)$ is specified, dZ/dX can be evaluated and both sides of Eq. (1) can be integrated.

Although E may be an arbitrary function of position over the receiver surface, it must have an adjustable parameter so that conservation of energy is satisfied. The adjustable parameter in E is obtained by integrating (1) and substituting the limits of integration.

For a flat receiver at $Z = Z_0$, we have

$$\int_{X_0}^{X} EX\ dX = \int_{x_0}^{x} \sigma x\ dx. \qquad (1a)$$

For uniform flux over a flat receiver which fills up according to Fig. 2(a), that is, integrating Eq. (1a) from $X_0 = 0$ to the upper limit of the receiver plane, then E = constant = $E_0 = \sigma(x_f^2 - x_0^2)/X_f^2$. This value of E_0 is substituted into the integrated form of Eq. (1a) to yield the connection between X and x. Thus

$$X = [\sigma(x^2 - x_0^2)/E_0]^{1/2}, \qquad (2)$$

with E_0 given as above. We now write the ray trace equation for a ray connecting coordinates x, z, and X, Z. If $\mathbf{a}$ is a unit vector along a ray incident upon S_1 and $\mathbf{A}$ a unit vector along the reflected ray, we have from the law of reflection

$$\mathbf{A} = \mathbf{a} - 2\mathbf{N}(\mathbf{N} \cdot \mathbf{a})$$

where $\mathbf{N}$ is a unit vector normal to the reflector surface S_1. Since $\mathbf{N} = (z'\mathbf{I} - \mathbf{K})/(1 + z'^2)^{1/2}$ where $z' = dz/dx$,

$$\mathbf{A} = [2z'\mathbf{I} + (z'^2 - 1)\mathbf{K}]/(1 + z'^2).$$

The ray trace equation is then

$$\frac{A_x}{A_z} \equiv \frac{2z'}{z'^2 - 1} = \frac{X - x}{Z_0 - z}. \qquad (3)$$

Abbreviating, $\ell \equiv (z - Z_0)/(x - X)$, Eq. (3) can be solved as a quadratic equation in the vari-

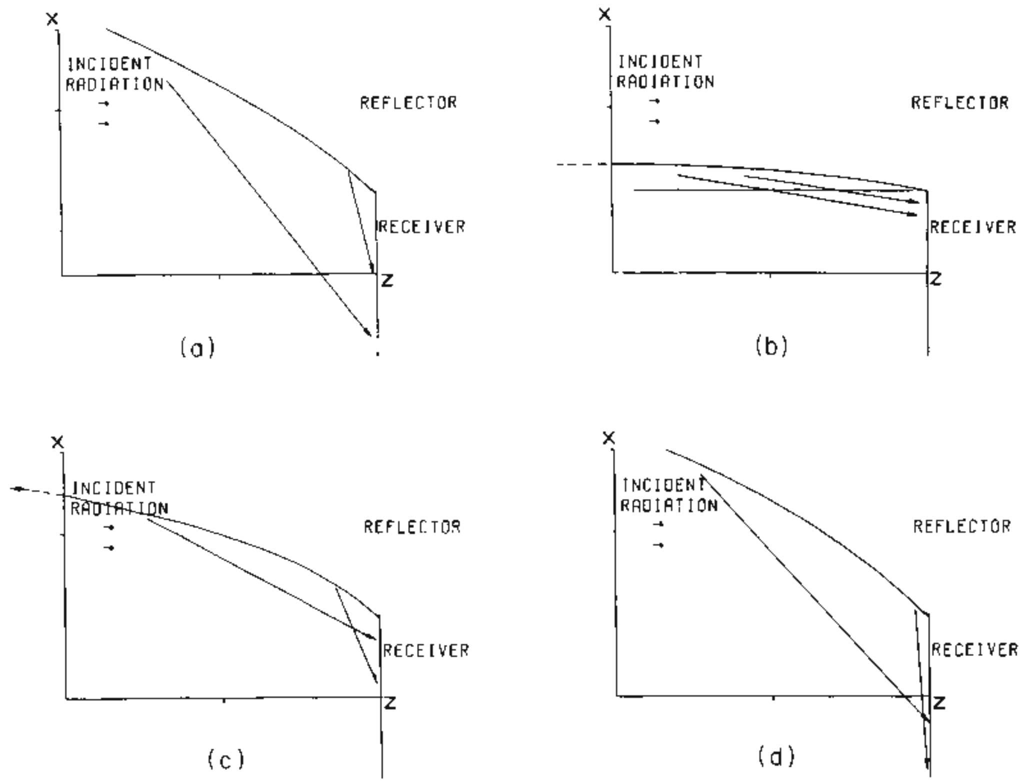

FIG. 2. Various rays in which the light can be reflected to and fill up the receiver base. The limits on the flux conservation integral determined the filling order. One would normally follow graph (a), but the options are shown to emphasize the choice involved.

able z' for the differential equation for the reflecting surface:

$$z' = \ell \pm (1 + \ell^2)^{1/2} \qquad (4)$$

where the +(−) sign is used when the concave side of the reflector is oriented toward the positive (negative) z direction. In the following discussion we shall only consider the − sign in Eq. (4).

Using the energy balance equation (2) to relate X to x,

$$\ell = (z - Z_0)/\{x - [\sigma(x^2 - x_0{}^2)/E_0]^{1/2}\}. \qquad (4a)$$

We can now solve the first-order differential equation (4), usually numerically, to any precision required. The initial conditions are $z = z_0$ when $x = x_0$; these conditions are also involved in the choice of $X_0 = 0$ for the lower limit of integration in Eq. (1a).

Figure 2 shows some of the ways in which reflected light can fill the axially symmetric collector for forward reflection. If the starting and terminating rays are as shown in Fig. 2(a), then the limits on x are x_f to $-X_0$ while X varies from X_0 to 0. In Fig. 2(b) x goes from x_f to $-X_0$ while X goes from 0 to $-X_0$. In Fig. 2(c) x goes from x_f to $-X_0$ while X varies from $-X_0$ to 0. In Fig. 2(d) x goes from x_f to $-X_0$ while X varies from 0 to X_0. X_0 is the radius of the base. The configuration shown in Fig. 2(a) has the widest aperture. The graphs are based on exact calculations for normal incidence on a conical concentrator. The light that reaches the base without reflection must be added to the desired concentration factor.

Two-Dimensional Geometry The preceding equations are modified slightly when light impinges upon a cylindrical reflector with axis perpendicular to the direction of the incident light. The heated surface may be a pipe, for example, parallel to the axis of the reflecting cylinder. We shall write the differential equation of the reflecting surface when the receiver surface is flat. We shall require uniform heating.

The only equation which is changed is the energy balance equation, since the reflector is no longer axially symmetric about an incoming axis. The variable x is now the Cartesian x-coordinate perpendicular to the axis of the trough.

Thus for energy balance

$$\int_{X_0}^{X} E[1 + (dZ/dX)^2]^{1/2}\, dX = \int_{x_0}^{x} \sigma\, dx. \qquad (5)$$

For a flat surface, $dZ/dX = 0$. When the surface is filled in accordance with Fig. 1(a), that is, $X_0 = 0$ when $x = x_0$, we have $X = \sigma(x - x_0)/E_0$. E_0 has the value $E_0 = (x_f - x_0)/X_f$, where x_f is the maximum width of the entrance pupil and X_f is the half-width of the collector. The ray trace equation (3) applies as before; ℓ is now given by

$$\ell = (z - Z_0)/\{x - \sigma(x - x_0)/E_0\}. \qquad (5a)$$

The differential equation for the surface is Eq. (4) as before.

In the preceding discussion the sunlight is assumed to be normal to the aperture. It is possible to specify a given concentration when the sunlight is oblique to the symmetry axes. As the rays approach the symmetry axis the distribution of energy will change. As a limiting case, for the trough, one can specify a delta function concentration along one edge of the base of the trough when the sun rays make some angle, usually 10% or less, with the normal to the base. In this case the reflecting surfaces become parabolas and form the basis for the compound parabolic concentrator.[10] The edge of one side is the focal line for the parabolic surface forming the opposite side. Maximum energy reaches the base, but a hot strip is initially formed along the edge.

If the incident light is parallel to the plane of symmetry of the trough but makes an angle ϕ with respect to the normal to the base, the distribution over the base is attenuated by the obliquity factor cos ϕ but is otherwise unaffected.[11]

SOLAR ENERGY SOURCES

In the past 50 years the birth, the evolution and death of stars have been actively studied. It is now believed that stars form from the interstellar medium. At times hydrogen atoms assemble into condensed clouds, or protostars, under the influence of the gravitational force. This theoretical picture has been confirmed by the observation of localized hot spots of infrared radiation inside regions containing giant molecular clouds. Some of these clouds are so large that they contain thousands of solar masses of gas and dust.

The localized gravitational contraction continues until the pressure and temperature at the center of the protostar become sufficient to ignite thermonuclear reactions in which hydrogen nuclei combine to form helium nuclei. In this fusion process a large amount of energy is released. The star reaches equilibrium when the outward radiation pressure from γ-rays given off in the nuclear reactions is equal to the gravitational force causing the contraction. For a star such as the sun the period of contraction lasts about 100 million years. During this hydrogen burning stage a star is considered to be on the main sequence portion of a Hertzsprung-Russel diagram.[1] Our sun has been a main sequence star for 4.5 billion years and should go on burning hydrogen in this manner for another 5 billion years.

Extremely high temperatures are needed to maintain this hydrogen fusion process, probably above 10 million K. This constraint on the temperature, combined with the requirement for high densities restricts the energy production to the inner 25% of the sun. Here the temperature is probably of the order of 15 million K and the density ranges from about 160 g/cc at the center to about 20 g/cc at the edge of the core region. While 72% of the total mass of the sun is hydrogen, only about 10% of the hydrogen will be used up during the sun's 10-billion-year period on the main sequence.

The pioneering work of Bethe[2] and others over 40 years ago led to our present understanding of the nuclear reactions occurring in the core of the sun. Energy is liberated through several different networks of nuclear reactions which have the end result of combining four hydrogen nuclei into one helium nucleus. The dominant energy production process is thought to be the following proton-proton chain:

$$\text{PP I:}\quad {}^{1}\text{H} + {}^{1}\text{H} \rightarrow {}^{2}\text{D} + \beta^{+} + \nu,$$

$${}^{2}\text{D} + {}^{1}\text{H} \rightarrow {}^{3}\text{He} + \gamma,$$

$${}^{3}\text{He} + {}^{3}\text{He} \rightarrow {}^{4}\text{He} + 2{}^{1}\text{H}.$$

The first reaction involves a positive electron and a neutrino and takes place because of the weak force in nature. The slowness of this reaction process means that this reaction has never been observed in a laboratory experiment. The first and second reactions take place twice for each one of the third reactions. The energy released in the fusion of four protons into helium is 26.7 MeV, with 0.5 taken away by the two neutrinos.

The reaction mechanism PP I is believed to account for about 91% of the sun's energy production. The third step of PP I is not the only way to form ^{4}He. Occasionally (about 8% of the time) ^{4}He is made through intermediate steps involving the formation of ^{7}Be and ^{7}Li:

$$\text{PP II:}\quad {}^{3}\text{He} + {}^{4}\text{He} \rightarrow {}^{7}\text{Be} + \gamma,$$

$${}^{7}\text{Be} + \beta^{-} \rightarrow {}^{7}\text{Li} + \nu,$$

$${}^{7}\text{Li} + {}^{1}\text{H} \rightarrow 2{}^{4}\text{He}.$$

The total energy released in this set of reactions is also 26.7 MeV, including the energy taken away by the neutrino.

^{3}He can also interact with ^{4}He as in the first step of PP II, but then proceed through ^{8}Be as an intermediate state:

$$\text{PP III:}\quad {}^{3}\text{He} + {}^{4}\text{He} \rightarrow {}^{7}\text{Be} + \gamma,$$

$${}^{7}\text{Be} + {}^{1}\text{H} \rightarrow {}^{8}\text{B} + \gamma,$$

$${}^{8}\text{B} \rightarrow {}^{8}\text{Be} + \beta^{+} + \nu,$$

$${}^{8}\text{Be} \rightarrow 2{}^{4}\text{He}.$$

This process occurs less than 1% of the time, so that it is of minor importance from the standpoint of energy production in the sun. However, the highly energetic (14.1 MeV) neutrinos from ^{8}B are of major importance to an ongoing test of the reaction processes in the sun. To date only about one-third of the predicted neutrino flux at the earth is observed.[3] Further experimental tests of this highly important method of looking at the sun's interior are being considered.

Hydrogen burning can also take place in the sun through a cycle involving carbon, nitrogen, and oxygen:

$${}^{12}\text{C} + {}^{1}\text{H} \rightarrow {}^{13}\text{N} + \gamma,$$

$${}^{13}\text{N} \rightarrow {}^{13}\text{C} + \beta^{+} + \nu,$$

$${}^{13}\text{C} + {}^{1}\text{H} \rightarrow {}^{14}\text{N} + \gamma,$$

$${}^{14}\text{N} + {}^{1}\text{H} \rightarrow {}^{15}\text{O} + \gamma,$$

$${}^{15}\text{O} \rightarrow {}^{15}\text{N} + \beta^{+} + \nu,$$

$${}^{15}\text{N} + {}^{1}\text{H} \rightarrow {}^{12}\text{C} + {}^{4}\text{He}.$$

This carbon cycle is a minor contributor to the energy production for the sun, but it is an important source in more massive stars. For these reactions to occur, the temperature in the star's interior must reach more than 20 million K.

What happens when all the hydrogen in the core is converted to helium? As the energy produced in these primary fusion reactions decreases, the radiation pressure from the gamma rays given off is no longer sufficient to counteract the force of gravity and the star's core will contract. As this happens, gravitational potential energy is converted to thermal energy and the temperature rises. This heats up a shell of hydrogen around the core, and the star expands. As the radius of the star increases its temperature decreases, and it takes on the characteristics of a red giant. In about 500 million years the radius of the sun will be larger than that of the earth's orbit, it will have luminosity of the order of 10,000 times its present value, and its surface temperature will be about 4000 K. The core temperature of 100 million K allows three helium nuclei to fuse and form carbon. This helium burning process rapidly uses up the available helium and the star then goes on to the final stages of its existence.

Sunspots at the surface of the sun are manifestations of the dynamic activity taking place inside. Sunspot activity varies from a maximum to a minimum in 5.5 years. Sunspots are associated with a variety of complex phenomena such as magnetic fields, solar flares, and fluctuations in the solar wind of electrified particles from the sun. The origin of sunspots is due to some combination of the sun's magnetic field with its nonuniform rotation. The British astronomer E. W. Maunder discovered that not only do sunspot numbers vary during a cycle, but their location also changes. When the sunspot locations are plotted as a function of time, the migration of spots toward the equator gives rise to a "butterfly" pattern.[5]

One suggestion that has been advanced to account for the absence of solar neutrinos is that the sun is presently undergoing a period of reduced power generation. In 1893 Maunder, after a search through old books and journals, postulated that the sun was not the regular and predictable star that had previously been believed.[6] He found that almost no sunspots were observed during the 70-year period from 1645 to 1715. This study has been verified and extended using a method based on the analysis of the ratio of ^{14}C to ^{12}C in tree rings. Over the past 5000 years it appears that there have been at least 11 other similar minima in the sunspot activity. A detailed comparison of this long-term cycle in sunspot activity with climatological information shows that the sunspot minima appear to correlate very well with lower temperatures in the earth's atmosphere.[7] The Maunder minimum time period, for example, was associated with a period of unusual cold in Europe.

In conclusion, we note that the sun will continue to provide solar energy for the remainder of our existence on earth. Our knowledge of the processes taking place in the sun's interior has grown tremendously in the past half-century. But advances in observational techniques have also raised a number of new and interesting features. Obtaining an understanding of these new dynamical phenomena will keep scientists occupied for many years to come.

SOLAR ENERGY UTILIZATION

The use of solar energy is becoming increasingly important both on earth, because of the rapidly diminishing supplies of fossil fuels, and in man's expanding adventures into space.[1] The problem of economically using solar energy for various terrestrial needs has challenged us for many years, but there are still only a few economically attractive applications. For space applications, where reliability and weight are generally much more important than cost, silicon photovoltaic power supplies already have found extensive use.

The Sun as an Energy Source Our sun is a typical main sequence dwarf of spectral class G-2. In almost every respect (size, luminosity, mass, etc.), it is an average star. The mean distance from the earth is 93 004 000 miles, at which distance the sun subtends an angle of 31 minutes 59 seconds.

The sun's total radiation output is approximately equivalent to that of a blackbody at 10 350°R (5750 K). However, its maximum intensity occurs at a wavelength which corresponds to a temperature of 11 070°R (6150 K) as given by Wien's displacement law. Figure 1(a) presents the intensity of solar radiation outside the earth's atmosphere as a function of wavelength. The total irradiance at the mean sun-earth distance is approximately 442 Btu/hr ft^2 (0.140 watts/cm^2). Figure 1(b) shows how the energy in the sun's spectrum is distributed.

Sunlight passing through the atmosphere suffers both absorption and scattering. The solar irradiance reaching the earth depends upon the total air mass through which the sun's radiation passes and, of course, weather conditions. Figure 1(c) shows a typical plot of the solar irradiance at the earth's surface. For some applications, the radiation from the sky is also important. The day sky exhibits wide variations in brightness and in spectral distribution, depending upon the sun's position, weather conditions, and the "receiver's" orientation. Table 1 presents tyical values of direct and diffuse solar radiation for several different atmospheric conditions. A great deal of study has been made of the variation of the solar irradiance at the earth's surface with weather, atmospheric conditions, zenith angle of the sun, etc.[2]

Uses for Solar Energy Table 2 lists most types of application of solar energy of interest today. They are grouped according to the form of energy required by the application. As an example, supplying electrical power for space vehicles requires a conversion from solar to electrical energy which may be a one-step process with photovoltaic cells (solar cells) or a multistep process. A typical multistep process might involve conversion of solar energy to thermal energy by using a parabolic mirror to heat a working fluid in a boiler, then conversion to mechanical energy using a Stirling engine, and then conversion to electrical power using a generator.

Considerations in the Conversion of Solar Energy to Other Forms Table 2 indicates that most of the applications of solar energy require that the energy be delivered in one of four forms: thermal, electrical, mechanical, or chemical. Table 3(a) shows several methods of directly converting solar energy to these other forms.

Table 3(b) shows additional conversion steps that might be used in a multistep process. The devices described in Table 3(b) make use of processes which are well known and not restricted to solar energy utilization. Those in Table 3(a), on the other hand, are of prime interest to the present discussion.

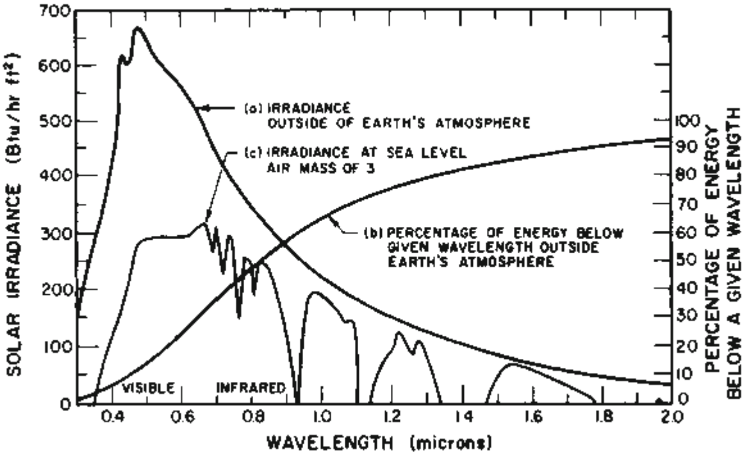

FIG. 1. Spectral distribution of solar energy.

Conversion of Solar Energy to Thermal Energy. Many of the systems which utilize solar energy first collect the energy and its heat. A solar heat collector intercepts radiation, converting this to thermal energy, and transfers this heat to a working fluid. Some collectors use mirrors or lenses to achieve high flux densities (concentrating collectors) while others do not (flat-plate collectors).

Flat-plate Collectors. The most common flat-plate collector consists of a metal plate painted black on the side facing the sun and thermally insulated on the edges and back. Above the plate, spaced on inch or so apart, are one or more glass or plastic covers to reduce upward heat losses. The absorbed energy is transferred to water or some other working fluid in tubes which are in thermal contact with the absorber plate or by circulating air past the absorber. Figure 2 displays several flat-plate collector designs. Design 2(b) is the conventional type described above; 2(a) uses air instead of water for heat transfer. In 2(c), the glass-shingle collector, heat is absorbed on the blackened bottom third of tilted glass plates and transferred to the air drawn down through these shingles.

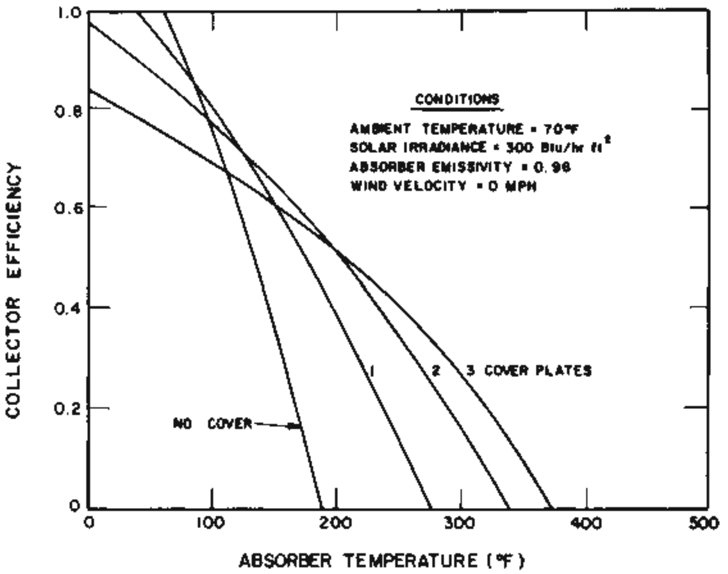

FIG. 3. Calculated performance of flat-plate collectors showing effect of multiple glass covers.

of conventional collectors are shown in Fig. 3. The emissivity and absorptance of the absorber plate was assumed to be 0.96, and the curves were plotted for zero, one, two, and three cover plates of typical single-strength window glass.[3] It is seen that for high efficiencies (with correspondingly low collector temperatures), it might be preferable to have only one or two covers. As an example, a two-cover collector is preferable to a three-cover collector out to a temperature of about 200 F (for the case analyzed); it is only at higher temperatures that the decrease in upward losses made by using one more cover is greater than the transmission loss of that cover.

Concentrating Collectors. An optical system using lenses or mirrors can be used to concentrate solar radiation into a very small area. If this energy is received into a cavity or absorbed on a metal plate, heat is generated and very high temperatures may be obtained.

The concentration ratio C is defined as the ratio of the flux density within the image of the sun formed by the optical system to the actual flux density reflected from the mirror. For a parabolic mirror, C is given by[4]

$$C = \frac{\sin^2 \theta}{\tan^2 \phi/2} \tag{1}$$

where θ is the rim angle of the mirror as defined by the sketch in Fig. 4 and ϕ is the angle subtended by the sun from the earth. Using $\phi =$ 32′,

$$C = 46.2 \times 10^3 \sin^2 \theta. \tag{2}$$

Figure 4 plots Eq. (2) and also a parameter called concentration efficiency which is defined as the ratio of the power received, within the sun's image to the total power reflected by the mirror. For the parabolic mirror, the concentration efficiency is given by

$$\eta_c = \left(\frac{1 + \cos \theta}{2}\right)^2. \tag{3}$$

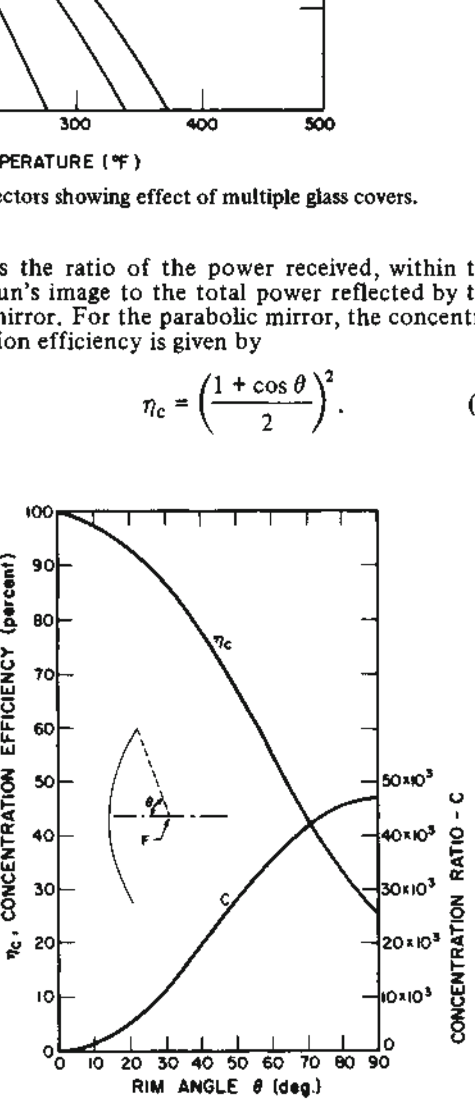

FIG. 4. Concentration ratio and concentration efficiency as a function of rim angle for a paraboloidal reflector.

The concentration ratio and the concentration efficiency are strongly influenced by the geometric perfection of the mirror and the location of the absorber with respect to the focus of the mirror.

Consider an example where the energy reflected from a parabolic mirror is collected by an ideal cavity receiver having an opening equal to the image diameter of the sun. The rate at which heat energy can be withdrawn from the cavity, P, can be calculated by substracting the radiative heat losses from the input flux. The result is:

$$P = \eta_c A \left[rH - \frac{\sigma T^4}{c} \right] \tag{4}$$

where A is the projected area of the mirror, r is its reflectance and H is the solar irradiance. T is the temperature of the cavity. Figure 5 uses Eq. (4) to plot the ratio of P/A as a function of cavity temperature for several rim angles. The intersection of the curves with the abscissa show the maximum attainable temperature for various rim angles, corresponding to $P = 0$ in Eq. (4).

A variety of optical systems has been studied for use as solar concentrators with various absorbers.[5,6] The parabolic mirror-cavity receiver example, however, is indicative of the ultimate performance attainable.

Conversion of Solar Energy to Electrical Energy. The PHOTOVOLTAIC EFFECT, particularly in silicon, has become very important to solar energy utilization. In the silicon "solar cell," photons create hole-electron pairs by removing electrons from valence bonds. This occurs in the junction region between p-type and n-type silicon where the electric field causes a current to flow in the cell. Equilibrium is restored by charge flowing around an external circuit through a load resistor.

Each silicon nucleus shares its four valence electrons with neighboring nuclei forming a stable tetrahedral crystal. In the junction region, most of the electrons are in the lower filled band, below the forbidden energy band. The electron may be thought of as either bound to a crystal lattice region or, with the addition of enough energy, free to move about and conduct electricity. The width of the forbidden region, or energy gap, represents the threshold energy necessary to remove an electron from the bound position to the conduction band. For silicon, the energy gap is approximately 1.1 eV. It follows that only photons of 1.1 eV or over can create hole-electron pairs in silicon. Higher-energy photons can create hole-electron pairs with the excess energy being dissipated as heat (see ENERGY LEVELS and SEMICONDUCTORS).

Since, at most, one hole-electron pair can be created for each photon possessing sufficient energy to do so, the ultimate efficiency that might be achieved depends upon the threshold energy at which the hole-electron conversion takes place and upon the spectrum of the radiation. Figure 6 is the plot of the maximum power conversion efficiency as a function of threshold level. It assumes that all of the photons whose energy is greater than or equal to the threshold energy are converted into hole-electron pairs at the potential of the energy gap.

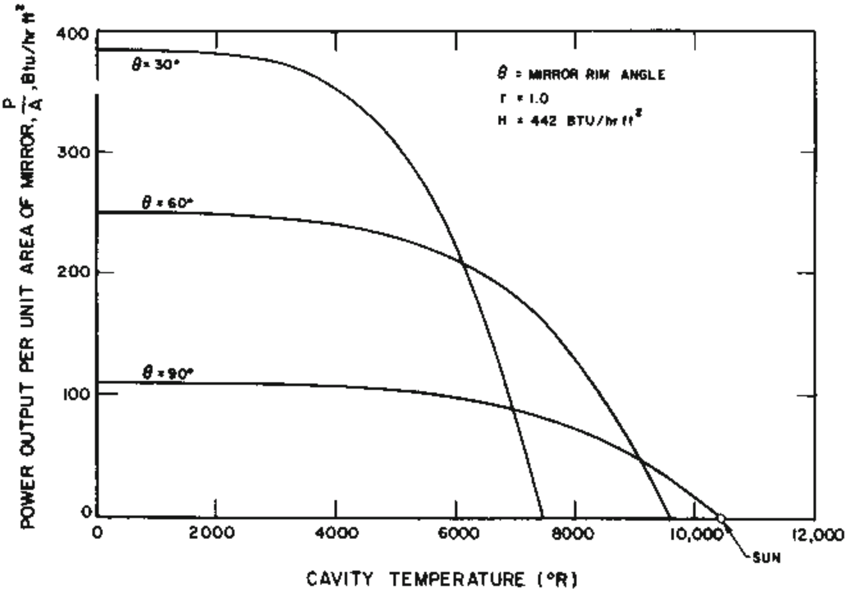

FIG. 5. Maximum power output from an ideal parabolic mirror-cavity absorber as a function of operating temperature.

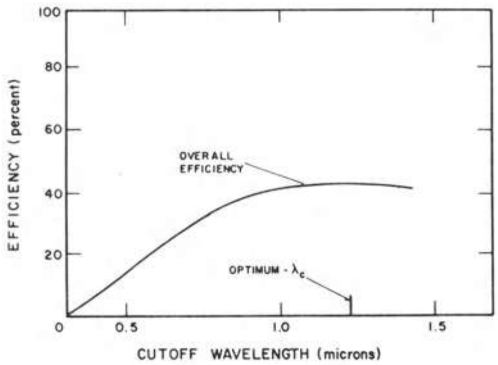

FIG. 6. Maximum solar conversion efficiency of an ideal quantum converter.

Some of the factors which limit the efficiency in a practical cell include:

(1) Some hole-electron pairs recombine before they can be separated by the field in the junction,

(2) Reflection losses from the front surface,

(3) Loss due to electrical resistance within the cell, and

(4) Loss due to leakage across the barrier (diode current).

In full sunlight, a good single-crystal silicon solar cell will operate at 12–16%; 20% cells have been demonstrated. Efficiencies well over 20% have been demonstrated for single-crystal gallium arsenide cells, although these are at present more expensive to manufacture than silicon.

For terrestrial applications, two basically different approaches are being pursued to reduce the cost per unit power output:

- Developing low-cost ways to manufacture single-crystal materials, including growth of silicon ribbons,
- Improving the efficiency of polycrystalline and thin-film cells, which are believed to be inherently cheaper to manufacture.

Thin-film cells have been demonstrated using silicon, silicon/fluorene/hydrogen compounds and mixtures of cadmium sulfide with copper sulfide.[7,8]

Figure 7 is a photograph of one of the solar panels used on the Ranger Spacecraft developed for NASA's Jet Propulsion Laboratory. The panel contains 72 strings of 68 cells each to provide 100 watts output at approximately 30 volts. The use of optical filters to cover the cells results in a lower cell temperature, hence higher efficiency, and provides improved resistance to radiation damage.[9]

Conversion of Solar to Mechanical Energy. Solar radiation incident upon a reflecting surface exerts a radiation pressure of approximately 0.8×10^{-4} dynes/cm^2 or 1.7×10^{-7} lb/ft^2. Although impractical for terrestrial applications, the use of radiation pressure for space propulsion (solar sailing) may prove to be worthwhile for some missions.

Conversion of Solar Energy to Chemical Energy. It has been estimated that only a few

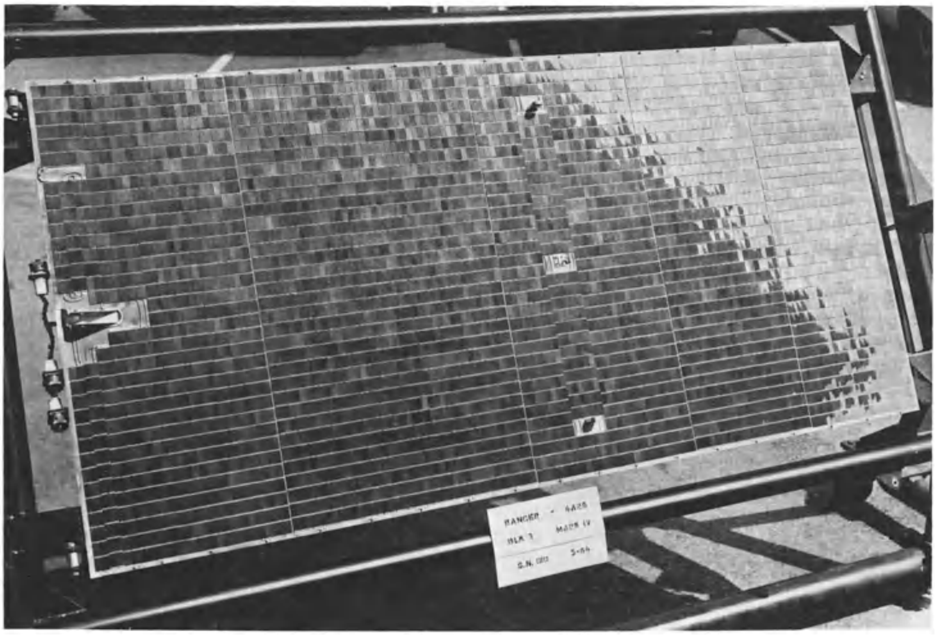

FIG. 7. Ranger spacecraft solar cell panel. (*Photograph courtesy Electro-Optical Systems, Inc.*

tenths of a per cent of a year's supply of incident solar energy is stored in an average farm crop. Research into the mass production of algae has been directed toward tenfold greater yields; research in other types of plants, toward the end of increasing photosynthetic efficiency, is also being conducted.[10]

The existence of photosynthesis raises the hope that other photochemical reactions will be found which can be effectively used to obtain chemical energy from the sun. What is needed is a reversible endothermic photochemical reaction which can utilize a large portion of the sun's spectrum. Most photochemical reactions evolve heat instead of absorbing it, or they reverse so quickly that the energy is lost even during exposure to sunlight.

Solar-hydrogen generators have long been of interest because of the potential advantages of using hydrogen as a fuel, either directly or in a fuel cell to produce electricity. Water is photochemically decomposed into hydrogen by ultraviolet light, though at very low efficiency. Two approaches that promise higher efficiency are[11,12,13]

- Chlorophyll-like metal organic compounds that create hydrogen through photosynthesis,
- Photovoltaic semiconductor cells that operate in water or in other hydrogen compounds to generate sufficient potential for hydrolysis.

The first approach uses molecules like zinc metalporphyrine as catalytic agents in the reaction. Present research efforts are directed to minimizing unwanted side reactions, thus permitting hydrogen production to continue for months or years. The second approach uses a suitable liquid electrolye and semiconductor combination. The *p-n* junction may be formed either by diffusion or at the liquid-semiconductor interface (e.g., cadmium selenide with a sulfaselenide solution).[14]

Unfortunately, 50% of the sun's energy is at wavelengths too long to be of much use for photochemical reactions, since the energy per photon is too low. All molecules which undergo photochemical change have a minimum threshold energy required to create a bond rupture. If a quantum is absorbed with energy above this threshold, the excess energy is dissipated (as kinetic, vibrational, etc.) and usually does not contribute to the conversion to chemical energy. The maximum theoretical efficiency of conversion of solar to chemical energy can be evaluated with the help of Fig. 6 providing the cutoff wavelength is known.

Current Progress Interested readers are directed to the references listed and current articles in two journals: (1) the *Journal of Solar Energy Engineering*, published quarterly by the American Society of Mechanical Engineers; and (2) *Solar Energy*, published monthly by Pergamon Press for the International Solar Energy Society. Progress on Federal solar energy programs is reported by the Solar Energy Research Institute in their annual reviews, published by the U.S. Government Printing Office.

In addition, solar energy handbooks have begun to appear which represent useful gatherings of information.[15,16]

SOLAR PHYSICS

The main activity of solar physics is the interpretation of the observed flow of energy away from the sun. Most of the sun's energy output appears as a nearly constant flux of electromagnetic radiation in the photographic, visual, and infrared regions of the spectrum, but extraordinary variations are characteristic of the x-, ultraviolet, and radio radiation. A small part of the sun's energy flows outward in highly variable streams of particles (mainly protons and electrons). Since the sun appears as a rather large disk, the observations forming the bases for the solar physicist's interpretations often refer to small areas of the solar surface, as well as the integrated radiation and particle streams from the entire sun. A reasonably good solar telescope can subdivide the apparent disk of the sun into about three million smaller elements of area. Streams of particles and radiation from each of these elements should be recorded, with all possible detail and precision, nearly continuously for a complete observational record. A close approach to such observational perfection probably is unattainable, perhaps it is unnecessary, but the fragmentary and incomplete nature of all solar observations continues to be a serious barrier in the search for a satisfactory general theory of the sun. Some progress has been made, but until an adequate theory is developed, it is best to consider the physics of the sun by reviewing the observations of possible importance.

The radius, mass, and luminosity of the sun are fundamental in the physical interpretation of the sun. Luckily, they can all be deduced with reasonable directness from observations. In principle, the radius of the sun can be obtained directly from angular and linear observations made on earth, but a number of practical difficulties limit the attainable precision. Somewhat devious methods, invoking gravitational theory, give more consistent results that converge on the value,

$$\text{Radius of the sun, } R = 6.9598 \pm 0.007 \times 10^{10} \text{ cm}$$

The mass of the sun is also derived from the application of gravitational theory: first, to the measurement of the mass of the earth; then, by way of the moon and planets, to the sun; with the result,

$$\text{Mass of the sun, } M = 1.989 \pm 0.002 \times 10^{33} \text{ grams}$$

A measurement of the total radiation received at the earth's distance from the sun is the basic observation from which its luminosity can be found (once the distance to the sun, and the radius of the sun are known). This measurement is extremely difficult and is seriously distorted by the earth's atmosphere, but the value

$$\text{Luminosity of the sun, } L = 3.90 \pm 0.04 \times 10^{33} \text{ ergs/sec}$$

can be derived from long, independent series of observations. The difficulties caused by the earth's atmosphere can be eliminated if observations are made from a space vehicle and measurements have been made in that way. After such data have accumulated over an interval of at least decades, perhaps the observed value of L can be evaluated with greater precision.

An additional parameter, or series of numbers, is essential for the construction of an adequate theoretical model sun. These are the abundances of the chemical elements. For convenience, abundances are stated in terms of the abundance of hydrogen. In the sun, the relative abundances of the important constituents are

$$\left.\begin{aligned}\text{Hydrogen} &= 1.00\\ \text{Helium} &= 0.23\\ Z\ (\text{all other elements}) &= 0.02\end{aligned}\right\}\ Q\text{, the relative chemical abundance}$$

The values of L, M, R, Q, deduced from observation for the sun, are somewhere near the middle of ranges of these quantities as derived for other stars. It is, therefore, sometimes said that the sun is an average star, but for the stars inside an imaginary spherical shell surrounding the sun, with a radius so small that it is reasonably certain that all stars within the enclosed volume have been observed, a different interpretation is valid. Most of the stars close to the sun are cool, red, dwarf stars, probably the most numerous of all stellar varieties. Only ten of the fifty-five nearest stars can be seen with the eye alone. Only three of these stars are brighter than the sun, most are exceedingly faint. Stars brighter than the sun are extremely rare, and the sun is outstanding in all of its properties.

Although the sun's L, M, R, and Q can be fitted into a coherent physical theory which, starting with a plausible nuclear energy source contained within a relatively small volume surrounding the sun's center, can trace the outward flow of energy from the deep interior through complicated transformations until quantities and qualities of radiation in adequate but limited agreement with observation are predicted at the solar surface, there is an outstanding exception. The flux of neutrinos measured at the earth is only about half as large as it should be in order to agree with the flux to be expected from a proton-proton reaction that is otherwise suitable as the source of solar radiation.

The synoptic general agreement of solar theory with observation, and the persistence of discordant details is well attested by almost innumerable studies concerned with the three visible subdivisions of the sun: the photosphere, the chromosphere, and the corona.

The photosphere of the sun is the surface observed directly by the eye through a protective dense black glass screen. In very transparent skies with the help of special telescopes or at times of total solar eclipses, the chromosphere and corona may also be observed visually. All three of these layers show structures in widely different sizes and rates of change. The theoretical problems connected with the photosphere-chromosphere and the chromosphere-corona interfaces are nearly intractable, and the individual layers are understood only slightly better.

Nearly three centuries of telescopic observation of the solar photosphere define this part of the sun as that imaged on a photographic plate, or seen by the eye, using the light in a spectral band at least 1000Å wide, centered near 5000Å in the blue-green part of the spectrum. The portion of the sun thus recorded is a spherical shell, 5×10^8 cm thick, whose outer radius is the edge of the apparent solar disk, 7×10^{10} cm from the sun's center. Good photospheric photographs show a granulation composed of small (10^8 cm, or less) bright, circular, or hexagonal, structures all over the sun except extremely near the edge. These are the tops of convection cells that carry much of the solar energy. They are a few hundred degrees hotter than the five-thousand-plus degrees absolute that is consistent with the sun's assigned total luminosity. Occasionally, small dark spots (pores) appear among the granulations, and still more infrequently, a pore will develop into a larger dark complex, a sunspot region. Spot regions are some thousands of degrees cooler than the granulated photosphere in which they are immersed. They mark the locations of sizable magnetic fields, and the spot regions may cover some tenths of the sun's disk. Since the spot regions are nearly fixed on the solar surface, they may also be used as markers for the measurement of the rate of rotation of the sun.

The angular rate of rotation, deduced from sunspot, or spectroscopic, observations, varies from the sun's equator to its poles. It is greatest on the equator, there corresponding to a period of rotation of twenty-five days. At the pole the period of rotation is nearly thirty-five days.

Sunspots are the main sources of difficult problems of the photosphere. How can the refrigeration of the spot regions be explained? What is the origin of the magnetic fields? How is the distribution of angular velocities established, and how is it maintained?

The chromosphere is most easily observed at times of total solar eclipse. It appears as a red-purple narrow irregular ring just after the beginning and again just before the ending of totality. The average thickness of the chromospheric layer is 10^9 cm, but it is so tenuous that it is undetectable under conditions satisfactory for observation of the photosphere. For the daily observation of the chromosphere, a filter transmitting a spectral band not wider than 1 Å must be used to produce monochromatic solar images, and the center of the spectral band transmitted by the filter must be adjusted to coincide with the center of an emission line that appears strongly in the spectrum of the chromosphere. Nearly all observations of the chromosphere are made with light from the center of just two spectrum lines: the H-alpha line of hydrogen in the red part of the spectrum; and the K line of ionized calcium in the ultraviolet. The pictures show the chromosphere as a continually seething part of the solar atmosphere, subject to spectacularly sudden changes in the neighborhood of sunspots. The changes in the chromosphere and the dominating changes that occur in the underlying sunspots are considered together as the phenomenon of *solar activity*.

Long before regular observation of the chromosphere became possible, records of the numbers of sunspots had led to the discovery of a ten-year cycle of variation. As solar observation has become more nearly continuous, nearly every aspect of the sun's activity has revealed cyclical behavior closely synchronized with the variation in the numbers of spots. This is especially true for the changes in the chromosphere. The solar flares and extensive systems of solar prominences in the chromosphere are apparently organized and controlled by the magnetic fields rooted in the sunspot regions.

However, the smallest structures in the chromosphere are not obviously connected with sunspot activity. The smallest features in undisturbed solar areas far from the dominance of spot regions undergo damped oscillations that are nearly periodic with characteristic times of about three hundred seconds. Perhaps these motions are enforced by the somewhat slower changes observed in the photospheric granulations on which the chromospheric structures are based. These and other quasi-periodic motions in the sun's outer layers can be observed continuously for long intervals and analyzed, somewhat as earthquake data are used, to yield information about subsurface solar conditions.

Like the chromosphere, the corona can only be observed with the unaided eye at the time of a total solar eclipse, but with telescopic, spectroscopic, and other instrumental aids, it can be observed every day. It is the most extensive of the divisions of the sun's atmosphere, its outer limits lying somewhere beyond the distance of the earth from the sun where the corona becomes indistinguishable from the interplanetary medium. The corona changes both gradually and suddenly in rather sensitive connection with the spot regions. It is the principal source of the sun's x-rays, extreme ultraviolet, and radio emission, and the combination of satellite observations near the short-wavelength limit of the solar spectrum and radio observations at the other end of the spectrum results in an attractive qualitative picture of solar activity.

At times when solar flares flash out in active regions, generally near sunspots, observations in the x-ray and radio sections of the solar spectrum can be interpreted as indicating motion of a disturbance starting away from the sun at the beginning of the flare and moving outward through the chromosphere and corona. Gamma radiation has been detected in some flares—certain evidence for nuclear transformations occurring near the photosphere or chromosphere. Frequently, streams of particles associated with the flare activity reach earth, and are detected as cosmic rays and by their secondary effects such as terrestrial magnetic storms, but many of the changes induced in the corona by activity in spot regions seem to be connected with variations in local solar magnetic fields and not with streams of particles.

It may be evident from this synopsis that the broad results from intensive solar observations, covering more than a century, have been accompanied by coordinating solar theories which are most satisfactory for parts of the sun inaccessible to direct observation. The attainable precision in solar observation narrowly limits the range of acceptable theoretical solutions, and especially limits attempts to combine hypotheses describing solar details into consistent synoptic theory. The neutrino anomaly indicates clearly a need for a careful reconciliation between the solar nuclear energy sources and their physical environment. Furthermore, there are two apparently fundamental phenomena for which no theoretical explanation has appeared: (1) How is the observed variation of angular rotation from the sun's equator to its poles to be explained? (2) What is the theory that includes the entire range of sunspot phenomena?

New results, flooding from new observatories and the exploratory applications of rockets and space technologies to solar studies have emphasized the persistence of unsolved problems and the remarkable opportunities for contributions to observational and theoretical solar physics.

SOLAR TOTAL IRRADIANCE AND ITS SPECTRAL DISTRIBUTION

Introduction The nature of the emission of radiation by the sun is of overriding importance to every life-form on earth. Interactions of the earth's atmosphere, oceans, and land masses with the sun's radiation completely determine the earth's weather and climate. Sustained variations in the total solar energy received by the earth from the sun, the *solar total irradiance*, would have significant effects on both. Variations of solar total irradiance were probably the cause of some of the many past climate changes. Variations of the spectral distribution of solar irradiance have significance for photochemical and thermodynamic processes in the earth's atmosphere.

In spite of its importance, solar irradiance has not been systematically measured in the past. Total irradiance observations with the precision required by climate studies did not begin until 1980. The solar spectrum in the 0.4–4.0 micrometer (μm) wavelength range, containing 90% of the total solar energy, has never been measured with the accuracy or precision required by modern atmospheric science.

The following sections will discuss the present knowledge of the absolute radiation scale, the solar total and spectral irradiance, and the significance of recent discoveries of solar irradiance variability.

Pyrheliometry and Radiation Scales The science of measuring total solar irradiance is *pyrheliometry*, derived from the Greek words *pyr* (heat), *helios* (sun) and *meter* (to measure). The instruments used to "measure the heat of the sun" are referred to as *pyrheliometers* or *radiometers*. Two basic types have been commonly used in solar observations. The first is an absolute or self-calibrating detector which can accurately relate radiation measurements to the International System of units (SI) by its standalone operation. The second basic type is a relative detector that simply provides a signal in response to solar heating and must be calibrated by comparison with a self-calibrating pyrheliometer or standard radiation source to produce a quantitative result in SI units.

Several radiation "scales" have been used during the 20th Century for referencing solar irradiance measurements to SI units. Each was based on the performance of electrically self-calibrated pyrheliometers, the most accurate standards of radiation measurement at the solar total irradiance level. The Angstrom scale, defined in 1905 and based on the performance of the Swedish Angstrom pyrheliometer, was widely used in Europe to reference meteorological solar irradiance measurements. Electrically self-calibrated cavity pyrheliometers developed in the U.S. at the Smithsonian Institution were the references for the 1913 Smithsonian scale used as the standard for their long-term program to detect solar variability from mountaintop observatories. Solar observations on the two scales differed by about 5% until a downward revision of the Smithsonian scale in 1932 reconciled them to within 2.5%. The Angstrom 1905 scale was perpetuated under the name of the International Pyrheliometric Scale of 1956 (IPS56), adopted by international agreement in that year to provide a common reference for solar irradiance measurements during the International Geophysical Year (1957–58). The IPS56 was employed as the principal international reference for solar observations from 1956 until the mid-1970s.

A new generation of electrically self-calibrating cavity pyrheliometers was developed in the latter half of the 1960s at several laboratories in the U.S. and Europe. Radiation scale experiments in the U.S. at the Jet Propulsion Laboratory's Table Mountain Observatory (1968–69) discovered a -2.2% systematic error in the IPS56, placing the absolute radiation scale within 0.5% of the 1932 revision of the Smithsonian scale. The error was confirmed by the First International Comparison of Absolute Cavity Pyrheliometers, convened at the Physical Meteorological Observatory of Davos (PMOD), in Switzerland, in 1975. A new solar irradiance reference scale was defined that incorporated this result, the World Radiometric Reference (WRR), defined by the average performance of five of the new pyrheliometers, as shown in Table 1. Measurements referenced to the WRR are uncertain by less than 0.3% in SI units. Newer versions of the WRR defining pyrheliometric instrumentation developed since 1975 have the theoretical capability of defining the radiation scale at the solar total irradiance level with less than ± 0.1% uncertainty. Experimental verification of this achievement is the present focus of pyrheliometry.

Solar Total Irradiance *Long-Term Solar Variability.* A systematic long-term solar variability monitoring program was conducted by the Smithsonian Institution during the first half of the 20th Century. Their measurements from mountaintop observatories, limited to a long-term precision of about 1% by fluctuations in atmospheric transmittance, provided no clear evidence of solar variability.

Experiments by the U.S. and U.S.S.R. on high-altitude aircraft and balloons in the 1960s were unable to produce unambiguous evidence of solar irradiance variability despite decreased uncertainties in atmospheric transmittance. The precision and accuracy of their results was not significantly better than the Smithsonian ground-based measurements, a limitation imposed mainly by the failure to employ self-calibrated flight instrumentation.

The results from solar total irradiance flight experiments that have contributed significantly to the present understanding of solar variability are described below and summarized in Table 2. The solar total irradiance outside the earth's atmosphere (*S*) is expressed in units of

TABLE 1. RESULTS OF THE FIRST INTERNATIONAL COMPARISON OF ABSOLUTE CAVITY RADIOMETERS (1975). The relative performance for the five cavity pyrheliometers whose average weighted results are used to define the World Radiometric Reference Scale (WRR) are shown.

SUMMARY

Type of Flight Experiment	Average 1 A.U. Irradiance (W/m^2)	Standard Deviation (1 sigma in %)
ESCC	1367.5	0.06
ESCC, ESCC/P, ESCC/PF	1368.4	0.26
ALL	1370.5	0.50

*Experiment approach for relating observations to the International System of Units listed in descending order of accuracy: ESCC = electrically self-calibrated cavity fully implemented in flight; ESCC/P indicates partial implementation of ESCC in flight; ESCC/PF indicates pre-flight electrical self-calibration only; the NIMBUS 6/ERB thermopile was a flat-plate sensor without self-calibration capability.

**The average of the 11 ESCC observations was chosen as the basis for the long-term variation study described in the text because they use the most accurate measurement approach and span the 11-year period covered by the table.

***The NIMBUS 7/ERB results have recently been scaled down, resulting in an average result for the 3.5 years' observations of 1372.6 W/m^2.

watts per square meter (W/m^2) at 1 astronomical unit (1 AU), the average annual distance between the earth and the sun. S has been referred to as the *solar constant*. In view of the solar variability discovered in recent experiments, this is no longer an appropriate characterization.

Solar monitoring with SI uncertainty smaller than 1% began in the late 1960s following development of a new generation of electrically self-calibrated cavity pyrheliometers. The first flight observations of solar total irradiance by these new instruments were made by the Jet Propulsion Laboratory in 1968–69. Willson's Active Cavity Radiometer (ACR) experiment on a high altitude balloon in 1969 yielded S = 1366 W/m^2, with an uncertainty less than ±0.3%. The first extended measurements by self-calibrated cavity pyrheliometers outside the earth's atmosphere were made the same year by Plamondon's TCFM experiments on NASA's Mariner 6 and 7 spacecraft. An uncertainty of ±1% was quoted for the S = 1363 W/m^2 TCFM result.

The first long-term solar irradiance flight observations were made by Hickey's Earth Radiation Budget (ERB) experiment on the Nimbus 6 satellite between mid-1975 and late 1978. The S = 1389 W/m^2 result quoted for ERB exceeded the 1969 JPL/ACR result by 1.7%. The first of a series of NASA solar irradiance rocket experiments, conducted in 1976 to provide an independent calibration of the NIMBUS 6 ERB solar measurements, found ERB's calibration to be 1.6% higher than SI units. This reconciled the NIMBUS 6/ERB measurements with the 1969 ACR results, to within the latter's SI uncertainty, eliminating the possibility of a detectable change in solar output between the experiments.

The NIMBUS 7 ERB experiment, launched in late 1978, included a Hickey-Friedan (HF) electrically self-calibrating cavity detector capable of greater accuracy and long-term precision than the NIMBUS 6/ERB thermopile. The average result of $S = 1376$ W/m^2 quoted by Hickey for NIMBUS 7/ERB was 0.6% higher than the SI corrected NIMBUS 6 result. A 1978 NASA rocket experiment found the difference to be due to calibration error and not evidence for a change in solar irradiance (see Figs. 1 and 2).

A high-altitude balloon-borne solar total irradiance experiment was conducted by the Swiss Physical Meteorological Observatory (PMO) in mid-1979. The $S = 1366$ W/m^2 (±0.2%) result quoted by Frohlich and Brusa for the experiment is close to the average of the JPL/ACR balloon and rocket results.

The Active Cavity Radiometer Irradiance Monitor I (ACRIM I) experiment, launched on NASA's Solar Maximum Mission (SMM) in early 1980, was the first dedicated satellite experiment for monitoring the long-term variability of solar total irradiance. The average result quoted by Willson for its first two years of operation was $S = 1367.8$ W/m^2 (see Figs. 1 and 2).

A third NASA rocket flight was conducted in May 1980 to provide the first calibration of the SMM/ACRIM I experiment and the second of the NIMBUS 7 ERB. The results for the five ACR's involved in the experiment (three on the SMM/ACRIM I and two on the rocket) were within ±0.05% of their average value of 1367.7 W/m^2. The NIMBUS 7 ERB measurement exceeded the ACR result by 0.6%, the same difference found by the 1978 rocket experiment.

A second PMO high-altitude balloon flight experiment conducted by Frohlich and Brusa in June 1980 found $S = 1366.8$ W/m^2, less than 0.1% lower than the 1980 average result for the rocket and SMM ACR experiments.

The most accurate and precise solar irradiance observations are those made by experiments with fully implemented electrically self-calibrating cavity detectors, denoted as ESCC in Table 2. These experiments operate in the differential active cavity radiometer mode. Constant relative temperatures are sustained within the instruments at all times and self-calibration occurs during a shutter closed period between each one-minute observation period, minimizing errors due to slowly varying electrical or thermal properties.

The partially implemented self-calibrating cavity (ESCC/P) instruments calibrate periodically in flight. The Mariner/TCFM was self-

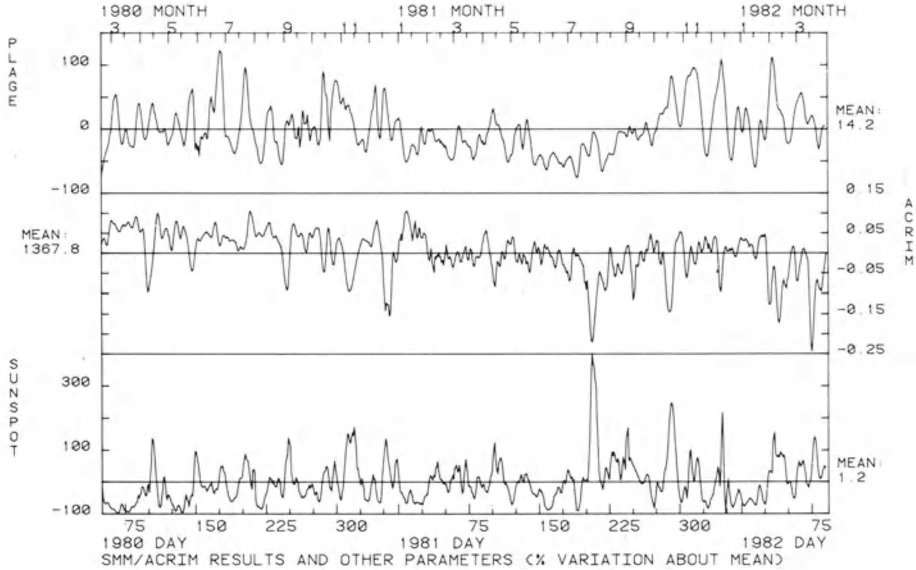

FIG. 1. Comparative plot of the total solar irradiance at 1 AU measured by the SMM/ACRIM experiment (middle panel), together with two indices of solar activity: the plage and sunspot areas (from the NOAA compilation in "Solar Geophysical Data"). The scales for the plots are in percentage variation about their means. The means are in units of W/m^2 for irradiance and thousandths of the solar disk area for plage and sunspot areas. Gaps in these data have been filled by linear interpolation over missing segments, and smoothing has been employed using a 3-day running mean to emphasize the variability on longer timescales appropriate to the evolution of solar active regions. The Calcium plage areas have been taken as an indication of the area of photospheric faculae, for which there are no regular observations.

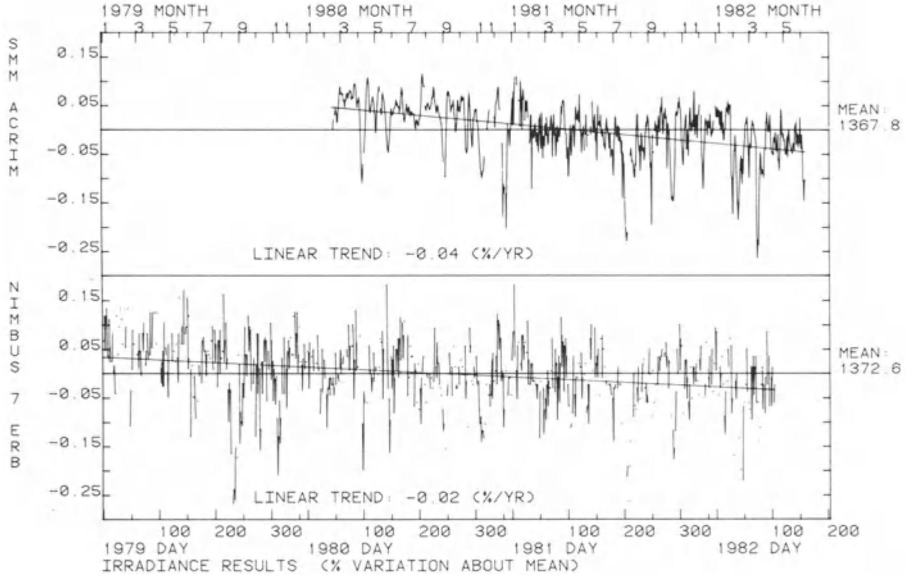

FIG. 2. Extended solar total irradiance observations from two satellite experiments. The daily mean irradiances at 1 AU measured by the Active Cavity Radiometer Irradiance Monitor experiment on the Solar Maximum Mission (SMM/ACRIM) and by the Earth Radiation Budget experiment on the NIMBUS 7 satellite (NIMBUS 7/ERB) are compared. The irradiances are plotted as the percentage variation about the means (shown in units of W/m^2). The daily means have been connected by straight lines to emphasize the short-term solar variability. Isolated points indicate daily means without adjacent data on at least one day preceding and following.

calibrated once at the end of its 150-day flight; the NIMBUS 7/ERB/HF self-calibrates approximately every two weeks. These experiments cannot eliminate the effects of electrical and thermal variations in the instrument occurring between self-calibrations.

Solar irradiance flight experiments relying on preflight calibrations are the least accurate type. The rocket ESP, HF, and PACRAD instruments self-calibrate prior to but not during flight experiments. The empirical corrections applied to the results for differences between preflight and flight conditions cannot produce measurement accuracy equal to the ESCC and ESCC/P experiments. The NIMBUS 6/ERB thermopile sensor is the least accurate experiment of this type. Lacking a cavity detector and self-calibration capability, its measurements are susceptible to the full effects of detector surface degradation and depend on preflight calibration by other instruments for interpretation in SI units.

There are only a few scattered ESCC results between the 1st, in 1969, and the launch of the SMM/ACRIM I in 1980, but they can at least provide an upper limit to long-term solar total irradiance variability over this 11-year period. Although the 1969 balloon and 1976 rocket ACR instruments were never directly compared, the relativity of their measurements was defined through cross-comparisons with WRR-defining pyrheliometers. The 0.15% difference between their results is comparable to the uncertainty of relating them, placing a probable upper limit of ±0.3% on long-term solar variability between 1969 and 1976.

The rocket ACR, SMM/ACRIM I, and PMO balloon experiments, extensively compared with each other and with WRR reference pyrheliometers, have demonstrated consistent performance throughout their various flight experiments at the ±0.1% level. The combined average of all ACR and PMO results is S = 1367.7 W/m^2 with ACR results systematically 0.1% higher. Accordingly, ±0.2% is both a likely lower limit of the SI uncertainty of any single measurement by these instruments from 1976 through 1980, and the range in which long-term solar variability over the period could have occurred without detection.

Short-Term Variability. The principal evidence from flight experiments for short-term solar irradiance variability comes from the SMM/ACRIM I experiment. Through periodic comparisons among its three independent ACR detectors, precision was sustained at the ±0.005% level through the 300-day period of normal SMM operation (Feb.–Dec., 1980). The larger range of scatter in ACRIM I results after mid-December 1980 is caused by the decreased number of daily observations in the spin-stabilized mode of SMM operation following loss of precision solar pointing capability by the spacecraft. Long-term precision throughout the 2+ years of the mission has been sustained at the ±0.02% level. The long-term decreasing trend in irradiance, averaging 0.04%/yr, has resulted in a cumulative decrease of nearly 0.1% in the total irradiance since launch.

The most striking features of the ACRIM I observations, the major irradiance decreases, demonstrate a high degree of inverse correlation with the total sunspot area (graphically shown by panels 2 and 3 in Fig. 1). This correlation, together with the theoretical prediction of the irradiance deficit by models based on the areas and lower radiative intensity of sunspots (about 50% of the normal solar photosphere), leaves little doubt about the cause of the principal irradiance variations observed by ACRIM I: The decreases are a modulation of the average irradiance by sunspots in solar active regions.

The proportionality between irradiance decreases and sunspot areas is not constant, however, and the effects of another solar activity phenomenon, the radiative excess of facular areas, must be taken into account to explain solar variability more accurately. The radiative intensity of faculae averages only 3% higher than the normal sun, but when present in sizable total area facular radiative excess can measurably moderate S. The effects of faculae can be seen in Fig. 1 (facular area is approximated by plage area in panel 1), where maxima of facular area cause irradiance peaks and decrease the amplitude of some sunspot-induced dips. Although the sunspot deficit effect dominates the days-to-weeks timescale, the irradiance appears generally to follow the longer-term (months-to-years) envelope of facular behavior.

A comparison of the results from a WRC/PMO balloon experiment in June 1980 with SMM/ACRIM I results for three hours of simultaneous solar observation has revealed a high degree of correlation between them. Solar variability on time scales of minutes to hours with amplitudes ranging from 0.005 to 0.02% were observed simultaneously by both experiments. Three filter photometers on the PMO balloon experiment detected spectral fluctuations in synchronization with the total irradiance variability. Measurements at three visible wavelengths demonstrated an inverse dependence of variation amplitude on wavelength.

A total irradiance signature for low-order p-modes of the solar 5-minute global oscillation phenomena has been detected in the SMM/ACRIM I results at the level of approximately 5 ppm of the total irradiance. No evidence of 120-minute oscillations reported from U.S.S.R. data has been found.

The multiyear record of solar measurements by the SMM/ACRIM I and NIMBUS 7/ERB experiments is shown in Fig. 2 (panels 1 and 2, respectively). The irradiance scale for the ERB results has recently been adjusted downward to yield an average value of $S = 1372.6$ W/m^2 (0.25% lower than the originally given value shown in Table 2). The ERB experiment measures S less frequently and with less precision than ACRIM I but shows unambiguous evidence of many of the irradiance decreases clearly seen in the ACRIM I results. The larger noise component in the NIMBUS 7/ERB results is partially due to the "quick look" quality of the data available for the period shown in Fig. 2. By 1982, final data processing had been completed for less than the first full year of the experiment, which began in 1978.

Solar Spectral Irradiance *Introduction.* No effort has been made to measure the spectral distribution of solar irradiance over the wavelength range containing most of the total energy since flight experiment opportunities above the atmosphere became available. Flight experiments during the last decade have explored relatively narrow ranges of wavelengths pertinent to specific physical processes in the earth or solar atmospheres. These have principally focused either on the ultraviolet (UV) and shorter wavelengths or infrared (IR) and radio frequencies. Extant models of the solar spectral irradiance over the 0.2–4.0 μm wavelength range (containing nearly 98% of the total solar flux) are constructed from the results of numerous experiments conducted from the earth's surface, aircraft, balloons, rockets, and spacecraft, and from models of solar emittance using graybody approximations.

The Solar Ultraviolet Spectrum (UV). The principal focus of solar spectral irradiance flight experiments in recent years has been on the UV. Most have been associated with aeronomy investigations, directed at specific upper atmospheric photochemical and thermodynamical processes. While the solar irradiance at wavelengths shorter than 0.3 μm represents only about 1% of the total flux, it is totally absorbed by radiatively active gases above 15 km, representing the primary source of energy for the upper stratosphere, mesosphere, and lower thermosphere.

The spectral variability of solar irradiance is known to be greatest at these short wavelengths, and the solar spectrum models below 0.30 μm are specified for average levels of solar activity with a range of variability on different time scales: (1) seconds to hours, resulting from solar flares and prominences; (2) days to weeks, resulting from active region evolution and solar rotation; and (3) months to decades, resulting from varying solar activity levels in the 11-year sunspot and 22-year solar magnetic cycles.

The irradiances between 0.2 and 0.3 μm of the composite solar spectrum, listed in Table 3 and shown in Fig. 3, were derived by Donnely and Pope from the results of Broadfoot, Simon, Thekaekara, Heath, and Ackerman, obtained by experiments on satellites, rockets, and balloons.

The Solar Spectrum from the Near UV to the Mid-IR. Many experiments have measured parts

*About 98% of the total solar irradiance is included within these wavelengths. The central wavelengths are listed for bandwidths of 0.01 μm between 0.2 and 1.0 μm, and for bandwidths of 0.1 μm between 1.0 and 3.0 μm. The spectral irradiance for each central band is the irradiance at 1 AU in units of milliwatts/square cm/μm. The spectrum is derived from the results of Donnely and Pope for wavelengths 0.2-0.3 μm; Arvesen, Griffin, and Pearson for wavelengths 0.3-0.4 μm and 1.3-2.5 μm; and Labs and Neckel for wavelengths 0.4-1.3 μm and 2.5-3.0 μm.

of the near UV to mid-IR solar spectrum and there have been numerous efforts to assemble comprehensive models of it. Here discussion will be limited to two experiments that covered a large fraction of this wavelength range and added significantly to the experimental data base on solar spectral irradiance.

The NASA/AMES Experiment of Arvesen, Griffin and Pearson: An Aircraft experiment to measure solar spectral irradiance over the 0.3–2.5 μm range was conducted by Arvesen, Griffin, and Pearson of NASA's Ames Research Center. Their experiment was flown on the NASA CV990 research aircraft at altitudes just

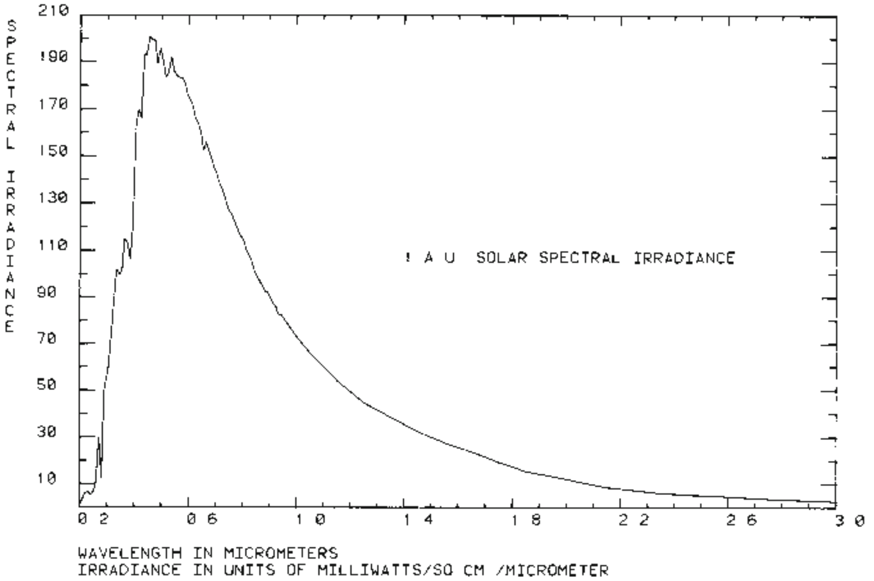

FIG. 3. Composite solar spectral irradiance between 0.2 and 3.0 μm (from Table 3).

above the troposphere. Calibration in SI units was provided by a spectral irradiance standard traceable to the US National Bureau of Standards.

The "zero air mass" or extra-atmospheric spectral irradiance was determined using an extrapolation procedure for data taken over a range of optical thickness. A solar spectrum model was developed covering the 0.2–4.0 μm wavelength range. Data from other experiments and a 5800 K graybody model were used to construct the spectrum below 0.3 μm and above 2.5 μm, respectively.

Their initial error analysis indicated uncertainties ranging from ±25% at 0.3 μm to ±3% in the visible. Following corrections for a systematic error in the standard lamp and some wavelength calibration errors, a final SI uncertainty of ±5% or less was probably achieved over the wavelength range 0.4–2.5 μm, which contains more than 90% of the total solar flux.

The Experiment of Labs and Neckel: The solar spectral irradiance experiment of Labs and Neckel was conducted at the Jungfraujoch Observatory, 3.6 km above sea level in the Swiss Alps. The disadvantages of increased atmospheric attenuation, relative to the previous aircraft experiment, were partially offset by the advantages of working in a laboratory environment.

Their well controlled experiment was comprised of observations of the spectral intensity at the center of the solar disk in the 0.33–1.25 μm wavelength range over a range of atmospheric optical thicknesses. The spectral irradiance from the full disk was then computed using empirical relationships for limb darkening. The SI calibration reference was a standard radiance lamp calibrated to blackbody emitters located at the Happel-Laboratory and the Berlin Institute of the Physikalisch-Technisch Bundesanstalt (PTB). The solar spectral irradiance outside the earth's atmosphere was computed using an extrapolation procedure based on the Bouguer-Lambert law.

The traceability of their standard lamp to SI units was claimed to be ±2% by Labs and Neckel. This is more accurate than the irradiance standards used in the aircraft experiment described and is one of the advantages of their laboratory experiment environment. Derivation of the full-disk spectral radiance from measurements of central intensity is a significant source of uncertainty due to photospheric variability, especially when solar active regions are present. (The angular field of view of their experiment, less than 0.01 degree, represents only 1.5% of the full solar disk.)

Labs and Neckel constructed a solar irradiance model for the 0.2–100 μm wavelength range, using the experimental results of others and modeling outside the range of their measurements. No systematic error analysis is given but an error bound of ±3.5% for wavelengths between 0.4 and 1.25 μm is likely required to accommodate the various sources of experimental and analytical SI uncertainty discussed above.

Spectral Irradiance Summary. A composite solar spectrum derived from the sources above is listed in Table 3 and shown in Fig. 3. The spectrum has a probable SI uncertainty in excess of ±10–30% for wavelengths shorter than 0.3 μm (see Table 4). The two principal con-

TABLE 4. WAVELENGTH DEPENDENT ABSOLUTE UNCERTAINTY (SI) AND TEMPORAL VARIABILITY OF THE SOLAR SPECTRUM OVER VARIOUS TIMESCALES.

		Timescale of Variability		
Wavelength Range (μm)	Uncertainty (SI)	Seconds to Hours	Days to Months	Months to Decades

0.24–0.33	10	??	2–1	??
0.33–0.4	5	??	<1	??
0.4–1.25	5–3	0.05	??	??
1.25–2.5	5	??	??	??
2.5–3.0	5	??	??	??

Wavelengths are in units of micrometers (μm), uncertainties and variability in ±%. Entries listed as ?? indicate the absence of experimentally determined values.

tributors to UV uncertainty are errors in calibration and the effects of inherent solar variability. Variable scattering and absorption by the earth's atmosphere for solar irradiance with wavelengths between 0.3 and 0.4 μm would cause a corresponding increase in uncertainty for measurements made over longer optical paths. The AMES data were obtained through the smallest "air mass" and are probably the most accurate in the 0.3–0.4 μm region, with uncertainties ranging from (±)10–5%, respectively. The results of Labs and Neckel appear to be the most accurate in the 0.4–1.25 μm range, with SI uncertainty of about (±)3–5%. Intensities in the wavelength range from 1.25 to 2.5 μm are determined most accurately from AMES data, once again due to the smaller "air mass" associated with the experiment. The SI uncertainty in this range is probably less than ±5%. The solar spectral model at wavelengths longer than 2.5 μm is taken from Labs and Neckel, who have used a combination of modeling and an assessment of experimental results of others. The SI uncertainty between 2.5 and 3.0 μm is probably near ±5%.

SOLID-STATE PHYSICS

Solid-state physics is the study of the crystallographic and electronic properties of solids. It is concerned not only with the inherent nature of solids as collections of atoms, but also with interaction of solids with external forces: mechanical forces, heat, electromagnetic fields, bombarding particles, light, etc. It includes both theoretical and experimental aspects of solids. It is a broad field, merging with the associated sciences of chemistry, biology, and astronomy and such technologies as metallurgy, ceramics, and electrical engineering. The boundary between solid-state physics and these associated disciplines is not well defined.

The atoms comprising a solid can be considered, for many purposes, to be hard balls which rest against each other in a regular repetitive pattern called the *crystal structure*. Most elements have simple crystal structures of high symmetry, but many compounds have complex crystal structures of low symmetry. The determination of crystal structures and the location of atoms in the crystal relative to each other is an absorbing study; it has occupied the lives of many geologists, mineralogists, physicists, chemists, and other scientists for many years. (See CRYSTALLOGRAPHY.)

The rigid, hard-ball model is not adequate to explain many properties of solids. We know that solids can be deformed by finite forces, so the crystal lattice must not be completely rigid. Furthermore, atoms in a solid possess vibrational energy, so they must not be precisely fixed to mathematically defined lattice points. This deformability of solids is built into the model by the assignment of deformable bonds between nearest atom neighbors. This ball-and-spring model has had many successes; one important early use was that of Einstein to devise a reasonably successful theory of specific heat. Later incorporation by Debye of coupled motion of groups of atoms led to an even more successful theory of heat absorption by solids.

Several measures exist of the strength of these bonds. One is the size of the elastic constants—for most solids Young's modulus is about 10^{11} newtons/m^2. The other is the frequency of vibration of atoms in solids, for which values around 10^{13}–10^{14} Hz are found. From these experimental observations, the intrinsic forces of deformation between atoms in the solid may be deduced; they are about 10 newtons/meter (about 10^{-4} dynes/angstrom).

This lack of perfection demonstrated by elastic deformation of solids is but one of many evidences of lack of crystal perfection. In the way crystals are produced, either in the laboratory or in nature, defects in structure are incorporated, often in profusion. Such defects may be characterized by three principal parameters—their geometry, size, and energy of formation.

All real crystals have external surfaces. As a consequence, atoms in surface sites do not possess the correct number and arrangement of nearest neighbors. This increases their local energy, so that the surface has an intrinsic energy and is characterized by a SURFACE TENSION. In addition, internal surfaces exist, grain boundaries and twin boundaries across which atoms are incorrectly positioned. In a crystal of reasonable size, say, 1 cm^3, these two-dimensional defects, called *surface defects*, account for only about 1 atom in 10^6, a small fraction. Even so, surfaces are important attributes of solids.

Some defects have extent in only one dimension—these are called *line defects*. The most prominent of these, the *dislocation*, is a line in the crystal along which atoms have either an incorrect number of neighbors or neighbors which do not have the correct distance or angle. In 1 cm^3 of a real crystal one might find wide variation in lengths of dislocation lines—from near zero in nearly perfect semiconductor material to perhaps 10^{11} cm per cubic cm in a deformed metal.

Defects which extend only to about one atomic diameter also exist in crystals—these are called *point defects*. Vacant lattice sites may occur—these are called *vacancies*. Extra atoms (*interstitials*) may be inserted between proper crystal atoms. Atoms of the wrong chemical species (*impurities*) may also be present.

Finally, solids exist in which the local atom arrangement is not repeated regularly. Among these are the glasses, polymeric materials, and amorphous alloys. Such solids are enormously important technologically, hence considerable effort is now underway to deduce local arrangements exactly.

The importance of the various defects is intimately related to their energy of formation. A standard against which this energy can be compared is provided by the energy of sublimation—the energy necessary to separate the ions of a solid into neutral, non-interacting atoms. This energy is about 81,000 cal/mole for a typical metal, Cu, at room temperature—i.e., about 3.4 eV per atom. Energies of surfaces, both free surfaces and grain boundaries, are about 1000 ergs/cm^2, i.e., about 1 eV per surface atom. Dislocation energies are of similar size per atom length of dislocation line, i.e., about 1–5 eV, so the energy of a dislocation is about 10^{-4} ergs/cm of length. Point defects, too, possess an inherent energy of about 1 eV each. Vacancies in Cu have an energy of about 1 eV, self-interstitials 2 or 3 eV. The energies per atom of these various defects, surface, line, and point, are all much larger than the average thermal energy per atom in a solid at reasonable temperatures: kT is only about 1/40 eV at toom temperature. Thus, defects can be produced only by conditions which exist during manufacture of crystals, by external means such as plastic deformation or particle bombardment, or by large local fluctuations in thermal energy from the average.

Even so, the total amount of energy bound up in ordinary concentrations of these defects is not large compared to the total thermal energy of a solid at normal temperatures. All the vacancies at equilibrium in Cu, even at the melting point, comprise less than 10 cal of energy per mole, much less than the enthalpy at 1357 K (the melting point) of more than 7000 cal/mole. In a material with very heavy dislocation density, 10^{12} cm of line length/cm^3 of material, the excess energy is only a few calories per mole. And the total energy of a free surface of a compact block of 1 mole of Cu is even less, about 10^{-3} cal. Thus the inherent energy of these defects is not large compared with the total thermal energy of the solid, because the chance of an atom being located in one of these defects is very small. Even so, defects are important in controlling many phenomena in crystals.

Crystallographic defects need not remain stationary in the crystal; they may move about. Some movements may reduce the overall free energy of the solid; others (these are chiefly movements of the point defects) may be the wandering of a random walk. Since these movements require the surmounting of a potential barrier invariably much larger than kT, the motion of defects depends upon large local fluctuations in energy. Consequently, their rate of motion depends on temperature through a Boltzmann factor exp $(-\Delta H/RT)$, where ΔH is the enthalpy change necessary to move the defect from the lowest energy site to the highest in its path of motion.

Description of the crystalline structure of solids is thus seen to consist of successive stages of approximation. First the mathematically perfect geometrical model is described, then departures from this perfect regularity are permitted. The deformability of solids is permitted by allowing the force constants between adjacent atoms to be finite, not infinite. Misplacement of atoms is permitted either by equilibrium thermodynamical justification or by the effect of external forces. Some defects have intrinsic features which directly affect properties of the crystal, others affect crystalline properties by their diffusive motion. In spite of their relatively small number, defects are of immense importance.

Some important solids do not possess long-range crystalline regularity. Glasses and polymeric solids are in this class. Although local atomic configuration may be known, the atomic arrangements are not spatially periodic. By rapid cooling or by deposition of atoms from vapor or plasma, materials which are normally crystalline can also be made amorphous. The correlation of atom positions in the usual metallic glasses or amorphous semiconductors is lost above 5–10 atom diameters. Beyond that distance the accumulated errors of atom positioning make spatial assignments unreliable. Important features of amorphous solids are atomic arrangements, chemical composition and chemical gradients, defects, voids, inclusions, phase boundaries, and electronic character.

Pure metals can be made amorphous by evaporation techniques, but most amorphous metallic alloys are made by rapid cooling from the melt. These are commonly binary or ternary alloys such as Au-Si, Fe-Pd-P, and Ge-Sn-S. They have interesting mechanical, electrical, and magnetic properties which may make them technologically valuable. Especially interesting is the property that many amorphous metallic alloys do not undergo structural or chemical changes to temperatures far above room temperature—say 400°C. When the amorphous structure is lost at high temperatures, recrystallized grains are often formed and compositional changes occur, since amorphous metallic alloys are indeed metastable. Thus, heat treatments can be devised to produce novel properties in the semi-transformed state.

The *electronic structure* of solids is determined, in principle, solely by the electronic structure of the free atoms of which the solid is composed, modified by interactions which take place when the atoms approach each other at normal interatomic distances—a few angstroms. Since the free atom structure is known rather well, especially for atoms of lower atomic number, the electronic structure should be readily calculable, even though the calculation might be tedious. However, the variety of interactions which take place between electrons on adjacent atoms make such calculations difficult. The use of the computer to do numerical calculations has made this process more manageable. (See the article on SOLID STATE THEORY.) The close interplay between theory and experiment in deducing the electronic structure of solids has permitted many general features of the electronic structure to be deduced. As for the crystalline structure of solids, two stages are useful in understanding the electronic structure. First, the perfect electronic structure is defined, then irregularities in this structure, again termed defects, are introduced. Although both the geometry and energy of crystalline defects are defined, description of the many electronic defects has been less straightforward.

The nuclei of the atoms in a solid and the ion cores have energy levels little different from corresponding levels in free atoms. The characteristics of the valence electrons are modified greatly, however. The state functions of these outer electrons greatly overlap those of neighboring atoms, and the restrictions imposed by the Pauli Exclusion Principle and the Uncertainty Principle force modification of the state functions and development of a set of split energy levels rather than the single level characteristic of isolated atoms. This set of split levels becomes a quasi-continuous band of levels several electron volts wide for most solids. Importantly, unoccupied levels of the atoms are also split into bands. The electronic characteristics of solids are determined by the relative positions and energies of the occupied and unoccupied levels as well as by the characteristics of the electrons within a band.

A solid is called a *metal* if excitation of electrons from the highest filled levels to the lowest unoccupied levels can occur with infinitesimal expenditure of energy. The excitation can occur by means of many external influences, such as electric fields, heat, light, or radio waves. Metals are good conductors of electricity and heat, they are opaque to light, and they reflect radio waves.

Some solids have wide spacing between the occupied and unoccupied energy states—2 eV or more. Such solids are called *insulators*, since normal electric fields cannot cause motion of an extensive fraction of the outer electrons. Examples are diamonds, sodium chloride, sulfur, quartz, and mica. They are poor conductors of electricity and heat are usually transparent to visible light (when not filled with impurities or defects).

Solids with conductivity properties intermediate between those of metals and insulators are called *semiconductors*. For them, the excitation energy lies in the range 0.1 to about 1.5 eV. Thermal fluctuations are sufficient to excite a small, but significant, fraction of electrons from the occupied levels (the valence band) into the unoccupied levels (the conduction band). Both the excited electrons and the empty states in the valence band (called *holes*) may move under the influence of an electric field, providing a means for conduction of electric current. Such electron-hole pairs may be produced not only by thermal energy, but also by incident light, x-rays, and many forms of radiation. The inverse process, emission of light by annihilation of electrons and holes in suitably prepared materials, provides a highly efficient light source (light-emitting diodes).

Crystallographic defects, in general, are also electronic defects. In metals, and alloys, they provide scattering centers for electrons, increasing the resistance to charge flow. The heating element in electric heaters, in fact, consists of an alloy of an ordinary metal such as iron with additional alloying elements providing scattering centers for electrons—nickel and chromium in solid solution are commonly employed. In semiconductors and insulators, however, alloying elements and crystalline defects provide an even greater variety of phenomena, since they can change the electron-hole concentrations drastically; in addition they provide scattering centers and electron-hole recombination centers. The entire semiconductor device industry is based on alloying of silicon, germanium, and compound semiconductors with selected impurities in carefully controlled concentration and geometries. The strong interplay between solid-state scientists and design engineers has provided a myriad of devices utilizing the alloying and geometrical principles in exquisite designs. Amorphous semiconductors are under intensive study from a basic point of view. Silicon, especially, is being examined intensively—primarily because of the cheapness with which thin layers of amorphous silicon can be deposited by sputtering techniques. However, amorphous silicon has many "dangling bonds" which spoil the electrical properties by reducing the lifetime of charge carriers and by affecting surface charge; addition of hydrogen is commonly made to satisfy local bonding requirements.

Crystal defects may produce important electronic defects in ionic crystals. Vacant atom sites and impurities of valence different from that of the host may trap electrons, which can be excited by incident photons, thus producing light absorption. Since the excitation occurs in specific ranges of frequency, crystals otherwise transparent may become colored. This phenomenon, of large intellectual interest, also has immense practical importance—the color of most gemstones has its origin in this selective absorption. Likewise the photographic process is a result of these effects in AgBr and AgCl.

Other geometries of conducting media are ultrathin layers, especially of elemental and compound semiconductors grown epitaxially on stable substrate crystals. Remarkably thin layers can be achieved and high stability is claimed for many layered structures. In the technological push toward ultraminiaturization, these thin-layer structures may be extremely important. Other types of composite structures are also being examined—composite layers and fiber structures. Thin films of nearly single-crystal silicon are being produced by growth from melt for possible use in solar cells.

The chemistry and physics of surfaces are being investigated widely. A large part of this effort is aimed at understanding catalysis and at solving problems in coal conversion, in chemical processing, and in photosynthetic reactions. Both improved methods of experimentation and interaction with theory are providing advances in this investigation—important technological features being the driving force.

Solids are 'useful because interaction with external forces or stimuli such as magnetic fields, heat, and mechanical forces are important to us. Yet among all of these interactions none is more important than interrelations between matter and light. The earth is warmed by the sun, photosynthesis provides food, vision is the most important of our senses. Yet the physics and chemistry of absorption processes on which these phenomena depend are only partially understood. That generation of light is also of great importance may be seen from the fact that some 25% of all electrical energy consumed in the United States is used in the production of light. Small wonder that immense effort is being spent on increasing lighting efficiency by high-pressure arc discharge lamps, by more efficient phosphors for fluorescent tubes, and by improved devices using cathodoluminescence and electroluminescence. The most efficient light source, the light-emitting-diode, is highly important as used in indicator lamps, but also in its laser form for telecommunication systems. This application has been made possible by the development of optical fibers with appropriate variation of the index of refraction across the fiber diameter to permit waveguide performance; at the same time the optical loss in the fiber has been reduced to tolerable limits. Communication over distances of thousands of kilometers using fiber optics is a commercial reality.

The interaction of light with matter is so important that a chief hallmark of physics in this century is the extraordinary development of spectroscopy and its application to processes in solids. First came investigation of emission and absorption of radiation from free atoms. Later investigations have included emission and absorption by atoms in solids, MASER and LASER phenomena, Mössbauer spectroscopy, nuclear magnetic resonance, x-ray diffraction, infrared spectroscopy, fluorescence, the Raman effect, and microwave emission and absorption. These investigations have led not only to an increasingly detailed perception of the nature of solids, but also to a host of practical devices such as light sources, laser generators and amplifiers, and x-ray generators.

MAGNETISM is an inherent property of the electrons in a perfect crystal. It is important both for insights which magnetic studies provide into the intrinsic properties of materials and for its practical importance. Two weak effects, DIAMAGNETISM and PARAMAGNETISM, are purely of academic importance. Ferromagnetism, however, is of immense technological value. The basic properties of ferromagnets (saturation magnetization, Curie temperature, magnetostriction, crystalline anisotropy) are inherent properties of the perfect lattice. The technological application of ferromagnets, though, demands careful control of defects, which exert strong influence on such properties as hysteresis loss, permeability, and coercive force. (See FERROMAGNETISM.) The amorphous metals have interesting ferromagnetic characteristics—in the amorphous state, they have soft magnetic qualities, similar to those of the important transformer materials. The domain walls must move easily in these amorphous metals. Partially recrystallized amorphous materials, however, have more nearly the characteristics of permanent magnets; spatial inhomogeneities of composition and crystalline character provide this appropriate magnetic character. The most striking feature of ferromagnetism is the enormous variety of properties which can be produced in a rather few materials—alloys of iron, nickel and cobalt plus a few oxides (spinels and garnets). This variety comes from the ability of scientists and engineers to tailor the chemistry and physical arrangement of alloy phases to produce desired magnetic qualities.

The physics of computers depends increasingly on the properties of solids. Active computational devices depend on ever increasing sophistication of semiconductor devices. The pressure for memory cores of smaller physical size, faster readout time, and lower power consumption puts great demands on continued development of magnetic and electronic materials.

The search for superconductors of ever higher critical temperature continues to be of importance to physicists. High-field critical temperatures among the alloys rose rapidly from the 5–10 K range to some 20–22 K in a few years. However, the rate of increase of critical temperature with time has slowed and the long sought goal of superconductors suitable for use in liquid nitrogen seems far away.

Summarizing: Solid-state physics, in its broadest sense, is the study of the perfect and imperfect crystalline and electronic properties of solids, ranging from attempts to understand these phenomena from the most fundamental point of view to the edge of the technological applications of solids. Indeed, the field is both driven by technological demands and provides, through basic research, innovations of often unexpected nature which make rapid technological application possible.

SOLID-STATE THEORY

The ideal, perfect crystalline solid possesses a true long-range order which is not found in other phases of matter. The periodicity of the crystalline lattice potential in a solid enables one to make detailed investigations of many properties of the solid by employing powerful mathematical techniques which exploit the long-range symmetry. In such studies the aid of high-speed digital computers is now routinely employed, and a group of computational solid state theorists is emerging. Most phenomena studied by solid state theorists are related to the *almost periodic potential*. However a substantial minority of theorists are studying systems which deviate markedly from those related to the periodic potential. Such studies include the properties of point defects and impurities (color centers), dislocations and phase boundaries between material media, solid surfaces, random alloys, phase transitions, and charge instabilities (spin-density waves or charge-density waves).

The problem of one electron in an ideal periodic potential has been solved in principle. The advent of fast digital computers has permitted many independent groups to perform calculations of the *band structure*, that is, the dependence of the energy of the one electron on its wave vector $\epsilon(\mathbf{k})$, as a routine task of numerical precision. Even if one obtains the potentials determining the bands in a self-consistent manner, the evaluation of an energy band structure is a task requiring at worst a few minutes' time on a large digital computer. These successes are tempered by the realization that the question of which "exchange" to use is as yet unresolved. There exists active investigation into the relative merits of "local," or "nonlocal exchange," and into the precise nature of self-interaction corrections. The increasing precision of the knowledge of experimental properties of solids is causing theorists to seek ever more precise theories with which to describe solids. This need is leading theorists to attempt to include the dynamical properties of electron-electron interactions into the basic band structure calculations. The band theory of solids of dimensionality less than three is of recent interest.

The effect of these electron-electron interactions, known as *many-body* or *correlation effects*, may determine both the qualitative behavior of solids and quantitative aspects as well. Currently, most researchers are using a density functional approach based upon the Hohenberg-Kohn theorem to include such effects in band structure calculations. In addition to these efforts a sizeable minority are using various many-body approaches such as *Green's functions*, *diagrammatic perturbation theory*, or a *coupled cluster method* to include correlation effects in one-electron band theory.

These energy band calculations are being used to predict other solid state properties beyond the basic $\epsilon(\mathbf{k})$ relationship. These properties include charge density, Compton profiles, cohesive energy, and other basic properties of the ideal three-dimensional solid.

Many research groups are concentrating on properties of nonideal three-dimensional solids which are analogous to properties studied in the band theory problem. These studies include determination of the electron density of states, $N(\epsilon)$, for random alloys; properties of glasses; the two-dimensionally periodic band structures of solids with surfaces or with interfaces between two types of solid; and electronic localization in random potentials. Study of symmetry-lowering instabilities in the ground state of many solids is an active field of research. Such instabilities include the formation of charge-density waves or spin-density waves, and may be commensurate or incommensurate with the basic lattice structure.

The atomic nuclei comprising a solid are not fixed in place but vibrate. These vibrations are in fundamental quanta called *phonons*. The basic calculation of the dispersion of the frequency of these phonons in terms of their wave vector $\omega(\mathbf{q})$ is not as simple as determining the basic energy band structure of a solid. This difficulty is due to the very complex nature of the interatomic forces existing in the solid. The phonons also interact with one another in complex ways due to the fact that the interatomic forces are not truly harmonic in nature. Furthermore, phonon properties may be a function of temperature. Considerable effort remains directed at these problems.

Still more difficult problems arise when one considers that the basic electronic properties and the basic vibrational properties are not truly independent, but interact. The bulk of the theoretical work on pure systems is based on (1) a description of the electronic structure as if no phonons or even zero-point vibrational motion were present, and (2) a description of the phonon properties which ignores the detailed nature of the electronic structure of the crystal. In the main, this approximation is not as crude as it might seem; the electronic wave function is in actuality often coherent over many atomic positions, and therefore the phonons are insensitive to small changes in the electronic structure, and vice versa. Thus in a simple metal under ordinary conditions one may ignore the change in the phonon dispersion curve as the electronic state is changed, say, by absorption of light or an external electric field. Nonetheless, many interesting phenomena do occur in such situations, in which one may not ignore the coupling of electronic and vibrational properties. Such phenomena include the lattice distortions which accompany the formation of a charge-density wave in a metal. In the study of electron transport in a semiconductor such as Ge, the interaction creates a *phonon drag*. In ionic crystals the presence of electron-phonon interactions is responsible for the formation of *polarons*, mobile electrons which drag a cloud of ionic distortion around with them. Such a polaron is called a *large* polaron. If the interaction is more severe, the electron and its ionic distortion may form a localized state termed a small polaron.

Solids at finite temperature are never perfect. The common imperfections present include vacancies, interstitials, impurities, and dislocations. Such imperfections manifest themselves in a number of ways. This manifestation may be in the formation of a local mode in the phonon spectrum of the solid. This mode is not found in the perfect solid. This local mode may be associated with the imperfection and exist primarily in its vicinity. A second manifestation may be in the formation of new electronic energy levels in the system. In this case the most dramatic occurrence is when the impurity generates energy levels in forbidden energy gaps in the band structure. Such occurrences are long recognized as the source of coloration in the alkali-halide crystals, for example. A third manifestation may be by means of generating new magnetic states for the solid. Active theoretical studies on all phases of the questions raised by the presence of defects in solids are under way. The problem here is severely complicated by the often strong interaction of vibrational electronic and magnetic degrees of freedom of these imperfections.

It is generally recognized that when an imperfection occurs in a crystal, the lattice will distort in the vicinity of the imperfection. This distortion, or *relaxation*, of the lattice may not preserve the basic point symmetry of the system. In some cases the symmetry of the electronic structure requires such a relaxation (Jahn-Teller effect). Furthermore, if the imperfection changes its electronic state the lattice distortion may change in response to the change of electronic state. These relaxations and changes of symmetry often cause severe modification of optical properties, not only in producing new absorption bands but also in reordering the strengths of existing absorptions. These relaxation effects were initially recognized as significant in studies on ionic solids and are now recognized as equally important in understanding imperfections in semiconductors. Several research groups, using powerful Green's function techniques and sophisticated computer techniques, are developing accurate methods for self-consistently determining the properties of imperfections in semiconductors, including lattice relaxation. As important as such local relaxations are in determining the properties of bulk imperfections, it is becoming equally clear from the efforts of many research groups that such relaxations are at least as important in the properties of imperfect solid surfaces.

If one considers the optical properties of the perfect crystal, there exists a simple selection rule related to the initial and final wave vector of the electron being excited which determines if a given optical transition is allowed. This is often a good approximation in the actual solid. Nonetheless, in many real systems important phenomena are associated with "indirect" transitions in which both phonons and light quanta (photons) are simultaneously absorbed or emitted. The silver halide solids used in photography are excellent examples of systems in which such indirect transitions are important. Detailed theories have been developed to account for the numerous new effects in the optical properties of solids such as laser action, nonlinear optical effects, and multiphoton effects. The interest in optical theories is broadening to include photoemission theories in both the ultraviolet and the x-ray spectral regions. Of particular new importance is the use of angular resolved photoemission data to test band theories. Theories relating to the optical properties of perfect solids in which the hole may be considered localized after its creation no longer just consider the creation of excitons but also include x-ray extended fine structure and also near absorption edge structure in x-ray absorption. These latter studies now involve many active research groups.

The mechanical properties of solids continue to receive much theoretical emphasis and are now becoming understood at a fundamental level largely through the development of the theory of dislocations and also through lattice statics and molecular dynamics calculations. Many new phenomena have been catalogued, such as spiral growth "climb," dislocation networks, pinning, "whiskers," and decoration with collodial particles. The use of lattice static calculations is permitting studies of solid phase segregation at zone boundaries, of crack formation at zone boundaries or imperfect ions, and in general is providing an atomistic view of the formation of dislocations, cracks, and voids in solid systems. Such studies now may include the effect of external stresses on the solid.

Magnetic phenomena of all types continue to receive much attention and fascinate the theorist. Nuclear and electron resonance phenomena continue to be useful tools in the investigation of the magnetic properties of solids. Similarly, the Mössbauer effect continues to provide insights into magnetic properties. The theory of ferromagnetism continues to attract the greatest amount of attention in this field. However, there are substantial numbers of investigators studying antiferromagnetism as well. From time to time, reports of anomalous diamagnetism or anomalous paramagnetism in solid systems also evoke substantial theoretical response. Some recent interest has been generated by the discovery of true two-dimensional magnets. Properties of spin-glasses also occupy the attention of many theorists. In general, although the specific details of the interactions among electrons which give rise to ferromagnetism or antiferromagnetism are not completely understood quantitatively, the qualitative features responsible for these magnetic phenomena seem to be well understood.

The phenomenon of superconductivity, which has been given an elegant explanation in terms of electron-phonon interaction in the BCS theory, continues to attract the attention of many theorists. Much work in extending and generalizing the BCS theory is being performed. Specific, detailed calculations of the electron and phonon structure and their interactions in several metals have been performed and transition temperatures predicted. Theories of the destruction of superconductivity by magnetic impurities continue to be of interest. Speculation continues that high-temperature superconductors may exist. In the search for high-temperature superconductors, theorists have been postulating that interactions other than the electron-acoustic phonon interaction might produce superconductivity. Recent efforts concentrate mostly on electron-exciton interactions or on electron-optical phonon interactions.

In the area of transport theory there are substantial attempts to achieve more sophisticated theories than the conventional one-particle Boltzmann equation methods permit. Many approaches for studying electronic transport are based upon *density matrix* methods. In these approaches one may study the actual scattering probabilities without the need for drastic approximations such as spherical energy surfaces or the Born approximation to obtain the scattering amplitude. The need to include Umklapp processes in order to obtain quantitative understanding of transport processes is appreciated. In some cases, studies now include the actual band structure of the solid in question in determining the transport of electrons. Studies of the transport of atoms in solids and on their surface are also of importance. In many cases, the technique of *molecular dynamics* is used to obtain detailed results for atomic transport.

The study of quasi-particles continues to expand. The lexicon of interesting quasi-particles now includes excitons, plasmons, magnons, phonons, helicons, polarons, polaritons, and solitons, among others. These quasi-particles are the elementary excitations of a solid, and may be characterized by an energy, a wave vector, and a polarization. Much current interest is directed at understanding the dependence of energy upon wave vector and polarization and the propagation of these quasi-particles in the solid. As one better understands the individual quasi-particle it becomes interesting to study the interactions among them and their interdependences. In the area of semiconductors, the interaction of excitons with each other has attracted much attention, and theories of the fusion of two excitons into a biexciton or of many excitons into an excitonic gas or into an electron-hole droplet have been of great interest. The study of the interaction of excitons and phonons or phonons and magnons is also attracting investigators. Many theorists are studying the corresponding fusion and/or fission properties of various types of quasi-particles.

Solid state theory continues to evolve new areas of high interest on a regular basis. There is much activity in studying the critical behavior of one-, two-, or three-dimensional systems. Much of the interest in one-dimensional systems is due to the discovery of highly conducting, polymerlike, one-dimensional organic solids. In this area Peierls instabilities in the lattice structure are of chief interest. In the case of two-dimensional solids there are many current studies related to melting, roughness, wetting, formation of ordered chemisorbed layers, or surface reconstructions. In the case of three-dimensional systems virtually all types of critical phenomena are of current interest. Of these, the insulator-metal transition, especially in random systems, probably attracts the most attention. There are many attempts to apply the techniques of critical phenomena to biological systems. Although it is not a solid system, solid state theorists continue to study the properties of liquid helium. Recent techniques developed for the study of critical phenomena in general are tending to unify the studies of critical phenomena in solids and in helium.

The most recent addition to the arsenal of techniques employed by the solid state theorists is that of *renormalization group theory*, which seems to be the most far-reaching of the new techniques for studies of critical phenomena. The renormalization group technique has finally permitted solution of a long-standing problem in magnetic alloys, the Kondo effect. This technique is of use in many areas of physics other than solid state and is providing a unifying link between several subdisciplines in physics. Theorists continue to exploit recent advances in fast digital computers. The advent of the array processor (vector processor) shows promise of further substantial increase in computer speed. The techniques of group theory, to codify and exploit the symmetry properties of solids, continue to be useful. Methods of quantum field theory and Green's functions continue to be of significant importance to solid state theory. In addition there is a reawakening of interest in the techniques of quantum chemistry among solid state theorists. These techniques are of particular use for studies of surfaces and point imperfections.

Work on the theory of solids is widespread. Significant contributions to the theory of solids are not the sole province of the physicist but are being generated by ceramists, metallurgists, chemists, and electrical engineers as well. Most notable is the work in the United States, the Soviet Union, Japan, England, and Italy. However, there are individual contributions of great value to solid-state theory from all parts of the world.

SPACE PHYSICS

Space physics is usually taken to be the physics of phenomena naturally occurring in space, but frequently space is not clearly defined. It normally includes at least the outer portions of planetary atmospheres (in which densities are low enough to permit satellite flight), the outer portion of the sun's atmosphere, and interplanetary space. It frequently also includes galactic space and intergalactic space but these are more often considered within the context of astrophysics. It is also sometimes taken to include planetary studies and the study of the earth's atmosphere at altitudes above those attainable by balloons. With such a broad coverage, there are many special areas of study included within the scope of space physics, and several of these are described separately; for example, see ASTROPHYSICS, COSMIC RAYS, IONOSPHERE, PLANETARY ATMOSPHERES, RADIATION BELTS, RADIO ASTRONOMY, and SOLAR PHYSICS.

Earth's Outer Atmosphere The earth's atmosphere extends far out into space, something which would not necessarily be expected on the basis of atmospheric properties near the earth's surface. There are two factors involved in this great extension. First, above 100 km, the atmospheric temperature increases rapidly with altitude, causing an outward expansion of the atmosphere far beyond that which would have occurred had the temperature stayed within the bounds observed at the earth's surface. Second, above about 100 km, the atmosphere is sufficiently rarefied so that the different atmospheric constituents attain diffusive equilibrium distributions in the gravitational field; the lighter constituents then predominate at the higher altitudes and extend farther into space than would an atmosphere of more massive particles. This effect is enhanced by the dissociation of some molecular species into atoms. The pressure p at altitude h, in terms of the pressure p_0 at the earth's surface, is given by

$$p = p_0 \exp\left(-\int_0^h \frac{\overline{m}g\,dh}{kT}\right) \qquad (1)$$

where $\overline{m}$ is the average mass of the atmospheric particles, g is the acceleration of gravity, k is the Boltzmann constant, and T is the atmospheric temperature. It is clear from this expression that the high temperatures and low particle masses above 100-km altitude act to maintain pressures at still higher altitudes in excess of those that would exist if the temperature and molecular weight were constant with altitude. Where diffusion equilibrium prevails, Eq. (1) applies to each constituent separately, provided $\overline{m}$ is replaced by the particle mass for the particular constituent under consideration and p_0 is the partial pressure at some reference altitude where h is taken to be equal to zero.

The composition of the atmosphere does not change much up to 100 km; there is a region of maximum concentration of ozone (still a very minor constituent) near 20 to 30 km (see PLANETARY ATMOSPHERES), the relative concentration of water vapor falls markedly from its average sea-level value up to 10 or 15 km, and the relative abundance of atomic oxygen begins to become appreciable on approaching 100 km, due to photodissociation of oxygen by ultraviolet sunlight. Above 100 km, atomic oxygen rapidly increases in importance, due to the combined influence of photodissociation and diffusive separation in the gravitational field; above 200 km, atomic oxygen is the principal atmospheric constituent for several hundred kilometers. However, helium is even lighter than atomic oxygen, so its concentration falls less rapidly with altitude, and it finally replaces atomic oxygen as the principal atmospheric constituent above some altitude which varies with the sunspot cycle between 600 and 1500 km. At still higher altitudes, atomic hydrogen finally displaces helium as the principal constituent. The hydrogen extends many earth radii out into space and constitutes the telluric hydrogen corona, or geocorona.

The temperature of the upper atmosphere, and hence its density, varies with the intensity of solar ultraviolet radiation, and this in turn varies with the sunspot cycle and with solar activity in general. The solar radio-noise flux is a convenient index of solar activity, since it can be monitored at the earth's surface, and since it varies more or less proportionally with the extreme ultraviolet emissions most important in heating the upper atmosphere. The minimum nighttime temperature of the upper atmosphere above 300 km has been expressed in terms of the 27-day average of the solar radio-noise flux $\bar{S}$ at 8-cm wavelength, as follows,[9]

$$T = 280 + 4.6\bar{S}$$

This varies from about 600 K near the minimum of the sunspot cycle to about 1400 K near the maximum of the cycle. The maximum daytime temperature is about one-third larger than the nighttime minimum.

Another important heat source for the upper atmosphere or thermosphere exists in the polar regions due to auroral and allied processes. Under geomagnetically disturbed conditions, auroral processes are enhanced and the associated strong heating in the polar regions causes a major perturbation in the general circulation of the thermosphere.[4] The normal circulation of the mid- and upper thermosphere under geomagnetically quiet conditions transfers heat from low lattitudes to high, as well as to the night side of the earth, but under geomagnetically disturbed conditions the circulation transfers heat away from the polar regions.

Magnetosphere The magnetosphere is that region of space in which the geomagnetic field dominates the motion of charged particles. Near the surface of the earth, the geomagnetic field resembles that of a dipole; the best-fit dipole is off center about 440 km and is inclined about 11° to the earth's axis of rotation. Well out into space, the field is severely deformed so that it no longer resembles a dipole field. The most apparent deformation is that due to a plasma of charged particles flowing away from the sun, a flow generally referred to as the solar wind. When the kinetic energy of the directed flow of the solar wind exceeds the energy density of the geomagnetic field, the plasma displaces the field. The diamagnetic properties of the flowing plasma tend to compress and confine the geomagnetic field,[2] at least on the side facing the sun. On the side away from the sun the geomagnetic field is very extended, perhaps indefinitely. Calculations indicate that the surface of the magnetosphere facing the sun is roughly hemispherical, with dimples over the earth's magnetic poles. Observations by space probes indicate that the distance that the geomagnetic field extends towards the sun is about 10 earth radii,[7] quite variable with the intensity of the solar wind.

The magnetosphere is a region within which many geophysical phenomena occur. Most deeply embedded within it are the plasmasphere and the Van Allen belts (see RADIATION BELTS). The plasmasphere consists of an upward extension of the ionosphere and hence it is made up of relatively low-energy particles; it has a sharp outer boundary that exhibits a diurnal pattern of movement. Beyond the plasmasphere there is virtually no low-energy plasma. The Van Allen radiation belts consist of high-energy particles, both electrons and ions, trapped within the geomagnetic field. The inner belt consists of protons with energies in the 10 to 100 MeV range and it is centered about half an earth radius above the geomagnetic equator. The outer belt consists of electrons with energies from 1 keV to 5 MeV that fill most of the magnetosphere almost out to the auroral zone. The tail of the magnetosphere is divided into two parts with oppositely directed field—one half with field lines directed away from the sun and connecting with the south polar region of the earth, and one half with field lines directed toward the sun and connecting with the north polar region of the earth. The neutral sheet separates the two regions of oppositely directed field, and the plasma sheet is a broader region extending on both sides of the neutral sheet containing more energetic particles than those in the neutral sheet.

The solar plasma that compresses the geomagnetic field and limits the magnetosphere flows away from the sun at a velocity that might be described as hypersonic—the ordered velocity greatly exceeds the average random thermal velocity of the particles. Although the medium is so rarefied that collisions are rare, the particles can interact with one another through the agency of magnetic fields contained within the plasma. As a result, a collisionless shock wave develops in the flow before it reaches the surface of the magnetosphere.[16] Space probes have shown that the shock front lies about 4 earth radii beyond the surface of the magnetosphere in the direction of the sun.[7]

Aurorae are luminosities in the upper atmosphere at high latitudes caused by energetic particles that flow from the outer magnetosphere into the atmosphere. The solar wind interacts with the outer magnetosphere so as to produce a dynamo action that provides the energy source for the aurorae. Electrons driven by this source provide the most spectacular displays because they enter the atmosphere in relatively well defined structures. Protons provide more diffuse, widespread aurorae. The degree of auroral activity depends largely upon solar activity and hence tends to follow large solar flares, extending to much lower latitudes than normal displays. (See AURORA and AIRGLOW.)

Interplanetary Space Up until about 1954, interplanetary space was thought to be essentially a perfect vacuum, devoid of interesting physical phenomena except for occasional sporadic events such as the ejection of gas clouds by the sun or the passage of comets. It is now recognized that interesting physical phenomena are always present. The solar corona expands continually, giving rise to a steady outstreaming into interplanetary space of ionized gas from the sun. As was mentioned above, this outflow of ionized gas is generally referred to as the solar wind.

The steady outflow of particulate matter from the sun was first recognized by Biermann in 1954 on the basis of the deflection of comet tails away from the sun—a deflection that was too great to be explained on the basis of light pressure. Biermann at first overestimated the strength of the outflow, because of an underestimate of the strength of the interaction between the solar plasma and the cometary plasma. The solar wind was first observed directly and measured with some accuracy in the spacecraft Mariner II.[14] This showed that the concentration of solar material near the earth was of the order of 5 protons/cm^3, along with a corresponding concentration of electrons, moving with a velocity of about 500 km/sec.[14]

Parker[10] has given the most satisfactory explanation of the solar wind, describing it as a continuous hydrodynamic expansion of the solar corona, with a continuous heat input into the outflowing gas for a substantial distance near the sun. The flow can be compared to the flow of gas through a rocket nozzle, where, in the case of the sun, gravity plays the role in restricting the gas flow that the throat plays in the rocket nozzle. Parker has also shown that the outflowing, electrically conducting gas must pull the solar magnetic field out radially and that the rotation of the sun must twist the radial pattern into a spiral. This provides a magnetic connection, or a guiding path, from the western portion of the sun to the earth for any cosmic radiation produced in solar flares, something that is confirmed by observation.

A surprising property of interplanetary space as observed by space probes, is the irregularity of the magnetic field. Although the average orientation of the field agrees with the spiral pattern predicted by Parker, many irregularities are present.[7] The magnetic field energy density is mainly due to the irregular fields, and it is approximately equal to the thermal energy of the solar wind particles, which is approximately 1 per cent of the energy of ordered flow. The real significance of these observations seems not to have been recognized at this writing.

A satisfying concept for the termination of the solar wind at some finite distance from the sun has been provided by Axford *et al.*[1] As the solar wind moves outward from the sun, its concentration falls according to an inverse square law, and the dynamic pressure that can be generated by stopping it falls accordingly. At some point, it must become so attenuated that its continued outward hypersonic flow will be stopped by the galactic magnetic field or by charged particles in galactic space. At this point, there must be a shock front and a conversion of ordered energy of flow into disordered thermal energy. The heated gas beyond the shock front should cool mainly by charge exchange between the high-temperature protons from the solar wind and cool hydrogen atoms from galactic space. After charge exchange, the hydrogen atoms will carry the energy away. The cool proton gas left behind is less electrically conducting than was the hotter gas, and the magnetic field is gradually released from the proton gas, allowing the magnetic field lines to merge and the proton gas to drift out into galactic space.

The hydrogen atoms that are heated beyond the shock front have high enough velocities to penetrate far into the solar system, even to the vicinity of the earth's orbit, before becoming ionized by solar ultraviolet radiation. The hydrogen atoms within a few astronomical units from the sun scatter hydrogen Lyman-alpha radiation emitted by the sun, and this scattered radiation can be detected with instrumentation flown in rockets and spacecraft.[3] The rocket observations can be used to determine the concentration of the high-velocity neutral hydrogen atoms in interplanetary space, and this in turn can be interpreted in terms of the distance from the sun to the shock front beyond which the hydrogen originates. Patterson *et al.*[11] have shown that this interpretation indicates that the distance to the shock front is about 20 astronomical units (AU). The solar magnetic field spirals around about three times in this distance, and in the outer portion of the solar system, the magnetic field lines in the plane of the ecliptic are approximately circular with the sun at the center.

Such a pattern of magnetic field in the solar system can be expected to produce significant anisotropies in the cosmic radiation, whether of solar or galactic origin. This is most pronouncedly true when cosmic radiation is released from a point on the sun that is connected by a magnetic field to the vicinity of the earth, in which case the cosmic radiation appears to approach the earth's magnetosphere from a point forty or fifty degrees to the west of the sun. A weak anisotropy is produced in the low-energy galactic cosmic radiation, and the anisotropy becomes smaller for the higher energy radiation.

Moon The nature of the interaction of the solar wind with a planetary body depends upon a number of factors including the conductivity of the planet, the characteristics of its atmosphere, and the presence of a planetary magnetic field, with each of these able under certain conditions to cause the deflection of the solar wind around the planet. In the case of the moon, there is neither atmosphere nor magnetic field to stop the solar wind, and the conductivity of the moon, mainly near the surface, controls the interaction.[5] Spacecraft observations have shown that the solar wind impinges directly on the lunar surface,[8,15] thus indicating that the moon is a poor conductor at its surface.

Measurements on the lunar surface have shown that magnetic field variations in the solar wind are magnified near the lunar surface on the sunward side. This indicates significant conductivity somewhere in the lunar interior, which permits the induction of internal currents that resist the field change, causing an enhancement of the field charge near the lunar surface. There are residual magnetic fields in lunar rocks, indicating the presence of magnetic field in an earlier era.

Planets There is great diversity among the planets and their influences upon physical phenomena occuring in space. Mercury, the closest planet to the sun, has no atmosphere. It does have an intrinsic magnetic field sufficiently strong to deflect the solar wind most of the time;[12] however the solar wind may impinge upon the planetary surface when it is usually strong.

Venus has a massive atmosphere, while that of Mars is thin, but still sufficient to produce an ionosphere. Venus does not have sufficient magnetic field to deflect the solar wind, whereas Mars apparently has enough field to deflect the solar wind when it is weak.[12] At Venus and most of the time at Mars, the solar wind interacts with the conducting atmosphere in such a way as to produce a shock wave in the solar wind and a deflection of the flow around the planet, but the details of the interactions are not entirely clear. The interaction between the solar wind and the atmosphere is not satisfactorily understood, but it is clear from observation that the interaction does produce a shock wave in the solar wind. Both planets have warm thermospheres, though not nearly so warm as the earth's.

Jupiter has a massive magnetic field[12] and hence the solar wind is kept well away from the planet. The magnetic field also has a strong asymmetry that strongly influences the interaction with the solar wind. Jupiter emits energetic electrons into space on a cyclic basis controlled by the asymmetry. Its behavior resembles that of a pulsar.[16] The energy source is the rotation of the planet. Jupiter is a strong source of radio noise, some of it triggered by its satellite Io. Jupiter has a belt of trapped radiation much more intense than the Van Allen radiation belt around the earth.

Saturn has a weak magnetic field compared to Jupiter,[12] but still strong enough to deflect the solar wind. The magnetic field seems not to have pronounced anomalies in it, and it is closely aligned with the rotation axis of the planet. Saturn emits radio noise sporadically. The energy source for the magnetospheric dynamics is the solar wind, similar to the case on earth and unlike that for Jupiter.

Both Saturn and Jupiter have aurorae that can be observed in the ultraviolet.

SPARK AND BUBBLE CHAMBERS

When particles such as protons, neutrons, or mesons, occurring naturally in the cosmic radiation or produced copiously by accelerators, move through matter, they can produce nuclear interactions which are studied in nuclear and high-energy or particle physics. Electrically charged particles also produce pairs of electrons and positively charged ions in frequent *atomic* collisions, which are used to detect and trace the paths taken by incident and outgoing particles in the nuclear collisions.

In spark chambers, the electrons freed in a gas are accelerated by electric fields between electrodes, so that in further atomic collisions they can free additional electrons, leading to electron avalanches. Space charge effects, also due to the positively charged ions, and energetic photons due to excitation of atoms contribute additional avalanches. "Streamers" result which increase in length until they reach the electrodes at which point spark breakdown occurs, the location of which is recorded. The necessary high voltage potential is applied to the electrodes only after passage of a particle, making spark chambers quite insensitive to background radiation, but allowing them to be triggered by interaction events under investigation.

Parallel-plate spark chambers consist of a number of spark gaps formed by metal plates or foils separated by plastic rectangular frames. Chambers consisting of concentric cylindrical electrodes have also been built. The gaps of 2 to 15 mm must be maintained to accuracies of a few per cent over the full area, up to 10 m^2, of the plates. In thick, heavy metal plates, entering particles can be absorbed by ionization losses so that their ranges and thus energies can be measured, or they can produce electron showers or nuclear interactions. More often, however, thin aluminum foils are preferred merely to track particles originating, for instance, from a liquid hydrogen or deuterium target; high-energy collisions of elementary particles with individual protons or with the one neutron in deuterons are much easier to interpret than events in heavier nuclei where interaction products can undergo secondary collisions.

The spark gaps are usually filled with a gas near normal pressure. Operation at higher gas pressures, and perhaps with liquids, is also possible if the origins of interactions are to be viewed or if very high accuracy for spark location is required. Most frequently used is a mixture of 90 per cent neon and 10 per cent helium which usually is continuously recirculated for purification. If every electron produces α additional electrons per centimeter of drift space, then an avalanche containing about 10^8 electrons can develop if a minimum drift space (or minimum gap width) $d = 20/\alpha$ cm is available. From this "Raether criterion" many operating features of a spark chamber can be predicted. α is the "first Townsend coefficient" which depends on the gas used and on the ratio E/p of applied electric field to gas pressure. For instance, for neon at atmospheric pressure and for a field of 10 kV/cm, $\alpha = 65$. Thus $d \geqslant 3$ mm. If the Raether condition is not met, sparks are not intense or are not formed at all. To obtain spark efficiencies near 100 per cent in a gap, the rise time, duration, and height of the voltage pulse must also be adjusted carefully, especially when many tracks are to be formed simultaneously.

The sensitive time in a spark chamber is defined by the maximum period between arrival of an event to be recorded and application of the voltage trigger pulse. It must be short enough to avoid recording of background events and can be decreased by application of a clearing field of 100 to 200 V/cm between pulses or by an admixture of, for instance, 1 per cent sulfur dioxide or alcohol to the gas filling. For multiplate chambers the sensitive time can be $\geqslant 1$ μsec. The number of events that can be recorded per unit time depends on the repetition time for the whole apparatus. If the sparks are photographed, this time is $\geqslant 0.1$ sec. TV vidicon cameras can be used, where the image focused on a photoconductive surface is scanned by an electron beam and the information stored on magnetic tape or fed directly into a digital computer. The Plumbicon operates similarly but with better space resolution. Repetition times $\geqslant 30$ msec can be expected. The space resolution or accuracy of 0.2 to 1 mm obtainable with a spark chamber is defined by the displacement between actual passage of a particle and resulting spark. An angle $<45°$ between direction of travel of the particle and electrode surface usually results in insufficient accuracy. Accuracy is also affected by time delay of high-voltage pulse, gas properties, Larmor precession in magnetic fields, etc.

Besides emitting light, sparks also emit sound the travel time of which can be recorded, as in acoustic chambers, and of course constitute electric currents used in wire spark chambers, where wires (often aluminum), $\geqslant 100\,\mu$m in diameter and 1 to 2 mm apart, are stretched and fastened across plastic frames to form planes or cylinders. A spark between two wires in two planes produces a current which can be "read out," for instance, after letting it pass through a computer-type ferrite core at the end of every wire, or after causing a sound wave in a magnetostrictive cobalt-iron wire placed across all the ends of the wires in a plane, or after charging a capacitor, the latter being insensitive to magnetic fields. So far magnetostrictive read-out is the cheapest, requiring less electronic circuitry. For unambiguous determination of the location of two or more tracks, three sets of planes with wires at different angles are needed. Wire spark chambers are relatively inexpensive, highly efficient, have repetition times ⩾ 2 msec, and supply digitized information on coordinates. Besides magnetic tape records, it is possible to put at least a fraction of the data pulses into a digital computer on line to the read-out system and display output data on an oscilloscope in the form of tables or histograms so that experiments can be continuously monitored.

In wide-gap chambers the electrodes are up to 60 cm apart so that under proper conditions, including a pulse of several hundred kilovolts, a long spark is produced which follows the path of a particle if inclined >45° to the electrode surface. In a magnetic field the track becomes part of a circle.

In the streamer chamber the duration of the high-voltage pulse is kept so short that a spark cannot develop, but individual streamers, a few millimeters long, are formed from electron avalanches and are photographed end-on, parallel to the direction of the electric field, through wire electrodes. Vidicon viewing usually requires image intensification. Particles must travel at *small* angles to the electrode planes. The density of the streamers along a track is a measure for the velocity of a particle, which decreases with increasing ionization density.

In multiwire proportional chambers, gas amplification proceeds only to the point of avalanche formation. Between planes of tungsten or other metal wires (⩾10 μm diameter) a dc potential difference of a few thousand volts is maintained. The electric field is highest near the fine wires where an avalanche due to a free electron can form and produce a signal which must be amplified at the end of the wire before further transmission. For higher ionization densities, several avalanches form near a wire so that a proportionally stronger signal will be transmitted. Repetition time is about 1 μsec, several orders of magnitude faster than for other types of chambers. Since the high voltage is applied continuously and since they respond in $\geqslant 2 \times 10^{-2}$ μsec, multiwire proportional chambers can be used to trigger other chambers. They are practically 100 per cent efficient for any number of particles and their read-out is not sensitive to magnetic fields.

If a free electron is produced by ionization in a space with known distribution of an electric potential, the electron will "drift" through the gas toward the anode with a velocity that can be predicted accurately from measured data on drift velocities. If the time when a fast ionizing particle entered the space is known by means of a signal from a fast-acting detector, such as a scintillator, and if the time when the electron produces a signal at the anode is measured, then the location where the particle passed through the space can be determined. This has been accomplished rather recently by means of "drift chambers" which, again, consist of arrays of wires, and which can provide excellent space resolution of ⩽100 μm at relatively low cost.

At high-energy accelerators, experimental arrangements can involve many kinds of electronic detectors simultaneously. A "spectrometer facility" might make use of a large magnet to determine particle momenta from track curvatures. The magnet gap may contain a liquid-hydrogen target, surrounded and followed by some of the mentioned electronic chambers. Additional equipment can be mounted outside the magnet, forming "arms" of the spectrometer. Events produced in the target by a beam of particles are selected by coincidences in a trigger system, combining scintillators, Čerenkov counters, or multiwire proportional or drift chambers, and very fast associated circuitry. The whole apparatus is monitored by an on-line computer and all data are stored on magnetic tape for further analysis. High-statistics experiments involving events with many secondary particles distributed over large solid angles are possible with this very powerful technique.

For comparison, the liquid in bubble chambers can act as a target so that the origins of events, as well as secondary events occurring nearby, are visible over a full 4π-solid angle. Excellent space resolution of 50 to 150 μm is provided, depending on the size of a chamber. However, sensitive times are ⩾0.5 msec, much longer than for spark chambers, and repetition times usually >50 msec, depending on size. Furthermore, bubble chambers cannot be triggered for selected events. For these reasons high-statistics experiments are not feasible. The spark and bubble chamber techniques have complemented each other very well, the discoveries with one technique often stimulating further research with the other. For example, neutrino interactions were first studied with spark chambers, but neutrino interactions in hydrogen and deuterium have been studied with very large bubble chambers. On the other hand, many of the hundreds of strongly interacting particles were first discovered in bubble chambers and then their properties were further investigated in spark chamber experiments.

A bubble chamber consists of a pressure vessel filled with a liquid, kept at proper temperature and pressure, which becomes superheated when expanded by means of a piston or diaphragm. A low-energy electron (δ-ray), produced at this time by an atomic collision of a particle passing through the liquid, generates a number of ion pairs which upon recombination cause local heating, or a heat spike, so that a bubble can begin to grow. The heat spike would diffuse in < 1 μsec, which is insufficient to trigger the expansion system. The number of electrons, and therefore bubbles produced per unit length, again depends on the particle's velocity. After a time $\geqslant 0.3$ msec bubbles grow large enough to be photographed. The liquid is then immediately compressed to reliquefy the bubbles. This produces some heat which must be carried off by conduction and convection through the liquid and exchanged at cooling surfaces. At least three glass or quartz windows are provided for complete stereoscopic viewing with camera lenses of high quality, to match the available space resolution. The available depth of the chamber must also be fully covered by the lenses, requiring small apertures and sensitive photographic film. While bubbles in heavy liquids can be dark-field illuminated at 90° to the viewing axis, cryogenic liquids have low indices of refraction and require dark- or bright-field illumination at small angles. Of particular interest is the wide application of a specially developed Scotchlite reflecting light within a narrow cone into the photographic lens located at the center of a ring-shaped light source. Usually, bubble chambers are mounted inside magnets providing fields as high as 40 kilogauss. Some very large magnets have employed superconducting niobium-titanium wires embedded in and stabilized by copper. Thus large amounts of electric power are saved, which will soon amortize the initial investment for required helium refrigerators operating at 4.2 K.

In heavy-liquid bubble chambers, mixtures of propane and freon have been used, which due to their short radiation lengths are especially important for detection of gamma rays by conversion to electron pairs. They are operated near room temperature at pressures up to 20 atm and must be expanded by about 3 per cent requiring very powerful actuating systems for expansions. Studies of interactions in liquid hydrogen or deuterium avoid complications due to heavy nuclei, but require cryogenic techniques at operating temperatures between 25 and 30 K. Cryogenic bubble chambers are expensive and require careful safety precautions and relatively large operating staffs. They are expanded by $\leqslant 1$ per cent from pressures $\leqslant 8$ atm. Liquid neon or neon-hydrogen mixtures can also be used for gamma-ray detection. "Track-sensitive targets" have been developed, consisting of transparent plastic containers filled with hydrogen or deuterium mounted in a bubble chamber filled with neon-hydrogen and expanded simultaneously with the chamber. A cryogenic bubble chamber requires multilayered aluminized plastic insulation in a vacuum chamber which may be shared with the magnet if it is superconducting. Cryogenic bubble chambers containing as much as 30 m^3 of liquid are in use.

Also of interest are sonic chambers which are expanded >20 times per second by producing a standing sound wave between two plates in the liquid. Sonic chambers, as well as other rapid-cycled chambers are especially useful at rapid-pulsed linear accelerators, in contrast with synchrotrons where expanding a chamber two or three times during the less frequent accelerator pulse is usually sufficient.

Bubble chamber and spark chamber photographs store a large amount of data which must be extracted by first scanning the film for events that may satisfy the requirements of a particular experiment. For simple interactions computer-guided pattern recognition methods may be applied in conjunction with human intervention and interrogation, combining the scanning and subsequent measuring processes. More often the scanned film is transferred to measuring machines of varying complexity where positions of bubble or spark images are measured with commensurate accuracy. As an example, on a flying-spot digitizer, a light spot, 15 μm in diameter, scans a photograph in a few seconds. A bubble image causes a signal in a photomultiplier, which is compared with time pulses similarly produced by a grating scanned by a synchronized light spot, locating the image with respect to fiducial marks. Hundreds of events per hour can thus be measured with excellent precision. In the spiral reader a fine slit spirals over the photograph, again producing light signals. A flying-image digitizer has scanned many different portions of a photograph simultaneously so that thousands of events were processed per hour. The processing of spark or bubble chamber data requires large amounts of computer time, on-line to scanning and measuring equipment and off-line for spatial reconstruction of events from the three or more stereoscopic views, for kinematic fitting and selection of probable events, and finally for interpretation of results.

SPECTROSCOPY

The term *spectroscopy* generally refers to the study of spectra of some quantum mechanical particles. The spectrum is a display of these particles arranged in order of their energy values. Traditionally, the term was used in a rather restricted sense to refer only to electromagnetic waves, i.e., the photons. In present practice, the use of the term has been substantially broadened to include various particles, as in mass spectroscopy, β-ray spectroscopy, neutron spectroscopy, etc., where the term is used jointly with the name of the particle in question. If no specific particle is mentioned, electromagnetic spectra are implied. In this article, spectroscopy is discussed as the study of the atomic and molecular properties which are revealed when they interact with an electromagnetic field. The main concern of spectroscopic study is (1) the

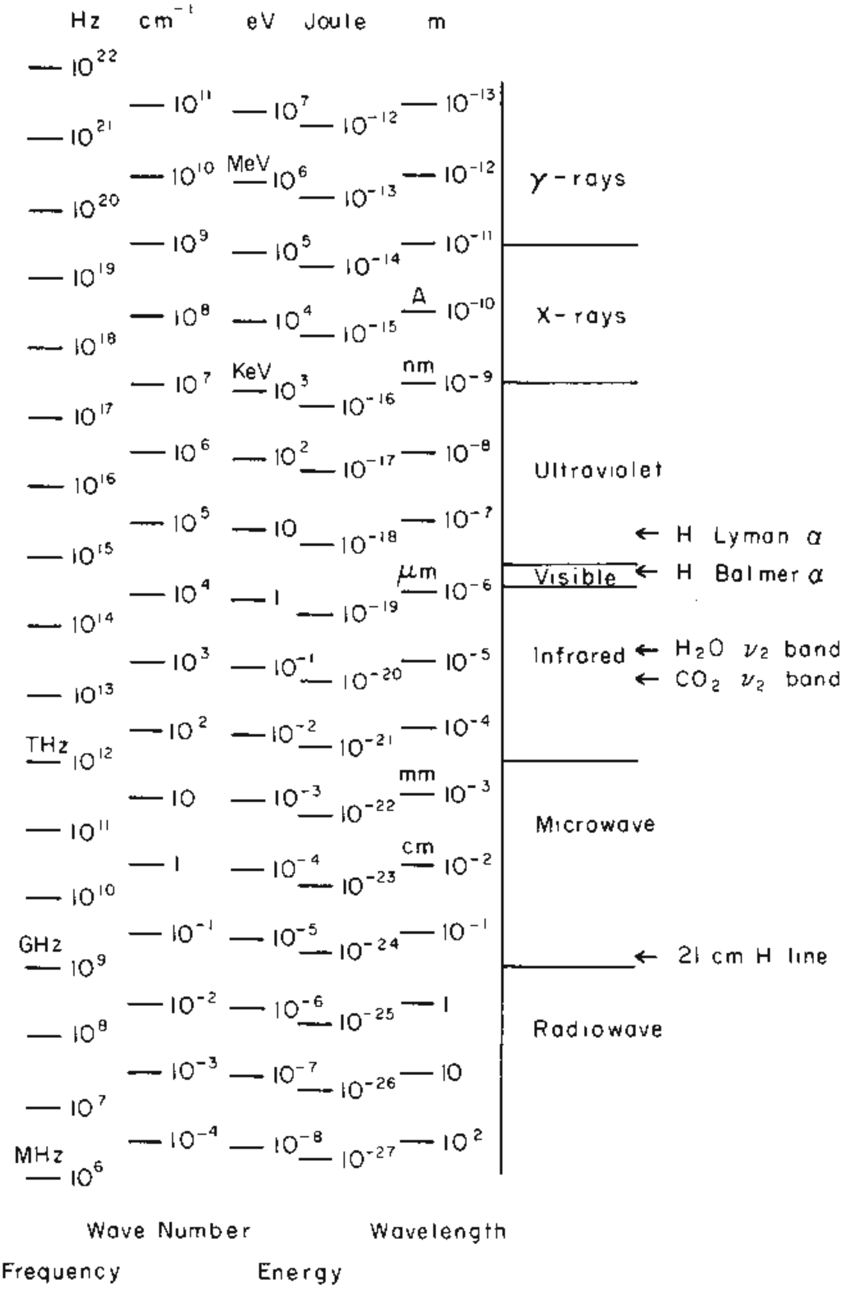

FIG. 1. Spectrum of electromagnetic waves.

atomic and molecular energy levels, and (2) the transitions which take place from a level to another as a result of their interaction with the electromagnetic field.

The electromagnetic spectrum is classified according to frequency or wavelength. The quanta of electromagnetism, photons, have a definite energy E given by the product of the frequency ν and the Planck's constant $h = 6.63 \times 10^{-34}$ J s:

$$E = h\nu.$$

Fig. 1 is a schematic diagram showing the electromagnetic spectrum, together with various units of energy, frequency, and wavelength. An atomic or molecular system interacts with an electromagnetic field through its emission or absorption process. The spectrum represents the emission or absorption of photons by the atoms or molecules. The various units which characterize the spectrum are shown in Fig. 1. Unfortunately, there is no conformity in usage of these units; spectroscopists working on a particular spectral region use their own preferred units.

General Description of Atomic and Molecular Transitions Both absorption and emission processes involve a quantum transition between two energy states of an atom or molecule. The energy difference covers a wide range, depending on the nature of the quantum transition involved (nuclear, electronic, vibrational, rotational, etc.).

Atoms and molecules have, in general, a size on the order of an angstrom (1 Å = 10^{-10} m). We can estimate the energy involved in electronic, vibrational, and rotational transitions using a simple atomic or molecular model having a size of 1 Å. The electrostatic energy which binds a nuclear charge of 1.6×10^{-19} coulomb and an electronic charge of -1.6×10^{-19} coulomb at a distance of 1 Å for a hydrogenlike atom shown (Fig. 2) is given by

$$E_e = \frac{Ke^2}{r} = \frac{9 \times 10^9 \times (1.6 \times 10^{-19})^2}{10^{-10}} \text{ J}$$
$$= 2.3 \times 10^{-18} \text{ J} = 14.4 \text{ eV}.$$

Balmer, in 1885, discovered that the four lines of the hydrogen spectrum (those marked α, β, γ, and δ in Fig. 3) formed a series. Subsequently, Rydberg found that those lines are given by

$$\bar{\nu} = R\left(\frac{1}{2^2} - \frac{1}{n^2}\right), \qquad n = 3, 4, 5, 6$$

where $\bar{\nu}$ is the *wavenumber*, which is equal to the inverse of wavelength, and R, the *Rydberg constant*, is equal to 109677 cm^{-1} = 13.6 eV, remarkably close to the value calculated above. Bohr formulated the atomic model that yields the energy level of a bounded electron in the

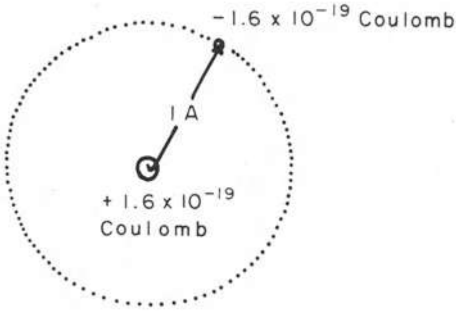

FIG. 2. The model of atom used for the calculation in the text.

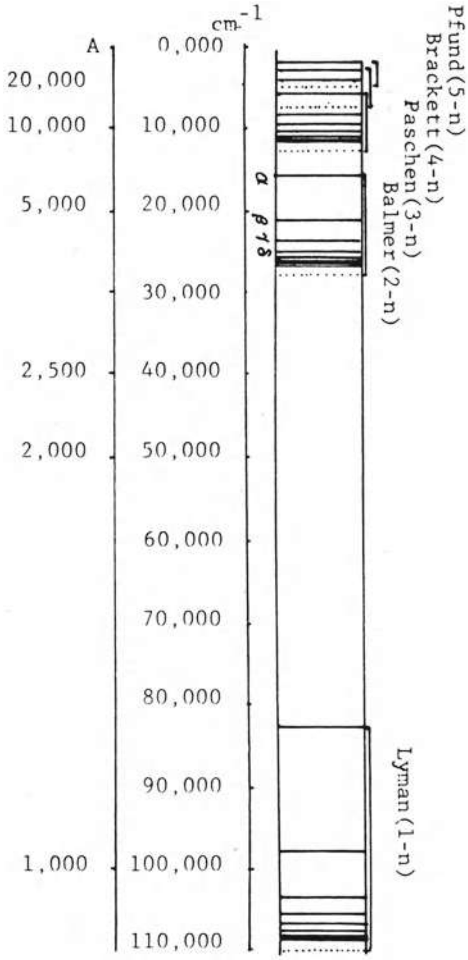

FIG. 3. Spectrum of atomic hydrogen: the wavenumber of these spectral lines is given by $\bar{\nu} = R(1/m^2 - 1/n^2)$, where $m = 1$ is for the Lyman series, $m = 2$ for the Balmer, $m = 3$ for the Paschen, $m = 4$ for the Brackett, and $m = 5$ for the Pfund.

electrostatic field of a proton by

$$E = -\frac{R}{n^2}$$

where n is the principal quantum number. The electronic energy levels in the valence shells of atoms and molecules are approximated by the Bohr model. Electronic transitions take place between two electronic energy states. They require energies ranging from several tenths of an eV to several eV. The corresponding spectral region ranges from the infrared to the extreme ultraviolet, as seen in Fig. 3.

Nuclear transitions involve the nuclear particles, the protons and neutrons. The electrostatic energy between two protons of 1.6×10^{-19} coulomb spaced at an average nuclear distance of 10^{-15} m is on the order of 10^6 eV. The nuclear binding energy is roughly equal to the electrostatic energy of this magnitude; without it, these particles would repel each other by the electrostatic force. A nuclear transition involves an energy of this magnitude, the spectrum of which falls in the γ-ray region.

The electrons in the inner shells of atoms have binding energies at least an order of magnitude higher than the Rydberg constant, since the electrons there are bound at distances that are a fractional part of the atomic size under the coulomb field of several proton charges. Inner shell electron transitions have a photon energy ranging from several hundred eV to several thousand eV, the spectrum of which falls in the X-ray region.

For a molecular vibrational transition, we can model a simple molecule of two 20-proton-mass nuclei spaced by a distance of 1 Å. The binding energy is approximated by the electrostatic energy 14.4 eV for two charges of 1.6×10^{-19} coulomb spaced at 1 Å. A quadratic function (Fig. 4) approximates the molecular potential at its minimum. We can use the quadratic potential for calculating the vibrational frequency. The vibrational force constant is then calculated by

$$\tfrac{1}{2} k x_0^2 = V_0$$

or

$$k = \frac{2V_0}{x_0^2} = \frac{2 \times (14.4\ \text{eV})}{(0.5\ \text{Å})^2} = 18.4 \times 10^2\ \text{N/m}.$$

We can calculate the vibrational frequency of the model molecule by

$$f_v = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}} = \frac{1}{6.28}\sqrt{\frac{1840\ \text{N/m}}{10 \times 1.6 \times 10^{-27}\ \text{kg}}}$$
$$= 5.4 \times 10^{13}\ \text{Hz} = 1800\ \text{cm}^{-1}$$

where μ is the reduced mass of oscillator, 10 proton-masses of $10 \times 1.6 \times 10^{-27}$ kg. The obtained vibrational frequency 5.4×10^{13} Hz or the wavenumber of 1800 cm^{-1} falls in the mid-infrared region. A majority of simple molecules show their fundamental vibrational transition in the mid-infrared spectral range.

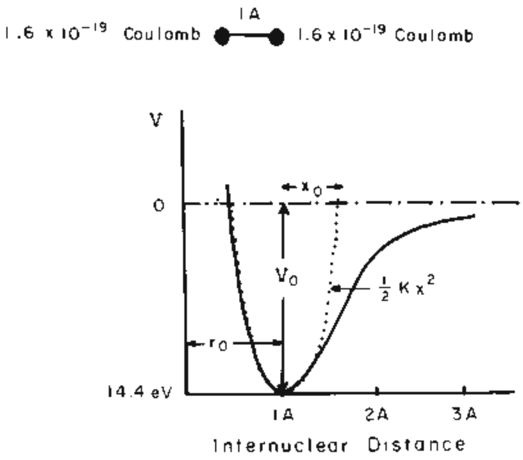

FIG. 4. The model of molecule used for the calculation in the text.

For molecular rotation, the model molecule has a moment of inertia

$$I = \tfrac{1}{2} m x_0^2 = \tfrac{1}{2}(20 \times 1.6 \times 10^{-27}\ \text{kg})$$
$$\times (10^{-10}\ \text{m})^2 = 1.6 \times 10^{-46}\ \text{kg m}^2.$$

Its rotational energy is calculated by

$$E_R \approx \frac{(\text{angular momentum})^2}{(\text{moment of inertia})}$$
$$= \frac{(1.06 \times 10^{-34})^2}{1.6 \times 10^{-46}}$$
$$= 3.5 \times 10^{-23}\ \text{J} = 2\ \text{cm}^{-1},$$

which falls into the far infrared or the microwave region.

The energy levels of a simple molecule can be classified into three major contributions: electronic, vibrational, and rotational. The molecular energy is expressed as a sum of these three terms:

$$E = E_e + E_v + E_R.$$

The electronic energy contribution is by far the largest. The molecular energy state is structured with an electronic energy state of fixed value E_e accompanied by many vibrational-rotational energy states. We can interpret this situation as an electronic energy state split into multiple levels characterized by different sets of E_V and E_R, the splitting being caused by the vibrational-rotational interaction. Most molecular transitions between electronic states are composed of several thousand lines, each of which is the transition characterized by a common value of the electronic energy change but a different value of the vibrational-rotational energy change. The very complex patterns exhibited by molecular transitions contrasts the simple patterns of atomic transitions, which we see for the case of the hydrogen spectrum in Fig. 3.

In general the quantum states of molecules and atoms are perturbed by various interactions. The molecular electronic energy state perturbed by the vibrational-rotational interaction is an example. The magnitude of interaction is quite different, depending on its nature. Table 1 summarizes the interactions observable in atomic and molecular systems, together with their magnitudes in Hz and cm^{-1}. Some interactions listed in Table 1 cause shifting of the atomic and molecular energy levels. In such cases, the transition frequency shifts accordingly. Most interactions, in addition to level shifting, cause level splitting. The corresponding spectral transition would exhibit a complex structure. When the resolution of the spectrometer is improved, a previously unobservable interaction may suddenly become observable, and a complicated structure may often be revealed. A challenge is always imposed to spectroscopic study (1) to discover complicated structures, and (2) to analyze the observed structures in terms of interactions hitherto unnoticed. Effort along this direction requires two elements: an improvement of spectroscopic technique and a development of theory to understand the interaction processes involved.

History of Spectroscopy Spectroscopy began long before the establishment of quantum mechanics. Isaac Newton documented the fact that the sunlight was dispersed into many colors when it was passed through a prism. Joseph Fraunhofer was instrumental in improvement of the art of spectroscopy. By the end of the 19th Century, spectroscopy had advanced to such a degree that the spectroscopic terminology now used for classifying observed atomic spectral lines was already established, even though the physics involved was not clearly understood until the advent of quantum mechanics. Indeed, the spectroscopic data collected in those days provided a driving force for development of quantum mechanics. By 1940, the quantum mechanical model of atoms and molecules as currently understood was firmly established, based on spectroscopic data taken mainly in the visible and the ultraviolet region during the 1920s and '30s.

The advent of the radiowave and microwave technology during the Second World War made it possible to extend spectroscopic measurement into these two regions. For the first time, atomic and molecular systems were investigated using a coherent monochromatic source. Spectral transitions which had previously been measured only in wavelength by applying optical techniques now became known in frequency. The development of magnetic resonance techniques was paralleled by microwave spectroscopy. The technique was applied to both electronic and nuclear spins. Transition frequencies for both spin resonances are very low, falling in the radiowave and microwave region. Spectroscopy extended to these low-frequency regions achieved a spectacular improvement in resolution, in part because the electromagnetic field applied for the spectroscopic measurement was coherent and monochromatic, and in part because the frequency itself was very low compared with the frequency resolution then available in other spectral regions. Extremely small transition frequency differences and consequently extremely weak interactions were measured with a great accuracy. W. Lamb succeeded in measuring the small energy difference between the

TABLE 1. ATOMIC AND MOLECULAR INTERACTIONS.

Magnitude of Atomic Interactions		
Electron Spin-Orbit (fine structure)	$\sim 10^{12}$–10^{13} Hz	10^{2}–10^{3} cm^{-1}
Nuclear Spin-Orbit (hyperfine structure)	$\sim 10^{10}$–10^{11} Hz	10^{-1}–1 cm^{-1}
Nuclear Quadrupole Moment	10^{10}–10^{11} Hz	10^{-1}–1 cm^{-1}
Zeeman Effect	10^{6} Hz/Gauss	10^{-4} cm^{-1}/Gauss
Stark Effect	10^{7} Hz/(kV $\text{cm}^{-1})^2$	10^{-3} cm^{-1}/(kV $\text{cm}^{-1})^2$
Lamb Shift	10^{10} Hz	10^{-1} cm^{-1}
Magnitude of Molecular Interactions		
Rotation Electron Orbit	10^{10}–10^{11} Hz	10^{-1}–1 cm^{-1}
Rotation-Nuclear Spin	10^{5}–10^{6} Hz	10^{-5}–10^{-4} cm^{-1}
Nuclear Spin-Nuclear Spin	10^{5}–10^{6} Hz	10^{-5}–10^{-4} cm^{-1}
Zeeman Effect (Rotation-Nuclear Spin)	$\sim 10^{3}$ Hz/Gauss	$\sim 10^{-7}$ cm^{-1}/Gauss
First-Order Stark Effect	$\sim 10^{6}$ Hz/V cm^{-1}	$\sim 10^{-4}$ cm^{-1}/V cm^{-1}
Second-Order Stark Effect	10^{4} Hz/(V $\text{cm}^{-1})^2$ $\sim 10^{5}$ Hz/(V $\text{cm}^{-1})^2$	10^{-6} cm^{-1}/(V $\text{cm}^{-1})^2$ -10^{-5} cm^{-1}/(V $\text{cm}^{-1})^2$

hydrogen $2S_{1/2}$ and $2P_{1/2}$ levels (the *Lamb shift*), confirming the validity of quantum electrodynamics.

A question concerning coherent sources in the infrared, visible, and ultraviolet regions was finally solved during the early 1960s when laser devices were developed. The laser provided a source of extremely long coherence length, of extremely good monochromaticity, and of excellent directionality. Because of these characteristics, it provided a large energy density and power density, which could not be obtained with the use of thermal light sources. Spectroscopic measurements which were previously unthinkable became realized in the spectral region from infrared to ultraviolet.

Spectrometers The monochromator spectrometer, which disperses incident light into its spectral components, plays a primary role in spectroscopy, although the development of tunable laser devices has diminished its importance somewhat. Primitive instruments dispersed the spectral elements by means of a prism. Soon it was found that diffraction gratings used as dispersive elements were characteristically much more favorable than prisms in achieving high-quality measurement. The ultimate spectral resolution which a spectrometer can achieve is determined by the maximum optical path difference produced by the dispersive element [see Fig. 5(a)]. The resolution is in essence limited by the size of the grating or prism used. A. A. Michelson circumvented the limitation imposed by the small dispersive elements available in his days by his invention of the Michelson interferometer, shown in Fig. 5(b), and achieved remarkable results. Resolution in his interference spectroscopy technique was limited by the maximum optical distance through which the movable mirror of the interferometer traveled during the measurement of the visibility curve. Even though remarkable spectroscopic data were obtained using interference spectroscopy, the mainstream of spectroscopists in the 1920s and '30s stayed with diffraction grating monochromator instruments. The best spectral resolution achieved using grating instruments was on the order of 0.1 cm^{-1} (3 GHz). The grating spectrometer has remained predominant in the visible and the ultraviolet region, while a new type of spectrometer has emerged in the infrared region, where the collecting efficiency of spectral power is one of the most critical issues, because the detectors generally available for that region are rather insensitive. By 1950, two important discoveries had been made in infrared spectroscopy: (1) The Michelson interferometer turned out to be better than conventional grating instruments in collecting incoming spectral energy. (2) Two-beam interference could be used for simultaneous observation of all spectral elements in the incoming signal. The Michelson interferometer used as a spectrometer produces an output proportional to the Fourier transform of the incoming spectral signal. The spectrum is computed by applying the Fourier transformation to the output signal which is obtained as a function of the optical path difference between two interfering beams. Because of this feature, the technique is generally referred to as *Fourier transform spectroscopy*. It brought enormous success to infrared spectroscopy. The spectrum obtained for the CO_2 ν_2 vibrational-rotational band using the FTS technique is shown in Fig. 6(a). An exceptionally clean spectrum obtained with a very high resolution figure of 0.004 cm^{-1} indicates the power that this spectroscopic method has accomplished with a combination of the traditional and modern approach.

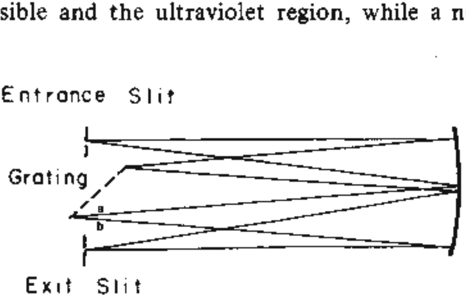

FIG. 5(a). Typical grating spectrometer. This is called the Ebert-Fastie mount. The maximum optical path difference is given by $a + b$.

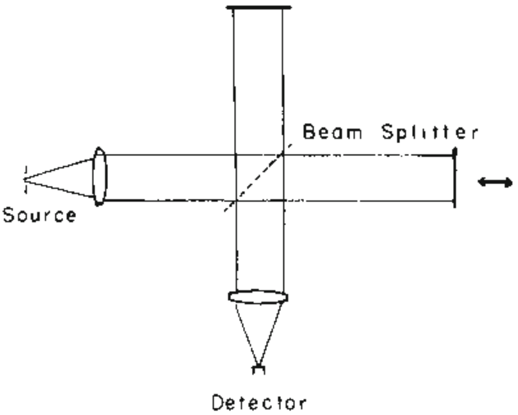

FIG. 5(b). Michelson interferometer. The optical path difference is given by twice the difference between the distance to the stationary mirror and to the movable mirror measured from a common point in the incident beam.

Selection Rules The atoms and molecules absorb photons to produce transitions from one energy state to another. The state reached by absorbing a photon must differ from the initial state by the energy and angular momentum of the absorbed photon. Since the photon is a Bose particle of spin quantum number 1, the angular momentum quantum number must be changed by 1 in an optically allowed transition of atoms and molecules. This condition is the

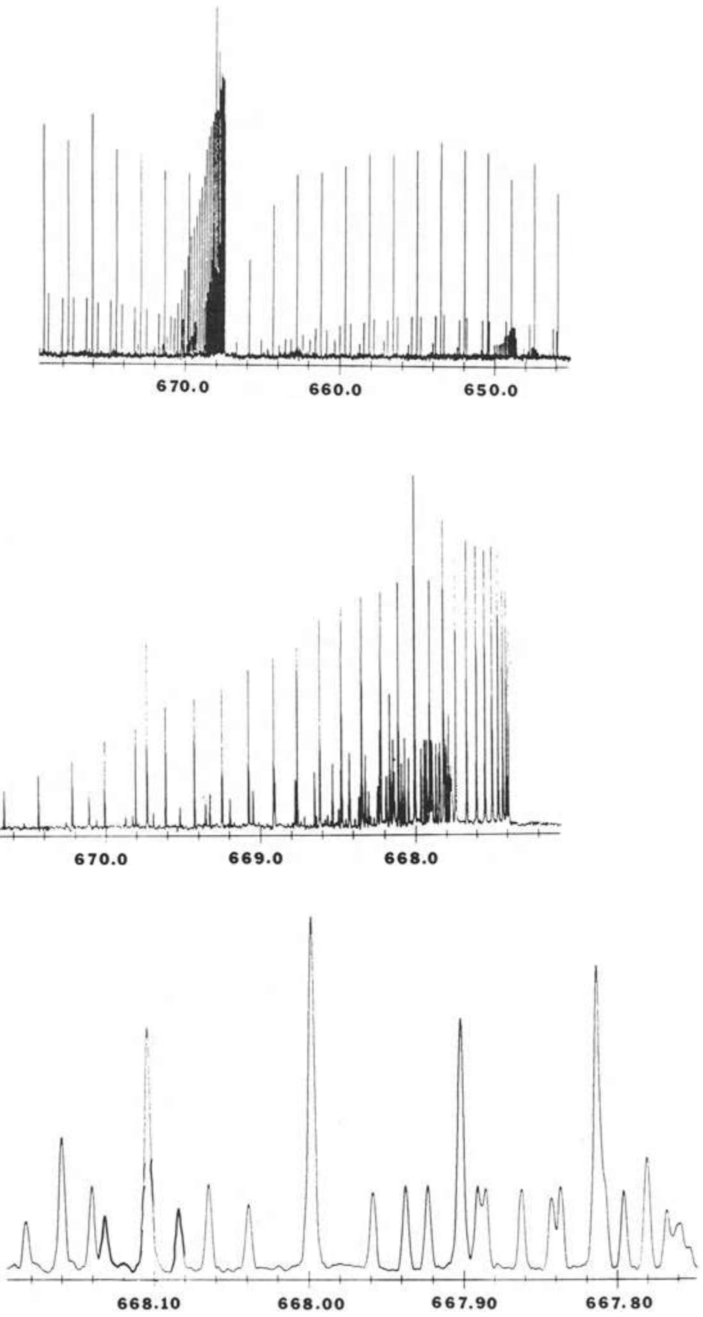

FIG. 6(a). The CO_2 spectral transitions observed in the 670 cm^{-1} region using an FTS instrument with a spectral resolution of 0.004 cm^{-1}. They are produced by its bending motion superposed by the rotational motion. In the top spectrum, the three branches (P, Q, and R) of the major band and the other minor bands are seen. A detail of the Q branch at the 667 cm^{-1} region is difficult to see. In the middle spectrum, the Q branch region is expanded to show three bands ($\nu_2 = 1 \leftrightarrow \nu_2 = 0$), ($\nu_2 = 2 \leftrightarrow \nu_2 = 1$), and ($\nu_2 = 3 \leftrightarrow \nu_2 = 2$). In the bottom spectrum, the region is further expanded. The line profile is observed to be Gaussian. (Courtesy of Henry Buijs, Bomem, Inc., Quebec, Canada.)

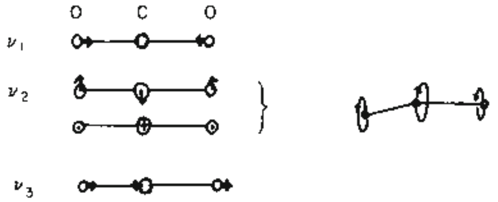

FIG. 6(b). Three vibrational modes of the CO_2 molecule. The bending ν_2 mode is a two-hold, up-and-down and in-and-out, motion shown in the figure. The combined two-hold motion produces the vibrational angular momentum parallel to the figure axis.

basis of the selection rules which formulate the possible optical transitions between two states. The strength of the transition is controlled by the electric dipole matrix elements defined between the two states. For a pure rotational transition, the dipole matrix element is proportional to the permanent dipole of the molecules. No pure rotational band is observable for a nonpolar molecule which has its electric charge distribution symmetric with respect to its center of mass. For the vibrational band, the matrix element is proportional to the first derivative of electric dipole with respect to the molecular geometry change which accompanies the vibrational motion in question.

The CO_2 molecule is linear in the ground state. No permanent electric dipole is associated with the ground state, therefore no pure rotational band is observed. The lowest vibrational frequency belongs to the bending motion shown schematically in Fig. 6(b). Since the bending motion of a linear CO_2 molecule is twofold, as indicated in Fig. 6(b), it carries an angular momentum along the molecular axis. If the optical transition may accompany a change in the vibrational angular momentum quantum number by 1, no change in the rotational angular momentum quantum number J takes place, so as to conserve the angular momentum of the whole system, the molecule and the photon. The transitions which belong to this category are classified as the Q branch ($\Delta J = 0$). If the vibrational angular momentum quantum number remains unchanged in the transition, the rotational quantum number J must change by +1 or −1 ($\Delta J = \pm 1$). The transition forms the P ($\Delta J = -1$) branch at the lower frequency side of the Q branch, and the R branch ($\Delta J = +1$) at the higher frequency side.

Practical Use of Spectroscopy The CO_2 spectrum described above demonstrates the extent of the information which can be collected by means of spectroscopy. The energy difference and the transition strength are the two quantities which are obtained in the observed spectral transition between two energy states. A collection of these observed values eventually reveals the exact nature of the entire energy states, and in turn it can be used to determine the field which specifies them. For the case of atomic spectroscopy it reveals the atomic field. For the case of molecular spectroscopy it reveals the molecular field. Spectroscopy in a particular frequency region yields a limited coverage of spectral transitions, hence the information collected is not extensive enough to reveal all aspects of the atoms or molecules in question. Nonetheless, spectroscopy with a limited frequency coverage is applied for the purpose of identifying atoms and molecules in a sample. For this purpose, characteristic transition frequencies exhibited by known atoms and molecules are sought in the sample, and identification is accomplished by finding them. Because of this feature, spectroscopy provides a vital tool in sample analysis for astronomy, chemistry, biology, and other sciences. Its practical merit lies in the fact that the information is transmitted through electromagnetic radiation, so that observation of spectra does not necessitate direct contact with the sample. The astronomer sitting on earth a million light years from an astronomical object is able to determine what atoms and molecules are in it by means of spectral observation of the electromagnetic radiation which arrives from it. Because spectroscopy can provide direct information on the nature of a substance as well as its environment without requiring direct contact, it is a very important experimental method not only for physics but for other branches of science as well.

Absorption and Emission Processes The spectral transition being observed is primarily controlled by two factors: the electric dipole matrix element and the population of atoms or molecules which occupy the initial state of the transition. A secondary parameter is the density of photons to which the atoms and the molecules interact. The atomic or molecular system establishes an equilibrium with the photon field by absorbing photons from the field and emitting photons back to the field. The absorption process is controlled by the photon density in the field, while the emission process consists of two terms: the spontaneous term, which is independent of the photon density in the field; and the induced (or stimulated) emission term, which increases its magnitude in proportion to the photon density in the field. If the upper state population is very small compared with the lower state population, the emission is predominantly spontaneous, and totally independent of neighboring atoms or molecules. Excitation to the upper states is accomplished either thermally in the case of thermal light, or by electron collisions in case of the electric discharge lamp. No laser action is present as long as the upper state population stays low. When this condition is broken, the emission is no longer dominated by the spontaneous process.

Profile of Spectral Lines The spectral lines emitted by a transition between two states are subject to the finite lifetime of the excited state. The uncertainty relation $\Delta E \Delta t \geqslant h$ demands that the spectral lines have a line profile of Lorentzian shape with half-width $\Delta E \approx h/\Delta t$ in accordance with the finite lifetime Δt of the excited state. If the emission is interrupted by collision with neighbors, the lifetime further decreases, resulting in an increase of the line width. In addition to the line broadening caused by finite lifetime, spectral lines are subject to inhomogeneous broadening processes. In a gas, each emitter moves at a different velocity and emits at a frequency slightly shifted from the value at rest because of the Doppler effect. Consequently, an ensemble of emitters produces a spectral line inhomogeneously broadened by the thermal motion of each emitter. A profile of the inhomogeneously broadened line differs from the Lorentzian profile broadened by a finite lifetime. It has a Gaussian shape because the emitters move in accordance with the Maxwell-Boltzmann velocity distribution law. If pressure is kept low, the absorption or emission spectral line exhibited by a gaseous sample is characterized by the Doppler broadened Gaussian line profile, as seen in the CO_2 spectral lines of Fig. 6.

Laser Spectroscopy The laser can play a very special role in spectroscopy because of its highly monochromatic nature and its high energy density. The tunable laser device, being highly monochromatic, provides a convenient source for absorption spectroscopy. The resolution obtained in such a measurement is not controlled by the line width of the source. It is limited normally by the Doppler width of the line being studied. Minor interactions responsible for splitting spectral lines into multicomponents may escape detection because the splitting may be completely smeared by Doppler broadening. The high energy density of laser radiation provides a solution to such a case.

The photon density in the intense field would influence the absorption process by producing a significant perturbation in the population distribution. The lower state may be pumped significantly by the laser field. If the pumping laser line is much narrower than the Doppler width of a molecular line, for example, those molecules which move at a proper speed for making a resonance with the laser frequency are pumped to their excited state. If a second probe laser is swept across the Doppler width of a spectral line, it detects the absorption reduced to a low value at the frequency of the pumping laser, and the absorption is unaffected at other frequencies. This phenomenon is referred to as the *hole-burning process*. A large perturbation in the population distribution is observable when a source of high energy density is used to excite a gaseous sample.

The case of laser beam excitation is unique because its highly monochromatic pumping produces a large population perturbation with an extremely narrow spectral range in Doppler width. If the probe beam and the pumping beam originating from a single laser source are sent into a gas cell from both sides, as shown in Fig. 7, the molecules which move at a certain speed in one direction resonate with one beam, and those which move at the same speed in the opposite direction resonate with the other beam [see Fig. 7(a)]. If the laser oscillates at the center frequency of the spectral line, the molecules which have zero velocity components along the beam direction are able to resonate with both beams. The probe beam can detect the hole burnt by the pumping beam only if the laser oscillates at the center frequency of the

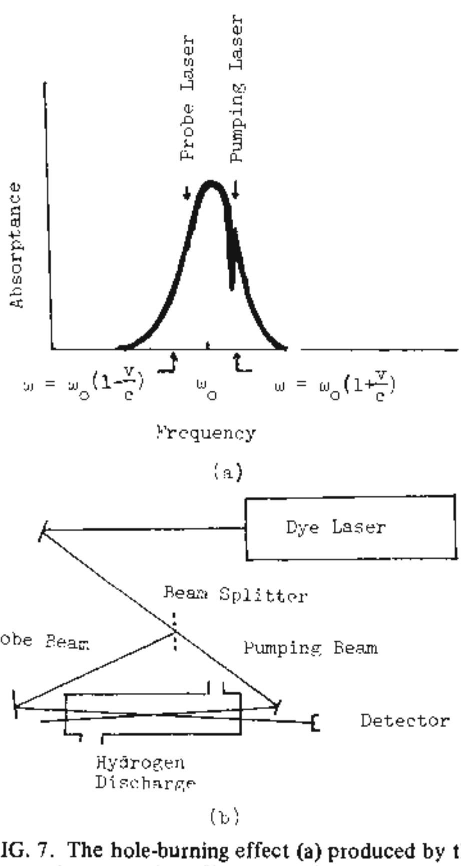

FIG. 7. The hole-burning effect (a) produced by the scheme shown in (b). The molecules moving at $+v$ make a resonance with the pump beam which is directed to the negative direction, while those moving at $-v$ make a resonance with the probe beam which is directed to the positive direction. The pump beam produces a hole at $\bar{\nu} = \bar{\nu}_0(1 + v/c)$. The molecules resonating with the pump beam see the frequency of the probe beam to be $\bar{\nu} = \bar{\nu}_0(1 - v/c)$, and they do not resonate with it.

TABLE II. ATOMIC AND MOLECULAR LASER SPECTROSCOPY.

spectral line. The absorption of the probe beam drops sharply at the line center if the laser frequency is scanned across the Doppler width of the line. Spectroscopy is then carried out free of inhomogeneous Doppler broadening. This Doppler-free technique has achieved measurements of hydrogen's Rydberg constant and Lamb shift with an accuracy of ±10 MHz.

Excited atoms and molecules by absorbing a photon jump back to the lower state either by emitting a photon or by transferring their internal energy to kinetic energy. The first process is referred to as *fluorescence scattering* if the involved initial excitation is to a discrete bound state, and as *Raman scattering* if it is to a certain undefined level. For either case, the emitted photon may or may not have the same frequency as the incident photon. The second process is called the *photoacoustic* phenomenon. Study of these processes began long before the development of lasers. Now, use of a laser beam as the excitation source for these relaxation processes is common practice, taking advantage of high photon density concentrated within an extremely narrow spectral width.

Nonlinear absorption of photons by atoms or molecules becomes pronounced when the density of incident photons becomes very large. The use of the laser has been essential for study of the nonlinear effects. Several spectroscopic schemes have been developed based on the nonlinear effect exhibited by atomic or molecular systems. The hole-burning spectroscopy mentioned above is an example. Another category which uses the nonlinear optical effect is multiphoton spectroscopy, where more than a single photon contributes to the absorption process. The double resonance scheme uses two photons of different frequencies to create a single transition, while the two-photon or multiphoton absorption spectroscopy scheme relies on excitation by two or more photons of the same frequency.

Spectroscopy performed with incorporated laser devices is generally classified as laser spectroscopy. The technique has been and is progressing rapidly. Table 2 summarizes various schemes practiced nowadays. Included in the Table are their salient features.

SPIN WAVES (MAGNONS)

General Properties In magnetically ordered solids such as ferromagnets, antiferromagnets, and ferrimagnets, the spins of the magnetic ions are oriented along certain preferred directions. Coherent deviations of the spins from their preferred direction which propagate in space and time with wave-like characteristics are called spin waves. They were first studied by F. Block in 1930.[1] Spin waves are similar to lattice waves in solids. The departure of the spin vector from its preferred direction is analogous to the atomic displacement of a lattice vibration. The spins of a ferromagnetic insulator, for example, may be pictured classically as precessing about the direction of magnetization as illustrated in Fig. 1. The radius of the precessional circle is proportional to the amplitude of excitation of the spin wave and the phase on the precessional circle varies in a wave-like manner. Spin waves are characterized by a propagation vector k and a frequency vs wave-vector dispersion law $\nu(\mathbf{k})$. According to quantum theory, spin waves are elementary (Bose) excitations called magnons which possess linear momentum $\hbar\mathbf{k}$, a quantum of energy $h\nu(\mathbf{k})$, and one ($\hbar$) unit of spin angular momentum. At low temperatures the magnetic contribution to thermodynamic quantities such as internal energy, specific heat, magnetization, and thermal conductivity is determined by the number and energy of thermally excited magnons. Spin waves have been observed and studied by a variety of experimental techniques. Some of the important physical phenomena associated with spin-wave excitations are presented in Table 1.

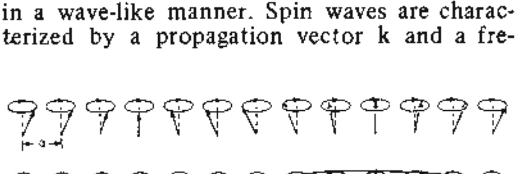

FIG. 1. In the top of the figure the spins are illustrated in perspective. The bottom shows the circular precession of each spin with the wave-like motion drawn through the ends of the spin vectors.

Microscopic Theory of Spin Waves Magnetic ordering in solids is a consequence of the Pauli exclusion principle, which leads to a dependence of the coulomb energy on the spin directions of the electrons comprising a quantum-mechanical system. The energy associated with this effect is called the exchange energy, and it may be represented by an exchange Hamiltonian[9]

$$\mathcal{H} = -\tfrac{1}{2} \sum_{\ell \neq m} J(\ell, m)\, S_\ell \cdot S_m, \qquad (1)$$

where S_ℓ is the spin operator of a magnetic ion located at the lattice position $\mathbf{R}_\ell$. The exchange integrals $J(\ell, m)$ depend on $\mathbf{R}_\ell - \mathbf{R}_p$ but are nonnegligible only for $|\mathbf{R}_\ell - \mathbf{R}_p|$ less than a few atomic lattice spacings. For a ferromagnet the J's are predominantly positive so that the minimum exchange energy results for a ground state $|\psi_g\rangle$ in which all spins are parallel. For the antiferromagnet or ferrimagnet the J's are predominantly negative leading to minimum energy for approximately antiparallel (or complex) spin arrangements in the ground state. The low-lying excited states $|\psi_\mathbf{k}\rangle$ of the exchange Hamiltonian are spin waves which correspond to a uniform probability of finding one quantum of spin disorder in the system. For a ferromagnet the magnon state is

$$|\psi_\mathbf{k}\rangle = \frac{1}{\sqrt{N}} \sum_\ell e^{i\mathbf{k}\cdot R_\ell}\, S_\ell^-\, |\psi_\mathbf{g}\rangle \qquad (2)$$

where $\bar{S_\ell}$ is the operator which lowers the spin at R_ℓ by one unit. These states are solutions of the exchange Hamiltonian only when the number of spin waves in the system is small. Neglect of magnon-magnon interactions is referred to as the spin-wave approximation. This approximation is valid at low temperatures where the energy of the system associated with the magnons is

$$\mathcal{E} = \sum_\mathbf{k} \bar{n}_\mathbf{k}\, h\nu(\mathbf{k}) \qquad (3)$$

with $\bar{n}_\mathbf{k}$ the number of thermally excited magnons. The quantity $\bar{n}_\mathbf{k}$ is given by the Bose dis-

TABLE 1. MAGNON-PARTICLE INTERACTIONS

tribution function. The fractional decrease ΔM in the saturation magnetization M with increasing temperature is given by $\Delta M/M \alpha \sum_{\mathbf{k}} n_{\mathbf{k}}$ which is proportional to $T^{3/2}$ for magnons whose dispersion law is of the form $h\nu(\mathbf{k}) \alpha k^2$ for small k. For a simple cubic ferromagnet with only nearest-neighbor exchange integrals the dispersion law is of the form

$$h\nu(\mathbf{k}) \alpha JM(T)(3 - \cos k_x a - \cos k_y a - \cos k_z a) \quad (4)$$

where k_α are the cartesian components of the wave vector, a is the lattice spacing, and $M(T)$ is the temperature-dependent saturation magnetization. The low-temperature specific heat is also proportional to $T^{3/2}$.

The exchange Hamiltonian described above applies to magnetic insulators in which the magnetic electrons are localized at lattice sites. An appropriate quantum-mechanical Hamiltonian for magnetic metals in which the magnetic electrons are itinerant can be defined. Long-wavelength spin waves in metallic systems have essentially the same qualitative features as those of insulating magnets with localized electrons. Short-wavelength magnons in metals, however, have a short lifetime due to decay into electron-hole pairs called Stoner excitations.[10]

Antiferromagnets In a simple two-sublattice antiferromagnet the spins on one sublattice are oriented opposite to those of the other sublattice so that the net magnetization of the solid vanishes. Two degenerate spin-wave branches occur for such systems. The spin waves of either branch involve excitations of the spins of both sublattices but in different proportions. The degeneracy of the two spin-wave branches is removed by an external magnetic field. The frequency of one branch is raised while that of the other is lowered. At a critical magnetic field called the spin-flop field, the frequency of the lower branch vanishes. For external fields in excess of the spin-flop field the spin system is unstable and the spins reorient approximately perpendicular to the external field. Long-wavelength spin waves can be excited by electromagnetic radiation with a frequency equal to the spin-wave frequency. This phenomenon is called antiferromagnetic resonance (AFMR) and ferromagnetic resonance[8] (FMR) in antiferromagnets and ferromagnets, respectively.

Special Types of Spin Waves In real crystals effects of impurities and surfaces lead to spin-wave oscillations having local properties. These localized excited states of the spin system are called localized magnons[11] (the amplitude of the spin deviation is localized near an impurity atom), and surface magnons (the excitation is localized near the surface of a magnetic solid but propagates parallel to the surface[12]).

Phenomenological Theory In a complete description of the magnetic system there exists, in addition to the exchange interaction, contributions which are relativistic in origin (dipole-dipole, spin-orbit). These interactions are weak but long range, and they are important in kinetic and relaxation processes, and microwave absorption at low frequencies.

Long-range interactions are most frequently treated by using a phenomenological theory of spin waves.[8] In this treatment spin waves are introduced as wave oscillations of the magnetic moment around the equilibrium value $\mathbf{M}(\mathbf{r})$. In this description the properties of the ferromagnet are described by Maxwell's equations and the equation of motion for the magnetization. Among the predictions of this model are magnetostatic modes of oscillations (magnetic modes principally characterized by the dipolar energy) and standing spin waves (dominated by the exchange contribution).[8] These long-wavelength modes have been studied by ferromagnetic resonance techniques. Ferromagnetic resonance of the $k = 0$ (homogeneous resonance) was first investigated by Griffiths[13] and is an important method for characterizing magnetic materials. The exchange interaction can be determined from measurements of the standing spin wave frequencies.[14]

STATES OF MATTER

In writing about the "states of matter" it would seem reasonable to begin by deciding what is meant by "matter" and by "state." Let, then, a short space be devoted to those questions.

As for "matter" consider it this way. Consider a brazen sphere, cube, and pyramid. What have they in common? They are brazen, or "of bronze." Now let the sphere be brazen, the cube golden, the pyramid of iron. What have they now in common? They are all metallic, or "of metal." Now let the sphere be brazen, the cube wooden, and the pyramid of earthenware. What have they in common? They are all solid, or "of solid stuff." Finally, let the sphere be brazen, the cube water, the pyramid outlined with smoke in the air. What have they in common? They are all material, or "of matter." So matter is that which is common to all material objects, but is not involved with immaterial things—the binomial theorem, for instance, or the right-angled isosceles triangle is not, as an abstract idea, material. This argument shows us, moreover, that we never have any experience of matter in the abstract. It is always "this ingot of iron," "that block of stone," "the pile of clay over there." However, just as, while we never see "man" but always John Jones or Sam Smith or some such individual, it is convenient to talk about the abstraction "man"; even so, the abstraction "matter" can be a convenient one.

As for "states," suppose we think this way. What is it that, above all else, distinguishes material objects? Is it not that they are tangible? For, on the one hand, a rainbow is visible, but we should not call it "material"; on the other hand, if we had something invisible, but which we could feel, we should declare it to be "material." So tangibility, it would seem, is the criterion. Now as to tangibility we might divide objects into: (a) unyielding, (b) yielding but quite tangible, and (c) hardly tangible. And these three classes, of course, we call solid, liquid, and vapour or gas: the three states of matter in which we are interested. This argument shows why we distinguish matter primarily into these classes, and not, for instance, according to color. It is because it is above all else tangibility in which we are interested.

It is true, of course, that the division into three classes will leave some doubtful cases at the borders, just as does the division of living things into animal and vegetable. And we can always deal with a thing according to the aspect which predominates in the circumstances in which we are interested, so that we might think of pitch, say, as a solid at one time, a liquid at another.

Gases A gas, of course, must be kept in some container, and it tends to expand the container, unless prevented from outside. We say that it exerts pressure; for instance, the pressure of air near sea level is about 14.7 psi, or just over 1×10^6 dynes/cm^2. It is found that the pressure of a given amount (by weight) of a gas in a container depends on the volume of the container, and on the temperature. The relation may be a very complicated one, but at sufficiently low pressure and sufficiently high temperatures, it is approximately true for all gases that

$$\frac{PV}{T} = \text{Constant}$$

P represents the pressure of the gas, V the volume and T the temperature measured from absolute zero, which is at $-273°C$ or $-460°F$, approximately. This kind of equation is called an equation of state, and this particular one is the law of ideal gases, and it is said that a gas behaving thus is an ideal gas. Actually, of course, there is no such thing as an ideal gas, but any gas under suitable conditions will behave nearly ideally.

Liquids It is sometimes said that there is no simple equation for liquids corresponding to the ideal law for gases. However, it is close to the truth, under many circumstances, to write

$$V = \text{Constant}$$

i.e., the volume of the liquid is constant independently of pressure and temperature. In fact, this is not true; the liquid is compressed a little by pressure, and the volume usually increases a little with increasing temperature. Nevertheless, this simple law is probably as close to the truth as is the law of ideal gases in many of the circumstances in which it is used.

Solids Likewise a simple law can be given for solids, i.e.,

$$L = \text{Constant}$$

L being the length of the line joining any two points in the solid. That is to say, not only does the volume not change, but neither is the solid distorted by any action on it. Again, this is only an approximation to the truth, and probably about as valid.

Changes of State We often tend to think of a given kind of stuff as being in a particular state; for instance we think of water as liquid, iron as solid, and air as gas. However we know that almost anything may exist in any of the states; water, for instance may be liquid, solid, or vapor. The ways in which things change from one state into another can be very interesting. (In books on THERMODYNAMICS, it may be mentioned here, in which these things are discussed in great detail, the word "phase" is often used instead of "state" as used here.) In general, the division between the different states depends on the pressure and temperature of the sample. Increasing the temperature makes the material go to a "looser" state; e.g., if ice is heated somewhat, it melts, and if the water is heated more, it evaporates. Increasing the pressure tends to squeeze the material into a "denser" state, either liquid or solid according to circumstances.

The way in which the state of a given material, say water, varies with pressure and temperature can be shown well in a graph such as that in Fig. 1. Every point on the graph will represent a certain combination of pressure and temperature, in the way of analytic geometry. The graph is divided into regions marked "solid," "liquid" and "vapor." At temperatures and pressures such as T_1 and P_1, which give a point in the region marked "solid," the material is solid. Likewise at temperatures and pressures such as T_2 and P_2, giving a point in the "liquid" region, the material is liquid. And at temperatures and pressures such as T_4 and P_4, it is a vapor. Thus, this graph indicates the whole behavior of the material with respect to temperature and pressure. Note that the line dividing the "liquid" from the "vapor" region just ends at a point at temperature T_C and pressure P_C. These are called the "critical point," and the "critical temperature" and "critical pressure", respectively. At temperatures higher than critical, there is no distinction between liquid and vapor. For water, the critical temperature is 374°C; critical pressure, 219 atmospheres.

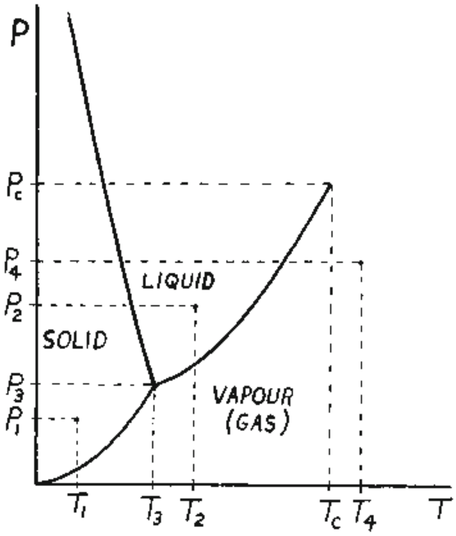

FIG. 1. Phase diagram: plot of pressure vs temperature for a typical material.

It can be seen that three parts of the curve meet as it were, at the point given by T_3 and P_3. This point is called the "triple point." For water, the triple point is at about 0.01°C and 4.6 mm of mercury. Note that if you warm a solid at pressures lower than the pressure at the triple point, it will change to vapor without first melting to a liquid at all. Such "dry evaporation" is called "sublimation." For carbon dioxide, for instance, the pressure at the triple point is about 5.1 times atmospheric. Thus, solid carbon dioxide, i.e., "dry ice," when allowed to warm up at atmospheric pressure, sublimes directly into vapor, as is well known. A process the reverse of sublimation happens when frost forms on cold objects without any intervening stage of liquid.

Vapor Pressure In Fig. 1, along the curve joining the triple point and critical point, the "liquid" and "vapor" regions meet; i.e., liquid and vapor can exist together. Note, however, that at a given temperature, they exist together only at a certain pressure. This pressure is called the vapor pressure of the liquid at the temperature concerned.

An analogous thing could be said about liquid and solid, or solid and vapor, along the appropriate curves.

Vapor Pressure and Relative Humidity In a certain volume, say one cubic foot, of air, there is, along with the air, ordinarily a small amount of water vapor. Suppose that this same amount of water vapor were put into a vessel of the same volume, i.e., one cubic foot, which contained nothing else at all. There would be a small pressure, perhaps about 1/50 of atmospheric pressure. This pressure is called the partial pressure of the water vapor.

The ratio of the partial pressure of water vapor in the air to the vapor pressure of water at the temperature of the air is called the relative humidity. (There is a bit of approximation here, because water vapor is not really an ideal gas.) For instance, at 70°F or 21°C, the vapor pressure of water is about 20 mm of mercury. (Standard atmospheric pressure is 760 mm of mercury.) If the actual partial pressure of water vapor were 10 mm the relative humidity would be 0.5 or 50 per cent.

Changes of Volume and Shape of Liquids and Solids The "equations of state" proposed above for liquids and solids are really too drastic; they ordinarily expand when heated. Typically, the volume of a liquid increases by 0.05 per cent for each degree Fahrenheit increase in temperature. (About 0.09 per cent for each degree C.) (Water may be anomalous in this, as well as other, respects.) They are compressed by the application of pressure; typically, the volume is decreased by 0.01 per cent for each atmosphere of pressure.

Solids are generally compressed only about 1/50 as much as liquids by the same pressure. It is more interesting to know how much force is needed to stretch a bar of solid material. For steel, it takes about 30 000 pounds force for each square inch of cross section of the bar to stretch it by 0.1 per cent. (About 2×10^9 dynes for a bar of cross section 1 cm^2.) For other solids, the force needed is mostly less, typically one-third to one-tenth of that.

The Surface of Liquids A liquid, if it does not fill the container entirely, has an exposed surface. If an attempt is made to stretch the surface, for instance by withdrawing a horizontal piece of wire from the liquid, the surface acts as if it were an elastic sheet. The force necessary to stretch a unit length of surface is called the SURFACE TENSION. For instance, the surface tension of pure water around room temperature is about 72 dynes/cm. The addition of impurities, e.g., soap to water, reduces the surface tension greatly. The rising of liquids in fine tubes or in porous materials is connected with surface tension.

Molecular Theory of the States of Matter The molecular theory considers all matter to be built up of molecules in some arrangement (or lack thereof!), each molecule, in turn, consisting of one or more atoms. The molecules attract one another with forces of electrical origin, and thus may stick together. However, they are also in motion or at least vibration, and this tends to make them break apart. The motion increases with increasing temperature, hence the structure "loosens." In a gas, around atmospheric pressure and room temperature, the molecules are about 3×10^{-7} cm apart; the forces between them are very small and they move almost freely and randomly. In so doing, they bombard the walls of the vessel; the effect of this bombardment is the pressure.

In a liquid or solid, the molecules are typically only about one-tenth as far apart. The forces then hold the molecules together; their motion is reduced to a vibration which never gets them far from one place. Occasionally, one molecule gets an extra hard push and flies away; this is evaporation or sublimation. According to the nature of the molecules, they may pile together as would a heap of spheres, or they may stick together in chains or other arrangements.

In a liquid the distance between molecules is about the same as in a solid. The different behavior may be because of a few "holes" in the liquid, i.e., places, a few per cent in all, where a molecule is missing. These spaces allow the liquid to flow, just as on a checker board when a few of the men are missing, the whole pattern can be moved by shifting men into and out of the holes. Of course this takes time, and it shows up in the viscosity or "slowness" of liquids. Molasses, for instance, is very viscous, water not very.

Polymers and Other Special Kinds of Solid Simpler solids, such as many metals, may be thought of as composed of atoms or molecules stacked together, as was mentioned above. The atoms may be considered spherical; then the whole arrangement is rather like a pile of oranges.

In other materials, the molecules are arranged in long chains. Often in such chains a simple sequence of molecules will be repeated many times, maybe hundreds. These materials are polymers. ("Polymer" means "many parts," i.e., the chains are made up of many, often identical, links.)

Some polymers, or polymerlike materials, consist of a whole jumble of these chains. Since the chains can move around with respect to one another to a considerable extent, such materials can be deformed easily. The elasticity of rubber, for instance, can be considered in terms of its construction from such chains. Ordinarily the chains are much curled and tangled. When the rubber is stretched, the chains can uncurl. It is for this reason that rubber can be stretched so readily.

In some cases, however, there are crosslinkages; the chains are connected to one another at many places, so that the result is like a net, or a three-dimensional lattice. Obviously, a material with many crosslinkages will be much more rigid, and less easily deformed. Treatments of plastics, or processes such as the vulcanization of rubber, can introduce such partial rigidity, to an extent suitable for the intended use.

Many biological materials are rather like polymers, and it may be that some useful insights will be gained by considering them from that viewpoint.

STATIC ELECTRICITY

Until it was accepted that galvanic currents are identical with moving electric charges, *static electricity* referred to all electric charges that were stationary or nearly so, including such charges as those on Leyden jars and pyroelectric crystals. Nowadays the meaning encompasses only the more or less immobilized electrification due to (1) charge redistributed on a single body through *induction* caused by the presence of charge on neighboring bodies; (2) charge transferred from one material (solid or liquid) to another by *contact* and subsequent separation; (3) charge accumulated on a body (solid or liquid) by *deposition* of electrons or ions from the surrounding atmosphere, as in charging by corona, flame, or radiation. One generally excludes separation and redistribution of charge in pyroelectrics, piezoelectrics, thermoelectrets, photoelectrets, capacitors, and electrolytic cells.

In scientific and technical work, it is often important to control static electricity, either to exploit its effects or to avoid them. For convenience we divide the subject into *generation* of charge and *dissipation* of charge. So far as generation is concerned, *induced electrification* is largely understandable in terms of classical physics; the fundamentals are well understood, and the applications are straightforwardly made as part of electrical engineering and safety engineering (see ELECTRICITY). *Contact electrification*, on the other hand, is far from being understood, and immediately comes to frontier problems in the modern theory of liquids and solids. *Deposition electrification* [from a gaseous ion cloud] is in an intermediate position. The fundamental processes of electrical discharge in gases are understood in principle, but real situations are so complex that theory is of limited use. As far as dissipation is concerned, the origin of the charge is largely irrelevant; a wide variety of physical and chemical processes of all degrees of complexity enter in analyzing the decay or neutralization of static charge.

Generation *Induction Charging.* Induction phenomena, as mentioned, are adequately described as a branch of classical electrostatics. Hence we devote the main part of our discussion here to the more poorly understood topic of contact phenomena, plus a brief overview of deposition from corona discharges or other ion clouds.

Contact Charging. When two materials differing at their surfaces in chemical composition, or even temperature or state of strain, are placed in contact, charge tends to flow from one to the other until their electrochemical potentials are identical. If the materials are subsequently separated, some portion of the transferred charge is retained, the potential difference between the materials increasing as the capacitance decreases. As a rule, this net transfer produces no noteworthy effects; in fact, a sensitive electrometer is ordinarily needed to measure it. With metal-metal contacts, the charge retained is invariably very small and is not detected by the senses. With metal-insulator or insulator-insulator contacts, the charge transferred while the materials remain in contact may be large, but it decreases during separation to an unimportant amount unless the insulator has quite high resistivity. At the speeds encountered in ordinary events, say about 100 cm/sec, the charge leaks back too fast to give noticeable effects whenever the resistivity of the more poorly conducting material falls below about 10^9 ohm-cm. At higher speeds, static effects become noticeable even at low resistivity, whereas at lower speeds they appear only at very high resistivity.

The combination of moderate or high speed and high resistivity frequently produces large enough charge transfer that the surrounding medium breaks down electrically. In air at atmospheric pressure, the requisite charge densities on a uniformly charged plane conducting surface are about 8 esu (statcoulombs/cm^2) or 25 μC/m^2, to give a field of about 30 kV/cm just above the surface. This density represents about 2 × 10^{10} electronic charges per square centimeter, so that only one in perhaps 10^5 surface atoms is charged even at the highest electrifications ordinarily occurring.

For practical purposes, the phenomena of interest in static electrification are the forces of attraction or repulsion resulting from excess charge (e.g., in textile processing, ore separating, and electrostatic copying), the occurrence of sparks and their consequences (e.g., in transfer of flammable liquids, or in handling of photographic films), and so on. From a fundamental point of view, these phenomena are simply consequences of transfer of charge and its subsequent behavior. Hence we may take as the central question in static electrification the following: Given two materials of specified chemical composition and physical state, what is the charge—in sign and amount—transferred when they are placed in contact under specified mechanical and ambient conditions, and then separated?

At the present stage of theories of matter, answers are available only for some quite special situations. For the rest of the time, we must content ourselves with trying to get some guidance from rather crude models of the type to be described.

Solid-Solid Contact. Let us restrict our treatment to bodies that are initially uncharged, and examine the charge q_0 that is transferred between two objects while they are touching. For many materials, q_0 will increase with duration of contact towards an equilibrium value q_∞. We designate as α the degree of attainment of this value, writing $q_0 = \alpha q_\infty$. We should expect q_∞ to depend on the chemical nature of the materials, as well as on the mechanical nature of the contact, i.e., on the size and shape of the objects, and the normal force between them. Let us write q_∞ as a factor b ("b" for band structure, in the case of solids) dependent on the electrochemical properties of the materials, multiplied by a factor g ("g" for geometry) dependent on the mechanical parameters of the contact. Upon separation some of the charge returns to its origin, either through conduction processes such as tunneling, or through atmospheric breakdown; let us call f that fraction of the initial charge q_0 that remains to give the observed charge $q = q_0 f$. Upon combining all these relations, we get a four-factor formula

$$q = \alpha bgf$$

The utility of this expression can be assessed only by experience. Note that α and f are both positive numbers between zero and unity, and that g is intrinsically positive; the sign of the charge enters in b.

An important qualitative consequence of the above scheme is the existence of a *triboelectric series*, i.e., a listing of materials such that any one in it becomes positive when rubbed against another lower in the series. When the materials, the ambient conditions, and the mode of contact are reasonably well defined, such series are generally conceded to exist. An example is the following: Wool, nylon, viscose rayon (regenerated cellulose), cotton, silk, cellulose acetate, polymethylmethacrylate, polyvinylalcohol, polyethylene, polytetrafluoroethylene. In principle, one ought to be able to predict the position of a given substance from its chemical properties, but as yet the attempts have been more suggestive than successful.

So far as quantitative results are concerned, prediction of α and b is possible in principle when detailed information is available on the energy levels of the materials. As yet, only metal-metal systems have been found to be simple enough to be analyzed successfully. With insulators, surface states of high complexity may occur.

Prediction of g is made, one hopes, by estimating the area of "true contact," namely, the area wherein atomic fields interpenetrate. The size of this area depends on the roughness of the contacting objects and on the normal forces between the objects up to the point where the area of "true contact" approaches a maximum approximately equaling the area of apparent contact. In the case of rolling contacts (and some sliding contacts) between cylinders and spheres, the area of apparent contact increases with normal force, in a fashion well understood for elastic deformation and pretty well understood for plastic deformation. Thus it is not uncommon in such cases to find reports of fractional-power dependence on normal force between contacting objects, the power taking values from near zero to unity. In the case of sliding contacts where one or both objects are planar, the "true contact" can apparently be increased by two or three orders of magnitude, as deduced from the much larger charge transfers sometimes observed in "frictional electrification," a not precisely defined concept in which "rubbing"—as opposed to mere "touching"—predominates. Here effects beyond mere "contact" enter, such as local heating, wear, and material transfer; then the Helmholtz theory that sliding simply serves to multiply the contact region loses much of its utility. Even so, in many cases of rolling or sliding contact, the effective area for given normal force is proportional to the *length* of the stroke.

Prediction of f is made, in the absence of atmospheric breakdown, by analyzing the time scale of the experiment. We expect f to be a function of the ratio of T, a time characteristic of the speed of separation, to τ, a relaxation time characteristic of the material of higher resistivity. The separation time T may be taken as l_0/v, where v is a speed of separation, and l_0 is some characteristic length; the relaxation time τ should be related to the time constant for redistribution of charge in a medium of dielectric constant ϵ and volume resistivity ρ. We have then $T/\tau = (l_0/v)/(\epsilon\rho)$, and we see that velocity may be traded for resistivity, since

$f = f(T/\tau) = f(l_0/\epsilon\rho v)$. For ordinary materials at ordinary speeds, f is very small for ρ lower than 10^9 ohm-cm. For metal-metal contacts in particular, where $\rho \sim 10^{-5}$ ohm-cm, static effects disappear, their only remnant being the slight transfer due to contact potential difference at the last points of contact. In the presence of atmospheric breakdown, a saturation value of charge q is reached, the magnitude depending on the properties of the surrounding atmosphere. Estimating f here is largely a matter of bookkeeping, and without much point.

Deposition Charging. When a gas is exposed to a high electric field set up between a pair of electrodes, it breaks down to produce a continuous electrical discharge when a threshold voltage between the electrodes is reached. This critical voltage depends on the nature of the gas, its density, and the geometry of the electrodes. To maximize field strength at a given potential, one of the electrodes at least should have a very small radius of curvature, as with a set of points or a fine wire. In a typical application in electrophotography, a cylindrical wire of 0.1 mm diameter might be mounted at a distance of 1 cm from a flat grounded surface. The threshold voltage to start the discharge would be about 3 kV, and the operating voltage might be about 5kV, to yield a corona current of say 100 μA per cm electrode length. The threshold voltage is nearly proportional to air density, and hence to pressure at constant temperature. It increases with increasing diameter of the wire. Details may be found in references on electrical discharges in gases. Other sources of free charge are ionizing radiation and flames. The copious and controllable amounts of charge provided by corona, however, have made it by far the most common source.

A plane surface (or other large surface) maintained in the neighborhood of the wire at a potential different from it will eventually accumulate electrostatic charge from the corona until the field between the wire and the surface vanishes. In practice one waits only long enough to charge the surface to several hundred volts, corresponding to 10^{11} to 10^{12} electron charges/cm^2. A particle in the charge cloud and hence in an electric field will pick up charge Q to the limiting amount

$$Q = pE_{\text{corona}}\, a^2 ,$$

where a is the "diameter" of the particle, E_{corona} is the electric field strength in the region of the corona, and p is a factor--of the order of unity--dependent on the dielectric properties of the particles and on the properties of the corona discharge. Since the electric force on the particle equals the charge times the electric field strength, and since the viscous drag in the Stokes' law regime is proportional to the diameter and the viscosity of the medium, the terminal velocity of a particle within the corona is proportional to the electrical field strength and the diameter, and inversely proportional to the viscosity.

Liquid-Solid (and Liquid-Liquid) Contact. The two major phenomena are *spray electrification* and *flow electrification*. The former is seldom of practical significance (except when deliberately induced by charged nozzles in electrostatically aided spray painting). The latter is often of great concern, notably in the handling of inflammable liquids. Although neither phenomenon is completely understood, there is available enough empirical knowledge to provide a basis for control.

Spray electrification occurs when a chemically homogeneous liquid is dispersed into a mist, the larger droplets on average charged with one polarity, the smaller ones oppositely. The source of differential charging is the dependence of the electrochemical potential on the droplet radius, as a consequence of the difference in molecular environment of the material near the surface. The effect would be expected to be most pronounced with polar molecules, as is indeed observed in the conspicuous example of water ("waterfall electrification"). The magnitude of the effect depends on the mechanism of formation of the droplets, and is difficult to predict.

Flow electrification appears when liquid moves relative to a solid with which it is in contact, as in pouring, wiping, pumping, or sedimentation; or relative to another liquid, as in settling of water drops in a petroleum tank. The charge-transfer mechanism appears to be the same as in the contact between solids, at least for field strengths below breakdown. (The language, however, is that of electrokinetic chemistry rather than that of solid-state physics.) The charge-separation mechanism, in contrast, proceeds differently. In charging, a double layer is set up between dissimilar materials in either case, because of the tendency for equalization of the electrochemical potential. With a liquid, part of the transferred charge is carried away within liquid layers, whereas with solids the charge is carried away in or on the separated object. In either case the transferred charge can leak back through low-conductivity paths and in some circumstances reduce the net electrification to a negligible amount.

The calculation of the streaming current, that is, the motion of charge entrained in a moving fluid, is on uncertain ground, embracing as it does a wide spectrum of complicated electrokinetic effects together with imperfectly known boundary conditions and empirical coefficients. Nevertheless the theory does predict, and experiment does confirm, that the streaming current rises as the square of the velocity at first, then varies linearly; and that it rises with conductivity from a negligible value at very low conductivity (say, 1 picomho/meter, corresponding to a resistivity of 10^{14} ohm-cm) where the double layer is very thick and hence of low volume charge density, through a maximum at intermediate conductivity (say, 100 picomho/meter), and finally decreases to perhaps a hundredth of the maximum at high conductivity (say, 10,000 picomho/meter). The higher streaming currents can carry enough charge into a container to cause sparking in it, even though grounded. To decrease the extent of electrification, then, the liquid velocity must be kept small, and the generation of charge must be kept very low (by avoiding ionizing impurities such as water in gasoline) or the conductivity must be made high (by addition of an antistatic agent). Piping size and mass-flow rate, impurity removal and antistatic-agent addition, are to be engineered for prudent and economical operation.

Dissipation Charge may be dissipated by currents within the body of the object or over its surface, or by currents within the medium in which the object is immersed. Charge in the interior of a body ultimately reaches the boundaries, decaying exponentially with a well-defined time constant $\epsilon\rho$. Charge on the surface of a body moves to attain an equilibrium distribution, decaying in a complicated fashion that is only approximately described by a time constant proportional to $\epsilon\rho$. Currents within the medium surrounding the object are described by the laws of electrical conduction in liquids or gases, as the case may be, in all their complexity.

Control of Static Electrification Effects of static charge, beneficial or harmful, can be controlled by influencing either the production of charge or its neutralization.

Production of Charge. In the case of induced electrification, the fields between objects may be controlled by altering the potentials of neighboring conductors, usually by screening and grounding. In the case of contact electrification, the four-factor formula may be used as a basis for discussion:

Control of α: The only practical control is through fixing of the charge state of the object. (We must accordingly generalize our analysis to include objects initially charged.) If one object has lost so much charge that it can lose no more upon contact with another object, this second object will remain in its initial charge state. (As an illustration, a yarn running through an insulating or insulated guide may not pick up more charge after a brief initial period in which the guide electrically "saturates.")

Control of b: In principle, the electrochemical potential for one given material may be matched against that for some other material so that charge transfer between the two is negligible; in practice the potentials cannot be controlled closely enough, particularly over a range of ambient and mechanical conditions. More significantly, objects usually must work against a variety of materials which will have a variety of electrochemical potentials. There have been proposed composite surfaces wherein a material high in the triboelectric series is interspersed with one low in the series to give a small average electrification. The efficacy of such blending is high in some applications.

Control of g: Decrease of the normal force almost always produces a decrease in charge transfer. In cases where the dependence follows a fractional power law, it may not be useful to go to great lengths to decrease the normal force to very small values. With respect to path length, action is obvious though seldom practical. If the nature of the contact can be changed somewhat, however, by modifying the extent of slip between contacting objects, the amount of charge transferred can sometimes be modified drastically.

Control of f: In practice, charge transfer is reduced by decreasing the product $\epsilon\rho v$. It is difficult to alter the dielectric constant by more than a small factor and hence to affect the rate of dissipation strongly in this way. The resistivity, on the contrary, may be changed greatly, either by changing the molecular structures of the body (say by grafting conducting segments onto polymers) or by adding conducting materials within or onto the object (say by adding moisture or various antistatic agents). With hydrophilic materials, one traditionally alters the moisture content of the surrounding air, with that of the object following. The resistivity varies as a high negative power of the moisture content, and a change in relative humidity of a few per cent may bring about a tenfold difference in charge observed at a given time, or a tenfold difference in the time required to attain a given charge state. In a few special applications, the resistivity may be lowered by increasing the temperature. The factor v can be decreased by simply slowing down the process, of course, and also by changing the mode of contact, say from sliding to rolling (with concomitant change in g), or by lowering the relative speed of the two contacting objects.

In the case of deposition electrification, the relation $Q \sim E_{\text{corona}}a^2$ shows that the limiting charge can be increased through increase of the electric field strength by increasing the voltage difference across the electrodes, or decreasing the distance between them, on the one hand; and working with larger particles, on the other hand. In practice the ultimate values are seldom approached, and the relevant design factors are those determining the time required for charging and for moving particles along a trajectory. We note in general that gravitational and inertial forces vary as the cube of the diameter, electrical forces as the square, and viscous forces as the first power. It is inappropriate to pursue these matters further here.

Neutralization of Charge. Surplus charge inexorably is neutralized, since the resistivities of even the best nongaseous insulators seldom exceed 10^{18} ohm-cm or so, and since natural radioactivity and cosmic rays produce mobile ions in surrounding fluids. When it is desired to hasten neutralization, charge must be supplied by other means. The conductivity of the body can be increased, especially at the surface, according to some of the ideas expressed earlier. More commonly, charge can be supplied through the surroundings. The medium in which the object is immersed can sometimes be rendered conductive by the electric field set up by the body itself, especially at surface regions of small radius of curvature, for example, at the points of tinsel or needles. Although the charge cannot be completely eliminated in this way, it can be made quite small if the ambient pressure can be brought near the minimum in the Paschen law for electrical breakdown in gases.

More often the surrounding atmosphere is ionized with the aid of external agents. Various commercial static eliminators have been developed to produce glow or spark discharges from high-tension wires or points. Electromagnetic radiation, in the form of x-rays or gamma rays, will ionize surrounding media, but it is often objectionable because of its hazards to personnel. Particle radiation, in the form of alpha or beta rays is very effective in producing ions, and is easier to control with respect to health hazard. Plutonium 240 with a half-life of 6600 years and americium 241 with a shorter half-life of 462 years are alpha emitters nearly free from gamma rays. They are modern substitutes for the nearly gamma-free polonium 210 with half-life of 138 days, and the gamma-active radium 226 with half-life of 1620 years. Flames produce copious ionization, but their action is usually only ancillary, as in flame-driers at the take-off of some printing presses.

References

Even if dated, the following three works are useful as an introduction to electrostatic phenomena:

Loeb, Leonard B., "Static Electrification," Berlin, Goettingen, and Heidelberg, Springer-Verlag, 1958. Covers solids, liquids, and gases.

Klinkenberg, A., and Van der Minne, J. L., "Electrostatics in the Petroleum Industry," Amsterdam and New York, Elsevier Publishing Company, 1958. An excellent coverage of liquid-solid contacts.

Montgomery, D. J., "Static Electrification of Solids," *Solid State Physics* 9, 139 (1959). An introduction into solid-solid contacts.

Some books of more or less generality are:

Gross, B., "Charge Storage in Dielectrics," Amsterdam and New York, Elsevier Publishing Co., 1964. An excellent source of earlier references.

Dessauer, J. H., and Clark, H. E. (Eds.), "Xerography and Related Processes," London and New York, The Focal Press, 1965. An extensive treatment of fundamentals of electrostatics and the application thereof to electrostatic printing.

Schaffert, R. M., "Electrophotography," London and New York, The Focal Press, 1965; 2nd Edition, 1975. An analysis of the theory of electrophotographic processes, and a list of patents pertaining thereto.

Harper, W. R., "Contact and Frictional Electrification," London, Oxford Univ. Press, 1967. A careful treatment of the significant phenomena in contact charging between solids.

Jowett, Charles E., "Electrostatics in the Electronics Environment," New York, John Wiley & Sons, 1976. A useful practical treatment of electrostatic problems.

Textbooks and treatises have difficulty in keeping up with the rapid developments in the field. Substantial surveys are available in proceedings of conferences. A highly useful series is the following:

Lowell, J. (Ed.), "Conference Series No. 48, Proceedings of the 5th Conference on Electrostatic Phenomena, 1979," Bristol and London, The Institute of Physics, 1979.

Blythe, A. R. (Ed.), "Conference Series No. 27, Proceedings from the 4th Conference on Static Electrification, 1975," London and Bristol, The Institute of Physics, 1975. (Previous reports are Conference Series No. 11, 3rd Conference, 1971; Conference Series No. 4, 2nd Conference, 1967; *British Journal of Applied Physics*, Suppl. No. 2, 1st Conference, 1953.)

Other series are described in:

Ong, P. H. (Ed.), "Fourth International Conference on Electrostatics, 1981," *Journal of Electrostatics* **10**, special issue (1981).

Asano, Kazutoshi, "Review of the 1980 Annual Meeting of the Institute of Electrostatics, Japan," *Journal of Electrostatics* **9**, 367 (1981).

In general, the *Journal of Electrostatics* (published by the Elsevier Scientific Publishing Company, Amsterdam) serves as the current center for dissemination of reports on static electrification.

Persons concerned with protection against ignition arising from static electrification may wish to read publications of the American Petroleum Institute (e.g., API RP 2003, API Bull. 1003), and of the National Institute for Occupational Safety and Health (e.g., DHEW (NIOSH), Publn. No. 78-206). A recent brief but cogent paper is "Electrostatic Hazards," a report prepared by Arthur Conway and published by Oyez Publishing Ltd., London, 1980 (ISBN 0 85120 442 2).

STATICS

Statics is the branch of MECHANICS which studies the conditions of equilibrium of forces acting on particles or rigid bodies, or on inextensible cords, belts and chains. Hydrostatics, the study of the equilibrium of fluids, is usually not regarded as a part of statics in the conventional sense of the term.

Statics is the oldest branch of mechanics, some of its principles having been used by the ancient Egyptians and Babylonians in their constructions of temples and pyramids. As a science it was established by Archytas of Taras (ca. 380 B.C.) and primarily by Archimedes (287-212 B.C.); it was further developed by medieval writers on the "science of weights" such as Jordanus de Nemore (thirteenth century) and Blasius of Parma (fourteenth century). In the sixteenth century, it was revived by Leonardo da Vinci, Guido Ubaldi and especially by Simon Stevin (1548-1620) who laid the foundations of modern statics (inclined plane, equilibrium of pulleys, parallelogram of forces).

Although the laws of statics can in principle be derived from those of dynamics as a limiting case for vanished velocities or accelerations, statics has been developed, since the end of the eighteenth century, independently of dynamics. Its fundamental notion, like that of dynamics, is the concept of *force*, representing the action of one body on another and characterized by its point of application, its magnitude and its direction (line of action) or briefly by a VECTOR $\mathbf{f}$. Two equal and opposite forces whose lines of action are parallel and non-coinciding are said to form a *couple*. The *moment* or *torque* $\mathbf{m}_0$ of a force f about a point O is a vector whose magnitude is the product of the magnitude of $\mathbf{f}$ and the length of the perpendicular distance of O from the line of action of $\mathbf{f}$, or in VECTOR notation $\mathbf{m}_0 = \mathbf{r} \times \mathbf{f}$ (vector product), where $\mathbf{r}$ denotes the vector from O to the point of application of $\mathbf{f}$.

The following four principles may serve as the basic postulates for statics. (1) *The principle of composition (addition) of forces*: two forces, $\mathbf{f}_1$ and $\mathbf{f}_2$, with a common point of application A can be replaced by a third force, the resultant $\mathbf{f}$, which is obtained graphically (geometrically) as the diagonal, from A, in the parallelogram determined by the two given forces, or analytically (algebraically) as the vector whose components, usually with reference to a rectangular reference system, are the sum of the corresponding components of the two given forces, $f_x = f_{1x} + f_{2x}$, etc. (vector addition). The resultant of more than two forces is independent of the order of addition. (2) *The principle of transmissibility of force*: the point of application of force acting on a rigid body can be transferred to any point on the line of action of the force provided the point is rigidly connected with the body (sliding vector). (3) *The principle of equilibrium*: the necessary and sufficient condition for the EQUILIBRIUM, that is, absence of accelerated motion, of a particle is the vanishing of the resultant of all forces acting on the particle, or $\mathbf{F} = \sum \mathbf{f}_i = 0$. The condition for the equilibrium of a rigid body is the vanishing of the resultant of all forces as well as the vanishing of the resultant of their moments about an arbitrary point O, or $\mathbf{M}_0 = \sum (\mathbf{r}_i \times \mathbf{f}_i) = 0$. If $\mathbf{F} = 0$, $\mathbf{M}_0$ is independent of the choice of O. (4) *The principle of action and reaction* (Newton's third law): the force exerted by one body on another is equal and opposite to that exerted by the second body on the first and both forces lie along the same line of action.

These principles imply the following results. Two parallel forces can be added if additional compensating forces are introduced. Any set of coplanar forces, with the exception of couples, can be reduced to a single resultant. The sum of the moments of any two intersecting forces about any point in their plane equals the moment of their resultant about the same point (Varignon's Theorem). Any system of forces acting on a rigid body can be reduced, in an infinite number of ways, to a single resultant $\mathbf{F}$ and a single couple $\mathbf{M}$. In all these reductions $\mathbf{F}$ is uniquely determined but $\mathbf{M}$ depends on the position of $\mathbf{F}$. There is one, and only one, line of action for $\mathbf{F}$, called *Poinsot's central axis of the system*, for which $\mathbf{M}$ is parallel to $\mathbf{F}$. Hence every system of forces is equivalent to a *wrench* as this particular force-couple combination is called.

Statical analysis of framed structures or trusses, collections of straight members pinned or jointed together at the ends, is based on the preceding theorems. Such structures rest upon supports whose reactions or pressures have usually to be determined in practical applications. The equilibrium conditions, according to (3), are two vector equations or, equivalently, six scalar equations and hence can be solved for no more than six unknowns (the reactions at supports and connections). If the reactions involve more than six unknowns, some of the reactions are statically indeterminate; if less, the body is said to be unstable. In case the unknown reactions arise from constraints, i.e., conditions restricting possible motions, a convenient method for the elimination of unknown reactions is the use of the *principle of virtual work* according to which the total virtual work (work due to a possible small displacement which need not necessarily take place) of the external forces acting on the body vanishes for any virtual displacement of the body. In general, internal forces, holding together the various parts of the structure, also have to be taken into account, e.g., for trusses which consist of straight members connected by joints.

In particular, parallel forces can always be replaced by a single resultant whose point of application is called the *center of the system of parallel forces*; it is invariant if all forces change their directions but remain parallel to each other. In this case the sum of the moments of these forces about any point equals the moment of their resultant about the same point; in particular, the sum of the moments about any point on the resultant is zero (generalization of the law of the lever). An important case of this kind is that of the earth's gravitational forces which act at a given place in practically parallel lines on every element of a not too voluminous body. The center of the system of forces, in this case, is the *center of gravity* and is identical with the center of mass or *centroid* which can easily be determined by summation for a system of discrete particles or by integration for continuous masses.

The study of friction, the resistance of a surface to the motion of a body upon it, belongs properly to applied mechanics. Since however many problems in statics involve, at least, considerations concerning *static friction* (the frictional force which just prevents motion), the study of FRICTION is often included in the science of statics.

STATISTICAL MECHANICS

The object of statistical mechanics is the explanation of the macroscopical physical phenomena as consequences of the laws of motion of the atoms and molecules. Equivalently, statistical mechanics can be defined as the mechanics of systems of a very large number of degrees of freedom. Whereas in "ordinary" mechanics even the three-body problem cannot be solved exactly, statistical mechanics takes advantage of the large number N of degrees of freedom and tries to formulate exact *asymptotic* results in the limit $N \to \infty$ (in a certain well-defined way).

The fundamental laws of motion of the atoms and molecules are those of quantum mechanics; however, in many statistical mechanical problems, classical mechanics provides a sufficient approximation.

In ordinary classical mechanics, a problem is completely specified when the initial positions and momenta of all its particles are specified. Such information is impossible to obtain, and moreover is completely useless, for systems consisting of about 10^{24} particles. The only initial data which are interesting for such systems are of a macroscopic nature: density, local velocity, temperature at each point of a fluid, correlations between the density fluctuations in two points of the system, etc. There is a very large number of microscopic initial configurations of the molecules which is compatible with a given macroscopic specification. Hence, in order to describe such systems, Gibbs introduced the concept of an *ensemble*. This is defined as a set of a very large number of systems, all dynamically identical with the system under consideration (i.e., having the same Hamiltonian H), differing in the initial conditions of the molecules but compatible with the macroscopic specification of the system.

The natural mathematical framework of such a description is the *phase space*, a many-dimensional space whose coordinates are the positions $x_1, \cdots, x_N$ (shortly: x) and the momenta $p_1, \cdots, p_N$ (shortly: p) of all the particles of the system. A point in phase space therefore represents a complete dynamical system in a definite microscopic configuration. A Gibbs ensemble corresponds to a cloud of points in phase space, which can usually be considered as a continuous distribution. The basic concept is therefore the *distribution function* in phase space $\rho(x, p; t)$, giving the density of the ensemble as a function of the positions and momenta of the particles (i.e., of the coordinates of the phase space) at time t. The connection between microscopic and macroscopic physics is then given by the following assumption: The observable value of a dynamical property of the system, (e.g., density, local velocity, average energy, etc.), $\bar{A}(t)$, is the average value of the corresponding microscopic dynamical function $A(x, p)$, weighted by the distribution function:

$$\bar{A}(t) = \int dx \int dp \, A(x, p) \rho(x, p; t) \qquad (1)$$

Practically all functions $A(x, p)$ of physical interest are sums of functions involving only one or two particles. Hence it follows from Eq. (1) that the functions of real importance are the integrals of $\rho(x, p; t)$ over all but one or two particles: these are called reduced (one- or two-body) distribution functions. Their main importance comes from the fact that they remain finite in the limit $N \to \infty$.

The evolution of the system in time is described by the change in time of the distribution function. According to the laws of classical mechanics, the latter obeys a partial differential equation called the *Liouville equation*:

$$\frac{\partial \rho}{\partial t} + \sum_{i=1}^{N} \left[\frac{\partial H}{\partial p_i} \frac{\partial \rho}{\partial x_i} - \frac{\partial H}{\partial x_i} \frac{\partial \rho}{\partial p_i} \right] \equiv \frac{\partial \rho}{\partial t} + [\rho, H] = 0 \quad (2)$$

The bracketted expression $[\rho, H]$ is called the Poisson bracket of the Hamiltonian H and the distribution function. The purpose of classical statistical mechanics is the solution of the Liouville equation in the limit $N \to \infty$.

In quantum statistical mechanics, the conceptual situation is much the same, but it is more complicated because of the proper statistical character of the quantum description of even a single system. Indeed, due to the HEISENBERG UNCERTAINTY PRINCIPLE, the momentum and the position of a particle can never be measured simultaneously with arbitrary accuracy. Hence the concept of a phase space has no meaning in quantum mechanics. The maximum information which can be obtained about a single system (in a "pure" state) is contained in its wave function $\Psi(x; t)$. The observable value of a dynamical variable in such a state is given in terms of the corresponding operator $\hat{A}$ by the expression

$$\bar{A}(t) = \int dx \, \psi^*(x; t) \hat{A} \psi(x, t) \quad (3)$$

To this statistical aspect of quantum mechanics is added the proper indeterminism of statistical mechanics. Suppose the wave function of a single system (n) can be expanded in a series of orthonormal functions $\varphi_i(x)$ [see WAVE MECHANICS]

$$\Psi^{(n)}(x; t) = \sum_i a_i^{(n)}(t) \varphi_i(x) \quad (4)$$

In the statistical mechanical description, the single system is replaced by an ensemble, in which each system (n) is weighted by a density p_n. The role of the classical distribution function is now played by the *density operator* ρ introduced by J. von Neumann (1932). The matrix elements of this operator in the present representation are defined by

$$\rho_{ij} = \sum_n p_n a_j^{*(n)} a_i^{(n)} \quad (5)$$

the sum over n running over all the systems of the ensemble.

The averaging prescription which replaces Eqs. (1) and (3) is now:

$$\bar{A}(t) = \text{Trace}\, \rho A \quad (6)$$

It is easily seen that this rule embodies the double averaging necessary for quantum and statistical mechanics. The evolution in time of the density operator is given by von Neumann's equation:

$$\frac{\partial \rho}{\partial t} + \frac{1}{i\hbar} [\rho H - H\rho] \equiv \frac{\partial \rho}{\partial t} + \frac{1}{i\hbar} [\rho, H] = 0 \quad (7)$$

H again being the (quantum) Hamiltonian of the system. The classical Poisson bracket has been replaced by $(i\hbar)^{-1}$ times the commutator of the operators ρ and H.

Quantum statistical mechanics shares with the usual quantum mechanical many-body problem the following characteristic feature. It is known that in a system of several identical particles, the latter are undistinguishable. In order to satisfy this requirement, the wave function of the system must be either symmetrical or antisymmetrical with respect to a permutation of any two particles. This symmetry requirement introduces the classification of quantum statistical systems into systems of *bosons* (Bose-Einstein statistics, symmetric wave functions) and systems of *fermions* (Fermi-Dirac statistics, antisymmetric wave functions). The purpose of quantum statistical mechanics is the solution of Eq. (7) with the proper symmetry condition.

The simplest solutions of Eqs. (2) or (7) are the time-independent solutions: these are functions of the Hamiltonian H alone. They describe systems in equilibrium. A particular function of the Hamiltonian is the *canonical distribution*:

$$\rho = Ce^{-H/kT} \quad (8)$$

where C is a normalization constant and k is called the Boltzmann constant. It can be shown that this distribution represents a system in thermodynamical equilibrium at temperature T. The main result in classical equilibrium statistical mechanics is the following. Consider the function

$$Z(V, T) = (N!\, h^{3N})^{-1} \int dp \int dx \, e^{-H(p, x)/kT} \quad (9)$$

the integration extending over the whole volume occupied by the system in phase space. $Z(V, T)$, as a function of the volume and of the temperature T, is called the *partition function*. It can be shown that the Helmholtz free energy $F(V, T)$ of the system [see THERMODYNAMICS] is given by

$$F(V, T) = -kT \ln Z(V, T) \quad (10)$$

The importance of this formula lies in the fact that the knowledge of a thermodynamic potential such as $F(V, T)$ enables one to calculate all thermodynamic properties (pressure, entropy, specific heat, etc.) by simple differential operations. A completely analogous result holds in quantum statistical mechanics.

Although the basic problem of equilibrium statistical mechanics is solved in principle (i.e., it is reduced to quadratures), the explicit evaluation of the $6N$-fold integral occuring in the partition function poses a formidable mathematical problem. Only in the case of systems of noninteracting degrees of freedom can one calculate the partition function exactly. Moreover, essentially three main groups of systems of interacting particles are thoroughly understood at the present time. All of these systems are characterized by the following Hamiltonian:

$$H = H_0 + \lambda V \tag{11}$$

where H_0 is the Hamiltonian of a set of independent particles, whereas V describes the interactions and λ characterizes the size of the interactions. The three cases mentioned are the following:

(a) *Weakly coupled systems.* In such systems the interactions between components are weak compared to some intrinsic energy. The components may be particles of a gas, or quantized oscillations of the atoms around their equilibrium positions in a crystal lattice (see PHONONS), or spins attached to atoms located at the sites of a ferromagnetic crystal (see FERROMAGNETISM), etc. In all these cases the partition function can be expanded in a power series in λ.

(b) *Dilute gases.* In real gases, the particles interact through forces which have a very short range (the molecules can usually be idealized as hard spheres). In a dilute gas the molecules move most of the time in straight lines and occasionally suffer collisions, which are more and more frequent and involve more and more particles simultaneously as the density of the gas increases. H. D. Ursell (1927) and J. E. Mayer (1937) have shown that the partition function, and hence the pressure, can be expanded as a power series in the density; the result is the famous *virial equation of state* (or *cluster expansion*). The original derivation of this equation made extensive use of a diagram technique, a procedure which establishes a one-to-one correspondence between certain mathematical expressions and certain graphs; such diagram techniques proved to be of major importance in modern perturbation theory. The coefficients of the various powers of the density (or virial coefficients) are expressed in terms of so-called cluster integrals, describing correlations of various types between a given number of particles (see KINETIC THEORY).

As the density increases, the cluster expansion breaks down and more powerful methods have to be used. The statistical theory of liquids is now well accepted, but it is based on more or less ad hoc assumptions, the justification of which from first principles is impossible. The advent of fast computers played a very important role in this field. The development of the methods of molecular dynamics allows one to perform detailed "numerical experiments" in order to determine the structure of complicated many-body problems (up to 1000 particles interacting with realistic potentials).

The theory of critical phenomena is one of the "hot points" of present research. The problem here is to understand the occurrence of singularities in a number of physical phenomena as well as the relations among them. Although no final solution of this problem has been reached as yet, considerable progress has been made in recent years. (See CRITICAL PHENOMENA.) A considerable amount of work in the last fifteen years has culminated in the so-called *renormalization group* theory of critical phenomena (originally due to K. Wilson). The latter provides a very elegant and original method of studying the partition function and yields a detailed description of the properties of systems in the neighborhood of the critical point.

We must also mention that, after Onsager's masterwork on the exact solution of the two-dimensional Ising model of a ferromagnet (1944), an increasing number of sophisticated models have been solved exactly, mainly by E. Lieb and by R. Baxter. These models have provided important information about phase transitions and critical phenomena.

(c) *Plasmas.* The ionized gases, or plasmas, have a radically different behavior as compared to "usual" gases. This is due to the long range of the Coulomb forces. As a result, one cannot speak of collisions in the ordinary sense: the interactions have a markedly collective character, involving many particles simultaneously. Mathematically, the various virial coefficients turn out to be divergent. J. E. Mayer (1950) has shown that by rearranging the cluster expansion and by performing summations of certain subseries, one can obtain a convergent equation of state for a plasma, the first term of which agrees with the one calculated by Debye and Hückel in their famous theory of electrolytes (which is semiphenomenological) (see PLASMAS).

Whereas equilibrium statistical mechanics is in a state where the difficulties are mainly mathematical, nonequilibrium statistical mechanics is still in a state where the principles and the ideas are not yet completely clarified and unified. Most of our present knowledge has been achieved in the last thirty years, and this field is still in rapid growth.

The main problem here is to understand the basic paradox of irreversibility: whereas the laws of mechanics are invarient with respect to an inversion of time, the macroscopic evolution (e.g., heat conduction, dissipative phenomena, etc.) is irreversible. In older theories (Boltzmann), it was argued that due to the large number of particles and their complicated motions, one could invoke a probabilistic argument which, superposed to mechanics, would readily yield an explanation of irreversibility.

The basic idea in the modern theories is to avoid the probability arguments. It is now widely accepted that the origin of irreversibility has to be sought in the *dynamical instability* of many-body systems. Two systems which are initially arbitrarily close together in phase-space may evolve after a finite time into widely separated positions. As a result, any finite domain in phase space becomes extraordinarily distorted in its motion, and the flow in phase space becomes highly chaotic, reminiscent of a turbulent flow (see FLUID DYNAMICS). Hence the concept of individual trajectories loses its meaning, and is to be replaced by a statistical description which eventually leads to irreversibility.

In a recent and quite illuminating version of nonequilibrium statistical mechanics, the theory is presented as follows. The distribution function $\rho(x, p; t) \equiv \rho(t)$ can be split into two terms

$$\rho(t) = \bar{\rho}(t) + \hat{\rho}(t) \tag{12}$$

If a certain number of very mild symmetry requirements are imposed [such as: $\bar{\rho}(t)$ must remain at all times in the subspace $\bar{\rho}$ as it evolves under the laws of exact mechanics], and if certain conditions on the nature of the interactions and the size of the system are met, the separation is unique. It can then be shown that the component $\bar{\rho}(t)$ has a "kinetic behavior." The reduced one-particle function determined from it, $\bar{F}_1(x, p; t)$, obeys a *closed* equation, independently of the correlations. This closed equation, called the *kinetic equation*, describes the approach of the system to thermal equilibrium. For dilute gases the kinetic equation is none other than the classical Boltzmann equation (see KINETIC THEORY).

As for the complementary (and complicated) component $\hat{\rho}(t)$, it can be shown that, even if present, it does not contribute to the calculation of some important physical quantities, such as the static transport coefficients (see below). For all these problems the kinetic equation provides a complete and self-contained description.

One of the practical purposes of nonequilibrium statistical mechanics is the calculation of transport coefficients (thermal and electrical conductivity, viscosity, etc.) from molecular data. This can be done by starting from the kinetic equations. Alternatively, it has been shown recently (M. S. Green, R. Kubo) that a compact expression for most transport coefficients can be obtained from general arguments. The "Kubo formulas" express these coefficients in terms of an autocorrelation function of two microscopic currents (electrical currents, heat flow, etc.) averaged over the equilibrium distribution function. These two equivalent approaches can be combined in order to form a basis for the rigorous calculation of transport coefficients (see TRANSPORT THEORY).

Many other important results have been obtained recently in statistical mechanics; they cannot be reviewed in such a short article. The interested reader is referred to the existing textbooks, such as those given below.

STATISTICS

Statistics has been called the art and science of making reasonable decisions in the face of uncertainty or incomplete information. Such a wide ranging description suggests that the basic procedures of statistics must be very much involved with what is usually called simply the scientific method. This is indeed the case.

Descriptive statistics deals with the problem of how to summarize and present masses of data so that they will be useful to the scholar and understandable to his reader. In recent years, new techniques of *computer graphics*, the growth of *principal component analysis* and *factor analysis* as methods of dealing with multidimensional data in lower dimensions, the development of *cluster analysis* or *numerical taxonomy*, and some recognition of the importance of *exploratory data analysis* have all led to a rebirth of interest in descriptive methods. Such methods often make use of matrix algebra and the mathematics of euclidean vector spaces.

Building on previous work in his field and, perhaps, using some descriptive statistical methods, a scientist builds a theory (model) that he hopes will explain some aspects of nature. He deduces from this theory predictions which he then checks against experimental data, thus confirming or repudiating his theory. When the theory has factors of uncertainty built into it, by way of probabilities, statistical methods must come into play.

Suppose we let X be a *random variable*. That is, X stands for the outcome of a certain experiment. We call the collection E of all possible values for X (i.e., the collection of all possible outcomes of the given experiment) the *sample space* for the random variable. We may well be uncertain as to which of the possible values of X will actually occur. But, in such a case, we can imagine a *probability distribution* for X. If E is a discrete set, this probability distribution assigns a probability to each point in E. If E is not discrete (e.g., E might be an interval on the real line) this probability distribution assigns probabilities to certain sets by way of a *probability density function.* The probability assigned to a set A is obtained by integrating the probability density function over A, much as integrating a mass density function yields a mass. We think of the probability assigned to a point or to a set as the long-run relative frequency with which that point or some point in that set will occur in repeated trials of the experiment. If we make n independent runs of the given experiment, we obtain the outcome $(X_1, X_2, \cdots, X_n)$ which is called a *random sample* for X. The process of drawing conclusions about the probability distribution from information about a sample is called *statistical inference*.

Quantities that we may compute from a given sample to be used in this process are called *statistics*. Some of the useful statistics that may be found for a sample are the mean, median, mode, range, and standard deviation. This last is the positive square root of the variance S^2 which is given by

$$S^2 = \frac{1}{n} \sum_{i=1}^{n} (X_i - \bar{X})^2$$

where $\bar{X}$ is the sample mean. Any statistic is itself a random variable in the sense that its value is obtained by performing an experiment—the experiment of drawing a random sample for X and then computing the value of the statistic from these sample values.

On the other hand, any probability distribution for a random variable will, itself, usually have a mean, median, mode, range, and standard deviation. Such numerical properties of probability distributions are called *parameters*. Parameters are *not* statistics.

A standard example of this situation would be the case where X_1, $X_2, \cdots$, and X_n are repeated measurements of some physical quantity and there is a random error in our measurement. (In this case, the standard deviation is often called the standard error.) The mean $\bar{X}$ of all our measurements would be a statistic and we would probably use $\bar{X}$ to estimate the underlying true value we are trying to measure. This unknown true value would be a parameter of the distribution for our measurements.

This is an instance of a broad class of problems where we wish to *estimate* one or more *parameters*. Another instance would be an opinion poll. The pollster is estimating certain parameters (the proportions of people in the population at large that would respond in certain ways to his questions) on the basis of the responses of people in his sample.

If θ is an unknown parameter for a random variable X and $(X_1, X_2, \cdots, X_n)$ is a random sample for X, we may consider a certain statistic $\hat{\theta}$, which will be a function of the sample values, as an *estimator* for θ. We would call θ an *unbiased* estimator if θ is the mean of the probability distribution for $\hat{\theta}$. The variance of the distribution for $\hat{\theta}$ is a measure of the *efficiency* of the estimator. A *best* estimator is one which is unbiased and of minimum variance (i.e., as efficient as possible) for the given sample size.

It is often desirable to give an *interval estimate* for an unknown parameter instead of giving a *point estimate* as above. Suppose it is possible to find two functions L and U which have the property that, no matter what the value of the unknown parameter θ, the probability that θ will be between L $(X_1, X_2, \cdots, X_n)$ and U $(X_1, X_2, \cdots, X_n)$ is, say, 0.95. If we then observe the sample values $X_1 = x_1$, $X_2 = x_2, \cdots$, and $X_n = x_n$, we say that the interval from $L(x_1, x_2, \cdots, x_n)$ to $U(x_1, x_2, \cdots, x_n)$ is a 95 per cent *confidence interval* for θ. Similar interpretations are given for other levels of confidence or for one-sided confidence intervals.

Aside from problems of parameter estimation, there is the broad question of which probability distributions seem feasible in view of some experimental data. The classical *Neyman-Pearson theory* of hypothesis testing is a widely accepted approach to such questions. Any assertion about a probability distribution may be considered to be a *statistical hypothesis*. In many scientific endeavors, the basic questions can be put in terms of deciding between competing statistical hypotheses. For example, we might wish to decide between the hypothesis H_0 that a new medical treatment produces no higher a proportion of cures than an older treatment, and the hypothesis H_1 that the new treatment increases the proportion of cures. Or we might consider the hypothesis H_0 that a rate of radioactive decay is independent of the temperature, against the hypothesis H_1 that it is not. Or we might want to look at the hypothesis H_0 that the proportion of physicists who are unemployed is no higher this year than it was last, against the hypothesis H_1 that it has increased.

When we wish to decide between two hypotheses H_0 and H_1 about the probability distribution for a random variable X, we usually may arrange it so that we base our decision on the observation of a random sample for X. A *test* for the given hypotheses will be a specification of the conditions under which we will accept one of the hypotheses and reject the other. Since there are only two hypotheses, H_0 and H_1, being considered, such a test is given completely by specifying exactly which samples will cause us to reject H_0. The collection of such samples is called the *critical region* for the test. If H_0 happens to be true and yet when we draw our sample and use the test we find that we reject H_0 (and thus accept H_1), then we have commited an error. Such a mistake is traditionally called an *error of the first kind*. To accept H_0 when actually H_0 is false is to commit an *error of the second kind*. In some cases, it is possible to compute the probability of rejecting H_0 when H_0 is true. This probability is called the *significance level* of the test. Thus, to say that we reject H_0 at the 1 per cent significance level is to say that our observations led us to reject H_0 using a test which has the property that it will reject H_0 only 1 per cent of the time when H_0 is true. When it is not possible to compute the probability of rejecting H_0 given that H_0 is true, it is customary to take the *significance level* of the test to be the maximum possible probability of rejecting H_0 when H_0 is true. If both H_0 and H_1 are concerned with the value of a parameter θ we may judge the value of a proposed test by considering its *power function* f. $f(y)$ is defined to be the probability of rejecting H_0 when y is the true value of θ. For an effective test we would want $f(y)$ to be small for values of y such that $\theta = y$ makes H_0 true, and large for values of y such that $\theta = y$ makes H_1 true. The function whose value at y is $1 - f(y)$ is sometimes called the *characteristic function* for the test.

We note that in view of the intimate connections between the mathematical models we are using, the decisions we want to make, and the experiments we carry out, it is of the utmost importance to plan our experiment in a manner which takes these factors into consideration. There are cases on record where large-scale experiments have been carried out without such planning and were of such a nature that no decision could be made on the basis of the experiment—no matter what the data came out to be. Common sense dictates that planning should take place *before* the experimentation. The broad field of study known as *design of experiments* attempts to give guidance in such planning.

Most of the ideas about estimation and hypothesis testing are useful only when used in conjunction with facts from the theory of probability distributions. Some of the most useful distributions can be described as follows. If X is the number of "successes" in n independent trials where the probability of a "success" on each trial is p, then X is said to have the *binomial* distribution $B(n,p)$. If X has the probability density function

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}}\, e^{-(1/2)[(x-\mu)/\sigma]^2}$$

where μ (the mean of the distribution) and σ (the standard deviation of the distribution) are real numbers with σ positive, then X is said to have the *normal distribution* $N(\mu,\sigma^2)$. If

$$Y = \sum_{i=1}^{n} X_i^2$$

where $(X_1, X_2, \cdots, X_n)$ is a random sample for X and X is $N(0,1)$, then Y is said to have the *chi-square distribution* $\chi^2(n)$ with *n degrees of freedom*. If X is $N(\mu,\sigma^2)$ and $\overline{X}$ and S are the mean and standard deviation for a random sample of size n for X, then

$$T = \frac{\overline{X} - \mu}{S/\sqrt{n-1}}$$

has the *Student's distribution* $t(n-1)$ with *$n-1$ degrees of freedom*. If Y is $\chi^2(n)$ and Z is $\chi^2(m)$ and Y and Z are independent, then $W = (Y/n)/(Z/m)$ has the *F-distribution* $F(n,m)$ with *n and m degrees of freedom*. Handbooks of mathematics and statistics usually contain tables that give certain probabilities for these standard distributions. Often these tables give only *critical values* that are the most useful. These are the values that cut off, on one side or the other, intervals over which, say, 5 per cent or 1 per cent of the probability lies.

Measurements that involve random errors are often observed to have distributions that are normal or approximately so. (In fact, a probability density function for a normal variable is often called a *Gaussian error function*.) Many other quantities that have approximately normal distributions seem to occur in nature. But even if this did not happen, normal distributions would be extremely useful because of the following powerful result which is called the *central limit theorem*: If X has a mean μ and a standard deviation σ, and $\overline{X}$ is the mean of a random sample of size n for X, then $(\overline{X} - \mu)/(\sigma/\sqrt{n})$ has a distribution which is approximately $N(0,1)$ when n is large. Notice that there is no assumption about the underlying distribution for X aside from the fact that μ and σ exist. Many standard statistical techniques rely heavily on the central limit theorem. These techniques would be part of what is called *large-sample theory* as opposed to *small-sample theory* where other results must be used. Many useful small-sample techniques are concerned with so-called *nonparametric tests*, which involve hypotheses which are not stated in terms of the values of certain parameters.

Student's distributions are of special importance in small-sample theory. Chi-square distributions are useful for certain *goodness-of-fit* tests which include standard procedures for handling *contingency tables*. F distributions come into play in *analysis of variance* where the underlying variables are assumed to be normal and we are interested in detecting differences between their means. Analysis of variance is an example of a multivariate technique that may be explained in terms of the *general linear model*, where we assume that a random n-vector $\mathbf{Y}$ can be written as $\mathbf{Y} = \mathbf{AB} + \mathbf{E}$ where $\mathbf{A}$ is an $n \times k$ structure matrix of known constants, $\mathbf{B}$ is a $k \times 1$ matrix of unknown parameters, and the entries in the n-vector $\mathbf{E}$ are independent normal deviates with mean 0 and a common variance. *Regression analysis* is also an application of the general linear model. A special case of regression analysis is *least-squares curve fitting*.

Statistical software packages are becoming common. These have built-in routines to carry out the more or less standard chores of description, estimation, and hypothesis testing. Regression analysis packages may be used for polynomial curve fitting. The wide availability of computers has encouraged a resurgence of interest in discrete (rather than continuous, as with normal variables) statistical situations such as multidimensional contingency tables. Some of the standard statistical calculations can easily be carried out using statistical packages on microcomputers or even on hand-held calculators.

Since statistical methods are so closely intertwined with basic questions about scientific methods it is not surprising to find that there are controversies about these methods. The *decision theoretic* approach to statistics questions some of the basic ideas of classical hypothesis testing and suggests that, where possible, we should take into account the *cost* of committing the different kinds of errors we may make. Here the proper approach would be to design a procedure that would, in some sense, minimize our expected loss. In a laboratory situation, however, it may be difficult to assign costs to the sorts of errors. In managerial or social situations it may make a great deal of sense to consider seriously how much we will lose if we follow certain paths.

Statistics relies heavily on the theory of probability, and the question of the exact nature (or natures) of probability is an old one in the philosophy of science. A growing group of theoretical and practicing statisticians takes a somewhat different view of probability than is usual. These people call themselves *Bayesians* or *subjectivists* and believe that it is most useful to consider a probability to be a subjective, personal thing which is based on an individual's knowledge (and ignorance) and is subject to modification (via what is known as Bayes theorem) in view of empirical information. We may determine an individual's probability for an event by offering him bets and discovering at what odds he will take either side of the bet. A Bayesian point of view has considerable impact on the question of what constitutes an acceptable statistical procedure and articles about this impact are common in the current literature.

This ferment in statistics happens to coincide in time with a great increase in the use of statistical methods in the natural and social sciences. With the continual pressures caused by a reconsideration of the foundations and a demand for useful tools for applications, the field of statistics will continue to grow in both depth and usefulness.

STRONG INTERACTIONS

Only two types of fundamental interaction operate in classical physics, which account for all macroscopic and chemical phenomena including atomic structure. There are the gravitational forces which control the motion of bulk matter, which is electrically neutral--particularly the motion of the planets in the solar system. Then there are the electromagnetic forces which govern the motion of the electrons in atoms, and also give rise to the interactions between atoms and, hence, form the basis of all chemical reactions.

An atom has a radius of about 10^{-10} m. In an atom, a cloud of electrons orbit about a central nucleus with a radius of about 10^{-14} m. These nuclei are made up of nucleons—protons and neutrons. The total charge, which is determined by the number of protons, fixes the chemical nature of the atom. The nuclei are extremely stable, remaining unchanged through the most violent chemical reactions. The gravitational forces within a nucleus are completely negligible compared with the electrical repulsion between the charges on the tightly packed protons. Since the electrical forces tend to blow the nucleus apart, it follows that a completely new, specifically nuclear, force must be operating to form these stable structures. This force is of short range, only effective when the nucleons are less than 10^{-14} m apart. Within this range, it is strong enough to overcome the powerful electrical repulsions. It is known as the *strong nuclear interaction*, to distinguish it from the other specifically nuclear interaction—the *weak* interaction—which causes the spontaneous disintegration of subnuclear particles (see WEAK INTERACTIONS). It is the strong nucleon interaction which is the source of energy in nuclear weapons and in nuclear reactors.

To investigate the workings of the strong nuclear interaction a beam of high-energy protons from a proton accelerator is directed at a target of liquid hydrogen (more protons) and scattered. At low energies, below 300 MeV in the laboratory, the protons are merely deflected by the strong nucleon-nucleon interaction. Above this energy, new particles are produced in the collision. The first to appear are the π-mesons, or pions. As the energy increases, more and more particles are found. The least massive are stable as far as the strong interaction is concerned, but they disintegrate through the weak interaction with mean lifetimes of about 10^{-10} second. The more massive particles decay via the strong interaction into other strongly interacting particles in about 10^{-23} second. These are tabulated in the article on ELEMENTARY PARTICLES. These strongly interacting subnuclear particles, which include the proton and neutron, are known collectively as *hadrons*. This distinguishes them from the *leptons* (electrons, muons and neutrinos) which are subject only to the weak and—if they are charged—the electromagnetic interactions.

Because of the strength of the strong interaction, it has not been possible to determine the details of the corresponding dynamics. However, considerable progress has been made by studying the conservation laws which govern the collision of hadrons and by analogy with the theory of electromagnetism.

The hadrons are specified according to their properties which correspond to those physical quantities which are conserved (i.e., do not change) in any collision which is dominated by the strong interaction. These are typically the mass, which contributes to the energy, and the spin which is part of the total angular momentum. If a particle has spin J (in units of $h/2\pi$) there are $2J + 1$ possible states, corresponding to the orientations of the spin axis allowed by quantum mechanics. These states are distinguished by the magnitude of the component J_z which ranges by integers from $+J$ to $-J$.

Other conserved quantities are the electric charge, the so-called hypercharge, and the baryon number. These are also tabulated in the article ELEMENTARY PARTICLES.

These hadrons appear in multiplets of nearly equal mass, but differing charge. Thus there are three pions (positive, negative and neutral) and two nucleons, one positive (the proton) and one neutral (the neutron). These are closely analagous to the $2J + 1$ spin states of a particle of spin J and may be explained by attributing to each mass multiplet a spin I (isotopic spin) in an abstract space. The different charge states are then interpreted as the different "orientations" in this abstract space and are specified by the $2I + 1$ values of the component I_3. Thus the pion has isotopic spin 1, with the three charge states specified by $I_3 = \pm 1, 0$. The nucleon has isotopic spin $I = 1/2$, with two charge states $I_3 = \pm 1/2$. Isotopic spin is conserved in strong interactions, just as total angular momentum is conserved. The conservation of angular momentum is related to the invariance of the whole colliding system with respect to its orientation in space. The conservation of isotopic spin is similarly equivalent to the statement that the strong interactions are invariant under a group of two-dimensional unitary transformations, known to group theorists as SU(2).

It has been conjectured that the strong interactions are approximately invariant under a wider group of three-dimensional unitary transformations, SU(3), which combines the notion of isotopic spin with that of hypercharge. According to this theory, the isotopic multiplets of particles of the same spin J can be combined into supermultiplets of roughly similar mass, which form hexagonal or triangular patterns when they are exhibited on a graphical plot of I_3 against Y. By 1963, three such supermultiplets had been established. They form octets of particles, with $J = 0, \frac{1}{2}$ and 1. (These are $\pi^+ \pi^- \pi^0 \eta^0 K^+ K^0 K^- K^0$; $\Sigma^+ \Sigma^- \Sigma^0 \Lambda^0 p\ n\ \Xi^- \Xi^0$; $\rho^+ \rho^- \rho^0 \phi^0 K^{*+} K^{*0} K^{*-} \bar{K}^{*-}$.) At that time, the known particles of spin $J = 3/2$ formed a tenfold triangular multiplet, with one particle missing—the Ω^-. This missing particle was an isotopic singlet ($I = 0$) with hypercharge minus two. It had remarkable physical properties very well defined so that its mass, mode of production, mean life time, and decay could all be predicted. This particle was discovered in 1964 exactly as forecasted, thus confirming the wider unitary scheme.

This scheme provides a kind of "periodic table" for the subnuclear particles which can clearly no longer be regarded as "elementary." The simplest explanation of these regularities is that all the hadrons are themselves composed of yet more basic entities—called QUARKS. Three quarks are required, corresponding to the three dimensions of the $SU(3)$ group, leading to the three conserved quantities: electric charge, hypercharge, and baryon number. The quarks form an isotopic doublet and an isotopic singlet. If they are assumed to be of approximately equal mass, the observed patterns emerge if the hadrons with baryon number zero are the various possible combinations of quark-antiquark pairs, while those with unit baryon number are bound states of three quarks. If the quarks are assumed to have an ordinary spin of $\frac{1}{2}$, they also provide a natural explanation of the spins of all the particles appearing in Fig. 1. This three-quark theory provided a very adequate and economic explanation of the known properties of hadrons for ten years following the discovery of Ω^-, but it has one very remarkable feature. For the hadrons to have the observed integer charges (in units of the electron charge) it is necessary for the quarks to have fractional charges of $\frac{2}{3}$ and $-\frac{1}{3}$. This should make them easy to detect and, if the known structure of atoms and nuclei is taken as a guide, the theory implies that it should be possible, given sufficient energy, for hadrons to be disintegrated and for free, fractionally charged, quarks to be observed directly. In spite of intensive searches no convincing evidence for such objects has ever been found.

The next important development came in 1974 with the discovery of the ψ/J particle with a lifetime of about 10^{-20} secs, with approximately three times the mass of the proton. This was found independently in proton-proton collisions and in the hadronic matter produced in high energy collisions of electrons and positrons. This particle lies outside the scope of the earlier three-quark model. It was not unexpected, as it had already been shown that if hadrons were to be incorporated in a unified theory of electric and weak interactions (see ELECTROWEAK THEORY), there must be a fourth, heavier quark carrying a new quantum number known as *charm*. The ψ/J is interpreted as the charm-anticharm quark combination, and

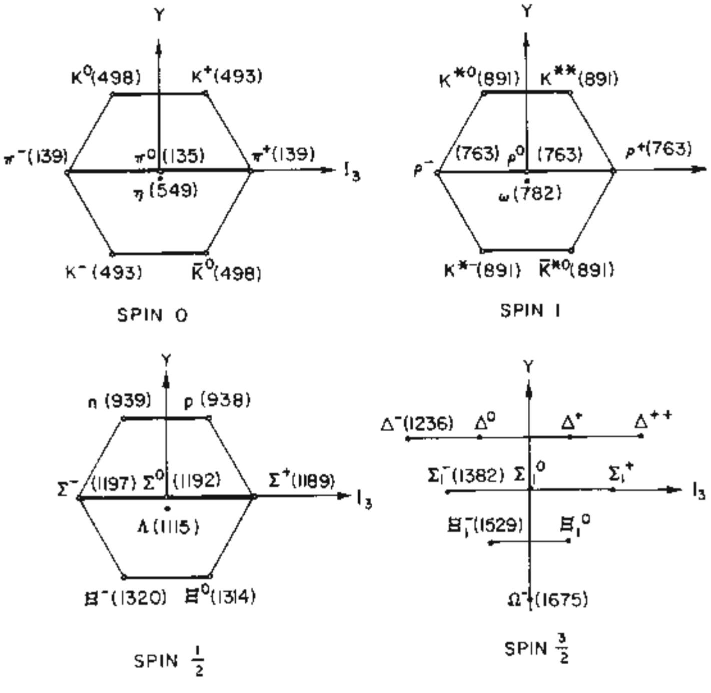

FIG. 1. The well-established SU(3) multiplets. In each of these, particles lying together on horizontal lines form sub-multiplets of SU(2) (isotopic spin). The figures in brackets indicate the masses of the particles in MeV/c^2.

the existence of three other hadrons expected from the combination of an anti-charm quark with the three quarks of the older theory was established within two years. Similar evidence now exists for a fifth quark and there are strong theoretical arguments for believing that there may be a sixth, corresponding to the six known leptons—e, ν_e, μ, ν_μ, τ, and ν_τ.

None of these five (or six) quarks has been observed as an independent entity. A qualitative explanation of this, which also makes the whole quark theory consistent with the Pauli exclusion principle, is contained in QUANTUM CHROMODYNAMICS (QCD). In this theory each quark appears in three forms, picturesquely denoted by *color*—red, blue, and yellow, say. Each quark carries a unit of color and the net total of each color is exactly conserved due to a new $SU(3)$ invariance with regard to the color variables. The forces that bind the quarks together to form hadrons are related to this invariance and these conservation laws by the same mechanism (local gauge invariance) which relates electromagnetic forces to the conservation of electric charge in QUANTUM ELECTRODYNAMICS (QED). In this picture, the hadrons in QCD are the subnuclear analogues of the atoms in QED and the strong interactions between hadrons are the analogues of chemical binding between atoms. It is conjectured that the QCD forces binding the quarks to form hadrons are so strong that individual quarks cannot be separated, except possibly under the most extreme conditions of temperature and pressure, which would explain why individual quarks have not been detected.

It should be emphasized that belief in QCD theory is based largely on aesthetic arguments. It is an elegant theory which seems to contain the general features required to explain the observed properties of hadronic matter. However, the calculation of its implications is so complicated that even some of its most important qualitative features, such as the containment of quarks, have yet to be established mathematically. It is also evident, with six different types of quark, each appearing in three different forms, that the substructure of hadronic matter is itself becoming rather complicated, suggesting a possible further synthesis of the strong nuclear interaction with the weak interaction and electromagnetism.

SUPERCONDUCTIVITY

This article describes the experimental facts relating to superconductivity, our present theoretical understanding, and some practical applications. No attempt is made to follow historical order or to provide an exhaustive treatment; the references at the end of the article will help those who wish to pursue the subject further.

The most spectacular property of a superconductor is the total disappearance of its electrical resistance when it is cooled below a critical temperature T_c. Very careful measurements show that the electrical resistance of a superconductor is at least a factor of 10^{17} smaller than the resistance of copper at room temperature and may therefore for all practical purposes be taken to be zero. Some 27 elements, and a vast number of alloys and compounds, have been discovered to be superconducting. In addition, a number of materials which are non-superconducting under ambient pressure in the bulk form, can be made superconducting by subjecting them to high pressures or by preparing them in the form of amorphous films. Even some organic chain compounds have been found to be superconducting. To name just a few from each category: elements In, Sn, Mo, Hg; Nb-Ti alloys; the intermetallic compound Nb_3Sn; As, Ge, Si under high pressure; amorphous films of Be, Bi, Ba; ditetramethyltetra selenafulvaleneperchlorate, $(TMTSF)_2ClO_4$ for short. Transition temperatures range from a few thousandths of a kelvin (tungsten, for example at 0.015 K) to the highest reported to date, about 23 K for Nb_3Ge. The search for superconductors with yet higher transition temperatures continues; there are occasional reports of such finds, but none has yet been convincingly confirmed.

Another important property is the destruction of superconductivity by a large enough applied magnetic field. The magnetic behavior of a superconductor falls into either one of two distinct classes, depending on the particular material. These are called *type I* and *type II* superconductors. The difference can be brought out by considering the response of a superconducting sample which is in a magnetic field swept from zero to a value large enough to make it normal, i.e., destroy the superconductivity. For a type I sample, the magnetic flux is almost totally excluded from the interior of the sample up to a *critical field* H_c. At H_c, an abrupt transition occurs, superconductivity is destroyed, and flux penetrates the sample fully. For a type II sample also, the initial behavior is the same; the flux is excluded up to a critical field H_{c1}. But now the transition is gentler. As the applied field is increased, some flux begins to creep into the sample. The entry of flux is completed at a higher critical field H_{c2}, at which point the sample becomes normal. These three characteristic fields H_c, H_{c1}, and H_{c2} vary from material to material, and depend on temperature. They all tend to zero as T tends to T_c, and go to finite limiting values as T tends to zero.

The state of a superconductor in fields up to H_c (for type I) or H_{c1} (for type II) is called the *Meissner state*, after the co-discoverer of the effect. The original paper in fact was by W. Meissner and R. Ochsenfeld, a fact which may interest social historians of science. The state of a type II superconductor between H_{c1} and H_{c2} is called the *mixed state*, because it turns out that the sample can be considered in some sense as breaking up into an intimate ordered mixture of normal and superconducting regions. Both types of magnetic behavior, in suitably prepared samples, are thermodynamically reversible and cannot therefore be deduced from the perfect conductivity.

In the Meissner state, the magnetic field decays exponentially to zero as one goes in from the surface of the sample. This characteristic decay length, denoted by λ, is called the *penetration depth* and is typically a few times 10^{-5} cm. The precise value varies with material. Thin films of a type I superconductor, of thickness d less than λ, have critical fields higher than the bulk critical field H_c, approximately in the ratio of λ to d. This result follows qualitatively from the thermodynamics of the Meissner effect: the metal in the superconducting state has a lower free energy than in the normal state, and the transition to the normal state occurs when the energy needed to keep the flux out becomes equal to this free energy difference. But in the case of a thin film with $d < \lambda$, there is partial penetration of the flux into the film, and thus one must go to a higher applied field before the free energy difference is compensated by the magnetic energy. The situation is more complicated for type II superconductors, because flux penetration begins at H_{c1} even for bulk samples.

All the elemental superconductors are type I, with the exception of Nb and possibly V. Practically all the alloys and compounds are type II, which is therefore by far the preponderant class. It is interesting that even though the phonomenon of superconductivity has been known for over 70 years, it is only within the past 25 years that type II behavior was clearly recognized, described and understood. The highest values of H_c, extrapolated to zero kelvin, are of the order of 10^3 gauss; values of H_{c2}, on the other hand, have been reported for some Chevrel phases in excess of 5×10^5 gauss. It may be noted that the typical field in an iron-core electromagnet is 10^4 gauss. It is clear that the discovery of such high critical field materials has opened up some exciting possibilities in technologies where high magnetic fields are desirable.

Since a magnetic field can destroy superconductivity, so should an electrical current flowing through a superconducting wire, through the self-generated magnetic field. One can therefore talk about a *critical current*, above which the wire becomes normal, and which should depend upon temperature and an externally applied magnetic field. But again, there are significant differences between type I and type II superconductors. A given wire of lead (type I) may carry 10^3 amp/cm^2 in a field of 100 gauss before going normal. But one can make a wire of Nb_3Sn (type II) which can carry 10^5 amp/cm^2 in 10^5 gauss, and still be superconducting. The technological implications are obvious.

The existence of two types of superconductivity does not at all mean that two separate theories are needed. There is a single comprehensive microscopic theory, as will be seen shortly, which gives a beautiful explanation of how the two types arise. Everything from here on, in fact, applies to all superconductors, unless explicitly stated otherwise.

All of the above properties distinguish superconductors from "normal" metals. There is another very important distinction, which contains a clue to the understanding of some of the properties of superconductors. In a normal metal at 0 K, the electrons, which obey Fermi statistics, occupy all available states of energy below a certain maximum energy called the *Fermi energy* ζ. Raising the temperature of the metal causes electrons to be singly excited to states just above the Fermi energy. There is for all practical purposes a continuum of such excited energy states available above the Fermi energy.

The situation is quite different in a superconductor; in a superconductor, the lowest excited state for an electron is separated by an energy gap Δ from the ground state. The existence of this gap in the excitation spectrum has been confirmed by a variety of experiments: electronic heat capacity, thermal conductivity, ultrasonic attenuation, far infrared and microwave absorption, and tunneling. It is to be noted that the excitation of electrons across the gap by photons requires a minimum energy of 2Δ, which is consistent with the description of the superconducting ground state in terms of Cooper pairs, as described further below. The energy gap decreases monotonically with increasing temperature, having a value $\Delta_0 = 1.75\ k_BT_c$ at 0 K (where k_B is the Boltzmann constant) and vanishing at T_c.

The superconducting state has a lower entropy than the normal state, and therefore one concludes that superconducting electrons are in a more ordered state. Without, for the present, inquiring more deeply into the nature of this ordering, one can state that a spatial change in this order produced say by a magnetic field will occur, not discontinuously, but over a finite distance ξ, which is called the *coherence length*. The coherence length represents the range of order in the superconducting state and in elemental superconductors is about 10^{-4} cm, though we shall see later that it can in many superconductors take much lower values, and lead to type II behavior.

Measurements of the transition temperature on different isotopes of the same superconductor showed that T_c is proportional to $M^{-1/2}$, where M is the isotopic mass. This isotope effect suggests that the mechanism underlying superconductivity must involve the properties of the lattice in addition to those of the electrons. Another indication of this is given by the behavior of allotropic modifications of the same element: white tin is superconducting, while gray tin is not, and the hexagonal and face-centered cubic phases of lanthanum have different transition temperatures. A third, and most striking, indication is that the current vs. voltage characteristic of a superconducting tunneling junction shows a structure which is intimately related to the phonon spectrum of the superconductor.

The theory of superconductivity has developed along two lines, the phenomenological and the microscopic. The phenomenological treatment was initiated by the brothers F. and H. London, who modified the Maxwell electromagnetic equations so as to allow for the Meissner effect. Their theory explained the existence and order of magnitude of the penetration depth, and gave a qualitative account of some of the electrodynamic properties. The treatment was extended by V. L. Ginzburg and L. D. Landau, and by A. B. Pippard, who in particular emphasized the concept of the coherence length ξ and showed that if ξ is greater than λ many of the properties of type I superconductors could be explained. A. A. Abrikosov used these ideas and showed that if the electronic structure of the superconductor were such that the coherence length ξ becomes smaller than the penetration depth λ, one would get magnetic behavior similar to that observed in type II superconductors, with two critical fields H_{c1} and H_{c2}. In particular, Abrikosov's work, as extended by others, showed that the state of such a superconductor in applied fields between H_{c1} and H_{c2}, the mixed state, consists of a triangular lattice of magnetic flux lines uniformly penetrating the superconductor. The core of each flux line, of approximate radius ξ, consists essentially of normal material, while the surrounding regions are superconducting. Each flux line core is surrounded by persistent supercurrents, and contains a quantum of flux $\phi_0 \equiv h/2e \simeq 2 \times 10^{-7}$ gauss-cm^2. The existence of such a lattice of flux lines received brilliant experimental confirmation through the work of Essmann and Träuble, who used a Bitter technique involving ferromagnetic powder to show up the magnetic lattice on the surface of a superconductor in the mixed state. The problem of high critical currents in unannealed (or otherwise metallurgically imperfect) alloys and compounds is more complicated because it involves the interaction between the microscopic metallurgical structure and the superconducting properties.

The microscopic theory of superconductivity was initiated by H. Fröhlich, who first recognized the importance of the interactions of electrons with lattice vibrations and in fact predicted the isotope effect before its experimental observation. The detailed microscopic theory was developed by J. Bardeen, L. N. Cooper, and J. R. Schrieffer in 1957, and represents one of the outstanding landmarks in the modern theory of solids. The *BCS theory*, as it is called, considers a system of electrons interacting with the phonons, which are the quantized vibrations of the lattice. There is a screened coulomb repulsion between pairs of electrons, but in addition there is also an attraction between them via the electron-phonon interaction. If the net effect of these two interactions is attractive, then the lowest energy state of the electron system has a strong correlation between pairs of electrons with equal and opposite momenta and opposite spin and having energies within the range $k_B\theta$ (where k_B is the Boltzmann constant and θ the Debye temperature) about the Fermi energy. This correlation causes a lowering of the energy of each of these *Cooper pairs* (named after L. N. Cooper, who first pointed out their existence on the basis of some general arguments) by an amount 2Δ relative to the Fermi energy. The energy 2Δ may be regarded as the binding energy of the pair, and is therefore the minimum energy which must be supplied in order to raise a pair of electrons to excited states. We see thus that the experimentally observed energy gap follows from the theory. The magnitude Δ_0 of the gap at 0 K is

$$\Delta_0 \simeq 2k_B\theta \exp\left(-\frac{1}{NV}\right)$$

where N is the density of electronic states at the Fermi energy and V is the net electron-electron interaction energy. The superconducting transition temperature T_c is given by

$$3.5k_B T_c \simeq 2\Delta_0.$$

It has been shown that the BCS theory does lead to the phenomenological equations of London, Pippard, and Ginzburg and Landau, and one may therefore state that the basic phenomena of superconductivity are now understood from a microscopic point of view, i.e., in terms of the atomic and electronic structure of solids. It is true, however, that we cannot yet, easily, calculate V for a given metal and therefore predict whether it will be superconducting or not. The difficulty here is our ignorance of the exact wave functions to be used in describing the electrons and phonons in a specific metal, and their interactions. However, we believe that the problem is soluble in principle at least.

The range of coherence follows naturally from the BCS theory, and we see now why it becomes short in alloys. The electron mean free path is much shorter in an alloy than in a pure metal, and electron scattering tends to break up the correlated pairs, so that for very short mean free paths one would expect the coherence length to become comparable to the mean free path. Then the ratio $\kappa \simeq \lambda/\xi$ (called the *Ginzburg-Landau parameter*) becomes greater than unity, and the observed magnetic properties of alloy superconductors can be derived. The two kinds of superconductors, namely those with $\kappa < 1/\sqrt{2}$ and those with $\kappa > 1/\sqrt{2}$ (the inequalities follow from the detailed theory) correspond respectively to type I and type II superconductors.

As the implications of the BCS theory were better understood, and its relationship to the Ginzburg-Landau and London theories further clarified, during the past few years, a profound and very beautiful new understanding of the nature of the superconducting state has been obtained. F. London had in his earliest work described the superconducting state as a *macroscopic quantum state*, and used a many-body wave function to describe this state. But it has now become clear that, while the full statistical-mechanical description of the condensation of the electrons into the superconducting state is indeed very complicated, the resulting macroscopic quantum state can be described by a complex "wave function" $\Psi(\mathbf{r}, t)$ which is a function of position $\mathbf{r}$ and time t. The amplitude of Ψ gives the fraction of the electron fluid which is in the condensed superconducting state, and its phase contains information about its dynamics. One notes the formal similarity with the Schrödinger wave function of a free particle,

$$\psi = \psi_0 \exp \frac{1}{\hbar}(px - Et)$$

where p is the momentum and E is the energy. The wave function of the superconductor, which is referred to usually as its *order parameter*, can be written

$$\Psi = \Psi_0 \exp(i\phi)$$

where for a uniform superconductor Ψ_0 is a constant and ϕ is in general a function of space and time, and also involves the magnetic field or more precisely the vector potential. The single-valuedness of the order parameter leads to the quantization of magnetic flux in units of ϕ_0, defined earlier, in any area which is fully surrounded by a superconducting region, such as the core of an Abrikosov flux line or a superconducting ring carrying a persistent current. It should be mentioned here that this concept of a complex order parameter provides a fundamental link between superfluid helium and superconductivity, which are now seen as two manifestations of the basic phenomenon of SUPERFLUIDITY, even though the microscopic origins are quite different in the two cases. In terms of the order parameter, one can now give a unified description of similar phenomena in the two areas, such as critical velocities, quantized flux/vortex lines, and the influence of magnetic field/rotation.

B. Josephson's important contribution was to recognize the implications of the complex order parameter for the dynamics of the superconductor, and in particular when one considers a system consisting of two bulk superconductors 1 and 2 connected by a "weak link." The basic requirement for the weak link is that the amplitude of the order parameter there should be substantially smaller than in the bulk regions. Experimentally such a situation has been realized in a variety of ways: two evaporated films separated by a thin (< 20 Å) oxide layer, a light point contact between two bulk superconductors, a single hourglass-shaped evaporated film with the constriction of dimensions small compared to the coherence length, or indeed even a bare niobium wire with a pendant frozen blob of soft solder, where the weak links, indeterminate in number, were formed by solder bridges through pinholes in the surface oxide. Collectively, all such weak link junctions are referred to as *Josephson junctions*.

The electrodynamic behavior of such a Josephson junction can be described at several levels of sophistication: as the solutions of the time-dependent Schrödinger equations for ψ_1 and ψ_2 with an assumed weak coupling between 1 and 2, by perturbation-theoretic methods, or by Green's function methods. All methods fortunately give the same two simple equations, the famous Josephson equations:

$$j = j_0 \sin\left(\phi_2 - \phi_1 - \frac{2e}{\hbar}\int_1^2 A\,dx\right). \quad \text{(J1)}$$

$$\frac{\partial}{\partial t}\left(\phi_2 - \phi_1 - \frac{2e}{\hbar}\int_1^2 A\,dx\right)$$

$$= -\frac{1}{\hbar}(\mu_2 - \mu_1) = \frac{2eV}{\hbar} \quad \text{(J2)}$$

where for simplicity a one-dimensional junction has been treated. In the above equations j is the supercurrent through the junction, ϕ is the phase of the order parameter, A is the vector potential, μ is the chemical potential, V is the voltage bias across the junction, and e and $\hbar$ have their usual meanings. The subscripts 1 and 2 refer to the bulk superconductors on either side of the weak link respectively.

From Eqs. (J1) and (J2) one can see easily that, in the absence of a magnetic field, i.e., $A = 0$, a maximum supercurrent j_0 can flow (which is a function of the junction parameters), and the application of a constant bias voltage V to the junction produces an alternating current at a frequency $\nu_J = 2eV/h$. These two effects constitute the dc and ac *Josephson effects* respectively. In addition, when a Josephson junction biased at a voltage V is exposed to electromagnetic radiation at frequency f, the beating of the two frequencies f and ν_J produces a zero-frequency current component, and consequently a constant-voltage step in the dc junction current, whenever $\nu_J = nf$ where n is an integer. Thus, at values of the voltage $V_n = nhf/2e$, the current-voltage characteristic of the junction shows vertical current steps.

Space does not permit a detailed discussion here of the various effects of a magnetic field on Josephson junctions in different circuit configurations. But it is apparent from Eq. (J1) that the integral on the right can in certain configurations be made to correspond to the magnetic flux through a portion of the circuit. Then j would show an oscillatory dependence upon the field, going through one cycle each time the flux changes by one quantum ϕ_0. For example, in the case of two junctions in parallel enclosing an area A, the maximum supercurrent goes through a cycle as the applied field changes by ϕ_0/A. If A is of the order of a square centimeter it is obvious from the magnitude of $\phi_0 \sim 2 \times 10^{-7}$ cm^2 · gauss that field changes of less than a microgauss can be detected.

Both the dc and ac Josephson effects have found some exciting and novel applications. The high sensitivity to magnetic field of the dc Josephson current in certain configurations has been used to develop a family of devices called "squids" (superconducting quantum interferometric devices) which are used to measure extremely small currents, voltages, and magnetic fields. The ac effect has been used to obtain a very precise measurement of $2e/h$ and thence the fine structure constant α, in terms of the standard volt and a frequency, by D. N. Langenberg and his collaborators. Their work has helped to resolve a number of discrepancies between experiment and the predictions of quantum electrodynamics. Since 1972, the U.S. legal volt has been maintained in terms of the Josephson frequency by the National Bureau of Standards, using the relation

$$1\ \mu\text{V} = 483.593420\ \text{MHz}.$$

The intriguing question of how high a transition temperature is possible has not yet been given a satisfactory theoretical answer. The BCS theory suggests as an upper limit the Debye temperature, which is a few hundred degrees Kelvin for most materials; but actual T_c's are a tenth of this or less. It appears that as one progressively modifies a given material in the direction of higher T_c's, lattice instabilities set in which inhibit the superconductivity. It is possible that these instabilities can be avoided by using metastable high-temperature phases of complex alloys and compounds.

There have been several attempts at technological applications of superconductors. The most spectacularly successful one is the use of certain type II superconductors like Nb-Ti alloys and Nb_3Sn in making electromagnets. In a conventional electromagnet employing normal conductors, the entire electric power applied to the magnet is consumed as Joule heating. For a magnet to produce 100 kilogauss in a reasonable volume, the power requirement can run into megawatts. In striking contrast, a superconducting magnet develops no Joule heat because its resistance is zero. Indeed, if such a magnet has a superconducting shunt placed across it after it is energized, the external power supply can be removed, and the current continues to flow indefinitely through the magnet and shunt, maintaining the field constant. Superconducting magnets have already been constructed producing fields of over 100 kilogauss in usable volumes. There is a natural upper limit to the critical field possible in such superconductors, given by the paramagnetic energy of the electrons (due to their spin moment) in the normal state becoming equal to the condensation energy of the Cooper pairs in the superconducting state. This leads to a limit of about 360 kilogauss for a superconductor with a T_c of 20 K. Coupling between the orbital motion and spin of the electrons, however, can sometimes raise this limit.

Once the technological problems of building superconducting magnets were overcome, they became natural candidates to replace conventional magnets which can produce only a tenth of the magnetic fields that the superconducting ones can. The past ten years have seen a burgeoning of activity in such applications, and the following are just a few illustrative examples. The Fermi National Accelerator Laboratory is constructing over one thousand large superconducting magnets to accelerate elementary particles to higher energies than ever before. In the U.S., a 500 MW generator is on the drawing boards, while smaller generators have been successfully built. Great Britain has a superconducting motor driving a ship, and Japan and West Germany have programs on levitated ground transportation using superconducting magnets. There is consideration of superconducting cable for power transmission, and magnets for fusion reactors.

Superconductors are beginning to find applications at the level of electronic circuits too. Reference has already been made to the use of squids for low-level electrical and magnetic measurements. The properties of thin films and Josephson junctions are being wedded by a well-known computer company in the U.S. and Switzerland to produce a prototype computer which will be smaller, lighter, and more than ten times faster than existing semiconductor-based computers.

SUPERFLUIDITY

Superfluidity is a term used to describe a property of condensed matter in which a resistanceless flow of current occurs. The mass-four isotope of helium in the liquid state, plus about one-half of the elements in the periodic table and a variety of alloys and compounds, are presently known to exhibit this phenomenon. In the case of liquid helium, these currents are hydrodynamic; for the metallic elements, they consist of electron streams. The effect occurs only at very low temperatures in the vicinity of the absolute zero (−273.16°C or 0 K). In the case of helium, the maximum temperature at which the effect occurs is about 2.2 K; for metals the highest temperature is in the vicinity of 23 K.

If one of these metals (called superconductors) is cast in the form of a ring and an external magnetic field is applied perpendicular to its plane and then removed, a current will flow round the ring induced by Faraday induction. This current will produce a magnetic field, proportional to the current, and the size of the current may be observed by measuring this field. Were the ring (e.g., one made of Pb) at a temperature above

7.2 K, this current and field would decay to zero in a fraction of a second. But with the metal at a temperature below 7.2 K before the external field is removed, this current shows no signs of decay even when observations extend over a period of a year. As a result of such measurements, it has been estimated that it would require 10^{99} years for the supercurrent to decay! To the best of our knowledge, therefore, the lifetime of these "persistent" currents is infinite. The persistent or frictionless currents in superconductors are not a recent discovery; they were observed first in 1911 (see SUPERCONDUCTIVITY).

In the case of liquid helium, these currents are, as mentioned, hydrodynamic, i.e., they consist of streams of neutral (uncharged) helium atoms flowing in rings. Since, unlike electrons, the helium atoms carry no charge, there is no resulting magnetic field. This makes such currents much more difficult to create and detect. Nevertheless, as a result of research carried out here and in England starting about 1960, the existence of these supercurrents in liquid helium has definitely been proved. These currents have been observed (1964) for periods as long as 12 hours, a time of the order of 10^3 shorter than is the case for electron currents. Nevertheless, our present belief is that these hydrodynamic currents also possess an infinite lifetime.

As mentioned, the empirical discovery of infinite-lifetime electron currents is of considerable antiquity, and from the beginning, many attempts have been made to explain the effect theoretically. Until recently all such attempts have failed completely, and as a matter of fact, the theoretical picture is still not completely satisfactory. Nevertheless, immense progress in this direction has occurred in the past three decades largely as the result of work in the U.S.A., England and Russia.

Although superfluidity in liquid helium is important to our basic understanding of the phenomenon, it is the effect in superconductors which arouses the most interest. This is due, in part at least, to the possible practical applications to which the effect might lead. In ordinary conductors (e.g., copper), the flow of an electric current is always accompanied by energy dissipation. The supercurrents propagate with no such power loss; superconducting transmission lines would be an economic advance of the first order. However, they would require "room temperature" superconductors, and unfortunately, modern theories, while they do not absolutely prohibit such, render their occurrence most unlikely.

In other ways, however, superconductors have already proved of practical value. Since the currents once created are there for all time, they have fairly obvious use as memory elements in computers. Again the persistent currents form a sort of super gyroscope more perfect than any so far devised. Alloy superconductors have been found (e.g., Nb_3Sn) which can support persistent currents even in the presence of intense magnetic fields of the order of 100 000 gauss. It is, generally speaking, a property of elemental superconductors that the persistent current is quenched in fields of a few hundred gauss; the situation in some alloys like the above is very different.

This has led to the development of intense field solenoidal magnets which maintain their magnetic fields with zero energy dissipation. A conventional electromagnet of the same size would consume many hundreds of kilowatts. This discovery has important consequences in several areas of physics.

Both aspects of superfluidity find their theoretical explanation in what is called a two-fluid theoretical model. We suppose that liquid helium and superconductors are quantum systems possessing a zero energy ground state plus a series of available states of higher energy called normal or excited states. The occupancy of the ground state is zero above the superfluid transition temperature (2.2 K for liquid helium) but grows steadily as the temperature is lowered. At absolute zero, the whole system is in the ground state. At any finite temperature, below transition, the system is in a mixture of ground and excited states. It is the particles in the ground state which form the persistent current.

A simple, though not entirely accurate, *raison d'etre* for the persistent currents lies in the fact that in the ground state, all the very many particles possess the same single wave function. It follows from this that such particles are not easily scattered out of the ground state—a finite amount of energy is required. Such an assembly will not readily interact with outside particles including those in excited states. Since fluid friction or viscosity is due to particle momentum interchange between neighboring layers of liquid, it follows that particles in the ground state will possess zero viscosity. This, in turn, means frictionless flow.

An assembly of particles obeying Bose-Einstein statistics will, below a certain temperature, possess a ground state like the one postulated above. It is known that Bose-Einstein statistics apply only to particles which possess zero (or integral) spin. The neutral He^4 atom possesses zero spin. The isotope He^3 (spin $\frac{1}{2}$) does not; and, in fact, liquid He^3 is not a superfluid. But this is also true of electrons which possess half integral spin and obey a very different statistic (Fermi-Dirac). In this statistic no more than two electrons can possess the same wave function. Hence a ground state, in the above sense, can clearly not exist. Thus according to our model, superfluid flow of electrons cannot occur—but it does!

A way out of this dilemma was suggested nearly 40 years ago. Namely, combine the electrons in pairs, with opposite spins. The resulting "particle" is then a boson and may properly reside in the ground state. The reason why this idea was not accepted by theoretical physicists until recently was because no mechanism could be found by which the electrons could be induced to form pairs. It turns out that the required mechanism arises as a result of a phonon (quantized lattice wave) emitted by one electron and absorbed by another at some other place. This couples the two together.

As mentioned, none of the current theories clearly explains persistent currents. It is not at all evident that their lifetimes should be infinite. It is thought by some that a better formulation for statistical mechanics than presently exists may be necessary before this becomes possible.

A system of persistent currents distinguished by the fact that many particles possess the same wave function constitutes a quantum effect on a hitherto unknown macroscopic scale. In other words, superfluids should exhibit quantum effects of such size that they are readily amenable to experimentation. Two such effects, one in each of the superfluids, have been found. A long thin cylinder with a hole along the axis (i.e., a tube) is similar to the previously mentioned superconducting ring in that persistent currents may also be produced in it. If the length of the cylinder is large compared to the diameter of the hole, the "trapped" magnetic field due to the persistent current is substantially uniform. The flux is the product of this field by the area of the hole.

As a consequence of the fact that the particles producing the current all possess the same wave function, it may be shown that this flux is quantized in integral multiples of hc/q (h = Planck's constant, c = velocity of light, q = charge on the particles).

This prediction has been confirmed experimentally (1961). Further, these experiments show that $q = 2e$, where e is the charge on an electron. Thus the pair hypothesis is very nicely proven.

An interesting consequence of the above effect is that it is impossible to have any field (below a certain value depending on the size of the hole) at all in the cavity. Thus the measurements show that $hc/q \cong 2 \times 10^{-7}$ so that with a hole 1μ in diameter, a field less than about 13 gauss could not exist. We should therefore have a truly field-free space.

A very similar situation, due fundamentally to the same cause, exists for the hydrodynamic currents in liquid helium. In this case, it is the hydrodynamic "circulation" which is quantized in units of h/m (h = Planck's constant, m = helium atom mass). By circulation we mean $\oint \mathbf{v} \cdot \mathbf{dl}$ where $\mathbf{v}$ is the velocity of the atom in the ring-current and $\mathbf{dl}$ is a line element of the periphery of the ring. This effect has also been observed in laboratory experiments (1958).

There is also a surprising consequence connected with this effect. Suppose the helium was being rotated in its containing vessel at a temperature above 2.2 K. Here the helium is "classical" and would rotate, like any other familiar liquid, at the same angular velocity as the vessel. Suppose, now, that the helium was cooled down to near 0 K with the vessel still rotating. If the initial speed were less than that required to produce one quantum of circulation, the rotating helium would come to rest while the container continued to rotate!

This is analogous to the behavior of the magnetic flux on the superconductor, the angular velocity being the quantity analogous to the magnetic field. To be sure, the above experiment has, to date, not been performed, but this is entirely due to difficulties with the existing instrumentation. With advances in technique, it seems very likely that the experiment can eventually be performed, and there is little doubt that the result perdicted will be observed.

SURFACE PHYSICS

Surface physics is the study of the composition, structure, and electronic properties of surfaces and interfaces. Its major goal is to develop an understanding of the macroscopic mechanical, chemical, and electrical properties of surfaces and interfaces in terms of fundamental quantum mechanical interactions. Whenever two distinct phases of matter are in contact, a boundary region is formed with physical and chemical properties which are different from those of the bulk phases on either side. This boundary region is called the *surface* or *interface*. Its thickness can be as small as a few atomic layers, as is the case for the metal-vacuum interface where screening by the conduction electrons is efficient, or as large as thousands of Ångstroms in the case of dielectrics.

Many processes which occur at surfaces or are influenced by surface properties are of great practical importance.[1] Examples include heterogeneous catalysis, crystal growth, thermionic and photoelectron emission, semiconductor devices, colloidal suspension, oxidation and corrosion, brittle fracture, and adhesion and friction.

Surface processes have also played a significant role in the development of modern physics. Photoelectron emission was first observed by Hertz (1887) and its properties were shown by Einstein (1905) to demonstrate the quantum nature of light. Diffraction of low-energy electrons from a nickel crystal surface by Davisson and Germer (1927) and of He atoms from LiF by Stern and Estermann (1930) demonstrated the wave-particle duality of matter. Individual atoms have been observed using the technique of field ion microscopy invented by E. W. Muller (1936).

There are several important reasons why our understanding of surface properties did not begin to increase rapidly until the 1960s. First, the technological importance of surfaces has increased, as is particularly evident in the semiconductor electronic industry. Second, high purity single crystal samples required for well-characterized experiments have become available. Third, the theoretical and experimental understanding of bulk properties has been sufficiently successful that it is reasonable to attempt to extend the results to the more complex case of surfaces which do not have the three-dimensional symmetry that greatly simplifies the description of many bulk properties. Fourth and perhaps most important, techniques have been developed to routinely obtain pressures less than 10^{-8} Pa. Such an ultra-high vacuum is crucial because many experimental measurements require 10–100 minutes during which the surface must not be contaminated from its environment. To see this, consider the rate (ν) at which molecules from the residual gas strike a surface

$$\nu = \frac{P}{(2\pi mkT)^{1/2}}$$

where P is the pressure, m the molecular mass, T the temperature, and k the Boltzmann constant. For a pressure of only 10^{-4} Pa at 300 K, about one monolayer of N_2 molecules will interact with a surface every second. Thus, the requirement of negligable contamination for 10–100 minutes requires background gas pressures three or four orders of magnitudes below 10^{-4} Pa.

The thermodynamic properties of surfaces were originally treated by Gibbs.[2] In this approach, the surface is defined by a reference plane and any extensive thermodynamic property such as the internal energy E^s associated with a surface of area A is given by

$$E^s = E^{\text{total}} - E^1 - E^2$$

where E^{total} is the internal energy for the entire system, E^1 and E^2 are the internal energies *if* the bulk phases on either side of the surface retained their properties up to the reference plane. E^s is called the *surface excess* internal energy. All other thermodynamic quantities associated with the surface can be defined in terms of similar excess quantities. The development of surface thermodynamics proceeds along standard lines following these definitions. The reversible work required to form a unit area of new surface of given orientation $\hat{n}$ at constant volume, temperature, and chemical potentials μ_i of each of the components is called the *surface tension* $\gamma(\hat{n})$. The equilibrium shape of a solid or liquid in contact with its vapor at constant T and V is that shape for which the total energy associated with the surface is minimized and is given by the minimum of the integral

$$\int_A \gamma(n)\, dA.$$

Surface tension is related to other surface excess quantities by the *Gibbs adsorption equation*

$$d\gamma = -s^s\, dT - \sum \Gamma_i\, d\mu_i$$

where s^s and Γ_i are the excess surface entropy and number of moles of each component per unit area, respectively.[2,3]

Surface statistical mechanics seeks to describe the macroscopic thermodynamic properties of a surface and interface in terms of the forces between the atoms composing the system. As for bulk systems this requires a calculation of the canonical partition function Z from which the Helmholtz free energy

$$F = -kT \ln Z$$

and thus all other properties of the system can be determined. Calculations of the surface composition of alloys, equilibrium defect concentrations, and the character of phase transitions and phase boundaries have been carried out for simple models of surfaces.[1,3,4]

A one-centimeter cube of matter contains about 10^{23} atoms; only about 10^{16} of these are exposed on the surface. The surface to volume ratio is thus about 10^{-7}. Clearly, experiments which are sensitive to surface properties must have a sample prepared in such a way as to increase its surface area, or an experimental probe sensitive only to the surface must be used. The second approach using techniques with enhanced surface sensitivity is more popular because these techniques can be applied to many more types and forms of material. Electrons, ions, atoms, and photons have all been used as probes.[1] The most widely used techniques employ electrons with energies in the range 10–1000 eV because these electrons penetrate only 5–50 Å into the substrate. Thermal atoms and low-energy ions are also sensitive surface probes but beams are more difficult to prepare. Techniques utilizing photons which generally penetrate far into a material achieve surface sensitivity by involving a second particle which has shallow penetration. Examples include photoelectron emission (photons incident, electrons emitted) and photon stimulated desorption (photons incident, atoms or ions emitted).

One of the most important properties of clean crystal surfaces, is that they exhibit crystalline order. In many cases, especially for metals, the surface atoms are at the positions which would be expected from a simple truncation of the bulk lattice; the only difference being a slight inward or outward relaxation of the surface layer spacing due to the absence of neighbors on one side. For a second, fairly large group of surfaces including most semiconductors and the metals platinum, iridium, and gold, the surface lattice is completely different from that of the underlying bulk. Such surfaces are said to be *reconstructed*. The most widely known examples are the (7 × 7) Si(111) surface and the (5 × 20) Pt(100) surface. (The notation (7 × 7) and (5 × 20) gives the size of the reconstructed unit surface mesh measured in units of the primative unit mesh for the unreconstructed surface.) Although extensive research has been directed toward determination of the structures of reconstructed surfaces, the (110) surface of GaAs is perhaps the only one whose structure is generally believed to be known.[5] A third, small group of clean surfaces undergoes *displacive phase transitions* in which the surface atoms are only slightly displaced from their bulk lattice positions to form a new structure at low temperatures. These transitions are reversible, but whether they are order-order or order-disorder transitions remains to be determined. One proposed mechanism for displacive transitions is that a soft surface phonon mode drives surface atoms into new positions which have slightly lower electronic energy. The only examples of displacively reconstructed surfaces are W(100) and Mo(100).[5]

When a molecule impinges on a surface, many events are possible.[1,3,4] The molecule may be elastically reflected or inelastically scattered into new electronic or vibrational states. If the molecule is to be absorbed it must discard some of its initial energy. This can be accomplished by dissociation, by excitation of internal electronic or vibrational modes, and by interactions with phonons and electronic excitations in the substrate.

A molecule is said to be physically absorbed, or *physisorbed*, when no charge is transfered between it and the substrate; bonding is via weak van der Waals forces and the heat of adsorption is on the order of a few tenths of an electron volt. Adsorption of inert gases is an example of physisorption. Chemical adsorption, or *chemisorption*, occurs when charge is transferred onto or away from the adsorbing atom or molecule due to the formation of a chemical bond with the substrate. Bond energies are typically an electron volt or larger.

Segregation occurs when atoms reach the surface by diffusing from the substrate rather than impinging from the gas or liquid phase.

Theoretical descriptions of adsorption are very complex, and although many aspects of adsorption are understood qualitatively, complete general theories have not yet been developed.[6] This is partly because adsorption is an "intermediate coupling" problem with no obvious single physical parameter dominating the process. Furthermore, any theoretical treatment needs to be self-consistent, particularly in cases involving charge transfer and/or electronic screening.

When clean surfaces adsorb gases, the adsorbed atoms or molecules take on a variety of ordered structures. In their pioneering experiments, Davisson and Germer observed ordered surface impurities, probably carbon or oxygen, on a Ni(111) surface. In some cases, such as oxygen adsorption on aluminum or silicon, the surface layer has no long-range crystalline order. However, in many important cases where adsorbate-substrate bonds are strong, the adsorbed species form ordered overlayers which are in simple registery with the substrate. In these cases, the lattice of the ordered overlayer is built up from a *unit mesh*, analogous to the unit cell in bulk crystal structures, whose dimensions are simply related to those of the underlying substrate lattice. This type of overlayer is said to be *commensurate*.

If the interactions between the adsorbed species are stronger than those between the adsorbate and substrate, the overlayer unit mesh may not be simply related to that of the substrate but instead becomes *incommensurate*. In several cases, an adsorbate which is commensurate at low coverages becomes incommensurate as the coverage is increased beyond a critical value. The properties of the commensurate-incommensurate transition have been extensively investigated in recent years but are still hotly debated.[4]

Adsorbed atoms can form several phases as their coverage on the surface increases. These phases are analogous to the solid, liquid, and gas phases of a three-dimensional system and are typically characterized using a temperature vs. adsorbate coverage phase diagram. Oxygen adsorbed onto the (111) surface of nickel[7] is the most carefully characterized chemisorption system, and inert gases adsorbed on the graphite basal plane are the most extensively studied physisorption system.[1,4] Only a few complete phase diagrams of this type have been determined. However, they are extremely valuable for testing statistical mechanical descriptions of phase transitions in two dimensions[4] and more work is needed.

Many experimental methods have been used to determine surface structures. The methods can be divided into three groups according to the type of information obtained: (1) long-range order; (2) local geometry; (3) single atom resolution.

Low-energy electron diffraction (LEED) is the predominant technique for studies of long-range order. The size and shape of the unit mesh are readily obtained and in favorable cases atomic spacings can be determined with an accuracy of about 10%. Other techniques with sensitivity to long-range order include photo electron spectroscopy and atom diffraction

Recently, it has been demonstrated that x-ray diffraction and Rutherford backscattering of high-energy ions can be applied to structure determinations for both surfaces and interfaces.[8] This development promises to revolutionize surface crystallography because both x-ray diffraction and Rutherford backscattering are easier to interpret than techniques previously used.

The local geometry of an adsorbed atom or molecule can be determined from measurements of its vibrational mode using infrared absorption spectroscopy or high-resolution electron energy-loss spectroscopy. The angular distributions of ions which desorb during electron or photon irradiation yield similar information. Bond lengths can be extracted from the energy dependence of electron or photon absorption near absorption edges. Several of these techniques are particularly important for studies of absorption on amorphous or polycrystalline surfaces where diffraction methods are not useful. Such surfaces are technologically important, for example, as catalysts.

Two techniques make possible the observation of individual atoms on surfaces. These are field ion microscopy and high-resolution electron microscopy.[1] Field ion microscopy has been particularly valuable for studying diffusion on surfaces.

Real surfaces are not perfect. Both point defects, such as vacancies and impurities, and extended defects such as steps, dislocations, and grain boundaries are always present. These defects can act as sites for preferential adsorption, alter surface transport properties, and influence crystal growth.[1,3] Only the properties of ordered arrays of steps have been studied in any detail because such arrays can be observed by LEED. These experiments show that steps influence the work function, change the energy distribution of electronic states, alter absorption kinetics, affect catalytic processes which proceed via bond breaking reactions, and induce asymmetries in surface diffusion.

Surface composition and electronic properties are studied using various spectroscopic methods.[1] These include Auger electron spectroscopy, ultraviolet and X-ray photoelectron emission, and electron energy-loss spectroscopies. Other methods for determining surface compositions include ion sputtering and scattering, nuclear reactions, thermal desorption, and radioactive tracers.

Surface physics is an important subdiscipline of physics with tremendous technological applications. Although, our knowledge about the basic properties of surfaces has advanced significantly in recent years, our level of understanding remains crude compared to that in condensed matter physics. Thus, the field of surface physics will have a brilliant future with many exciting advances.

SURFACE TENSION

Surface tension results from the tendency of a liquid surface to contract. It is given by the tension σ across a unit length of a line on the surface of a liquid. The surface tension of a liquid depends on the temperature and diminishes as temperature increases and becomes 0 at the critical temperature. For water σ is 0.073 newtons/m at 20°C, and for mercury it is 0.47 newtons/m at 18°C.

Surface tension is intimately connected with capillarity, that is, rise or depression of liquid inside a tube of small bore when the tube is dipped into the liquid. Another factor which is related to this phenomenon is the angle of contact. If a liquid is in contact with a solid and with air along a line, the angle θ between the solid-liquid interface and the liquid-air interface is called the angle of contact (Fig. 1). If $\theta = 0$, the liquid is said to wet the tube thoroughly. If θ is less than 90°, the liquid rises in the capillary, and if θ is greater than 90°, the liquid does not wet the solid but is depressed in the tube. For mercury on glass, the angle of contact is 140°, so that mercury is depressed when a glass capillary is dipped into mercury. The rise h of the liquid in the capillary is given by $h = 2\sigma \cos \theta / r\rho g$, where r is the radius of the tube, ρ the density of the liquid, and g is the acceleration due to gravity.

Surface tension can be explained on the basis of molecular theory. If the surface area of liquid is expanded, some of the molecules inside the liquid rise to the surface. Because a molecule inside a mass of liquid is under the forces of the surrounding molecules while a molecule on the surface is only partly surrounded by other molecules, work is necessary to bring molecules from the inside to the surface. This indicates that force must be applied along the surface in order to increase the area of the surface. This force appears as tension on the surface and when expressed as tension per unit length of a line lying on the surface, it is called the surface tension of the liquid.

The molecular theory of surface tension has been dealt with since the time of Laplace (1749–1827). As a result of the clarification of the nature of intermolecular forces by quantum mechanics and of the recent development in the study of molecular distribution in liquids, the nature and the value of surface tension have come to be understood from a molecular point of view.

Surface tension is closely associated with a sudden but continuous change in the density from the value for bulk liquid to the value for the gaseous state in traversing the surface (Fig. 2). As a result of this inhomogeneity, the stress across a strip parallel to the boundary—p_N per unit area—is different from that across a strip perpendicular to the boundary—p_T per unit area. This is in contrast with the case of homogeneous fluid in which the stress across any elementary plane has the same value regardless of the direction of the plane.

The stress p_T is a function of the coordinate z, the z-axis being taken normal to the surface and directed from liquid to vapor. The stress p_N is constant throughout the liquid and the vapor. The figure shows the stress p_N and p_T.

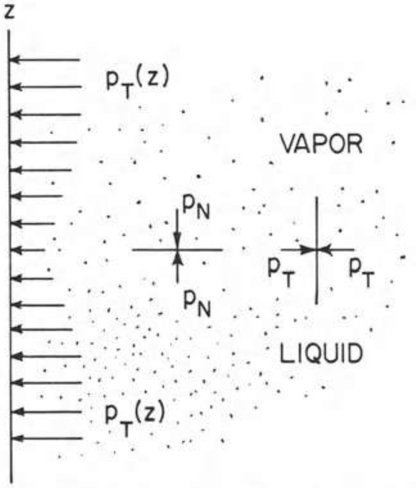

FIG. 2. Stress relationships in surface tension.

The stress $p_T(z)$ as function of z is also shown on the left side of the figure.

The surface tension is given by integrating the difference $p_N - p_T(z)$ over z:

$$\sigma = \int_{(\text{liquid})}^{(\text{vapor})} [p_N - p_T(z)]\, dz$$

A statistical mechanical treatment of the system leads to the expression of p_N and p_T in terms of intermolecular forces, density distribution, and the distribution of other molecules around a molecule which is located at a position z. The

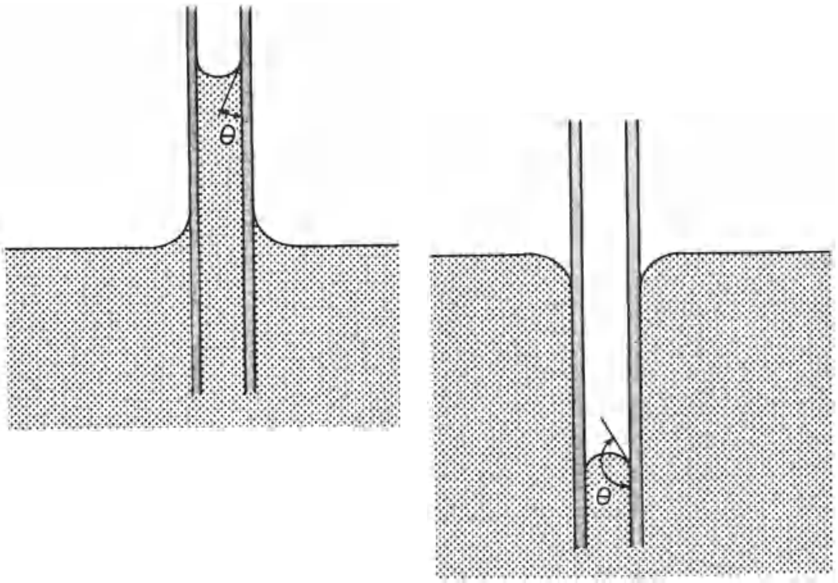

FIG. 1. Capillarity.

change of the number density and the distribution of other molecules around a central molecule at z are problems which have not yet been completely solved. Some simplifying assumptions such as to assume the transition layer to be a mathematical surface of density discontinuity have made the theory more amenable to numerical calculations. However, in spite of attempts by various authors, agreement between theoretical and observed values has not yet been attained.

SYMBOLS, UNITS, AND NOMENCLATURE IN PHYSICS

Introduction International communication and cooperation in science continue to grow in importance. Not the least important aspect of this cooperation is uniformity of international usage of symbols, units, and nomenclature in physics. The proliferation of research in countries throughout the world makes the problem of uniformity of usage a vital one in the dissemination of scientific literature, for it is obvious that much time and effort can be wasted in misunderstandings arising from terminology.

The recommendations given here are primarily those of the Commission on Symbols, Units and Nomenclature of the International Union of Pure and Applied Physics* as approved by the General Assemblies of IUPAP, 1960–1972. There is agreement on these recommendations among the following international organizations:

(1) International Organization for Standardization;
(2) General Conference on Weights and Measures;
(3) International Union of Pure and Applied Chemistry;
(4) International Electrotechnical Commission, Technical Committees 24, 25;
(5) International Commission on Illumination.

Physical Quantities—General Recommendations A physical quantity, represented by a symbol, is equivalent to the product of a *numerical value* and a *unit*. For dimensionless physical quantities, the unit often has no name or symbol and is not explicitly indicated.

EXAMPLES:

$$E = 200 \text{ J} \qquad n_{\text{qu.}} = 1.55$$

$$F = 27 \text{ N} \qquad f = 3 \times 10^8 \text{ Hz}$$

Symbols for Physical Quantities—General Rules. (1) *Symbols for physical quantities* should be *single letters* of the Latin or Greek alphabet with or without modifying signs: subscripts, superscripts, dashes, etc.

REMARK: (a) An exception to this rule consists of the two-letter symbols, which are sometimes used to represent dimensionless combinations of physical quantities. If such a symbol, composed of two letters, appears as a factor in a product, it is recommended to separate this symbol from the other symbols by a dot or by brackets or by a space.

(b) Abbreviations, i.e., shortened forms of names or expressions, such as p.f. for partition function should not be used in physical equations. These abbreviations in the text should be written in ordinary Roman type.

(2) *Symbols for physical quantities* should be printed in *italic* (i.e., sloping) *type*.

REMARK: Subscripts and superscripts should be in italic type when they are symbols for physical quantities or when they are running indices: e.g., C_p where p represents pressure but C_{g} where g means gas; F_{ik} where i and k are running indices but E_{k} where k means kinetic.

(3) *Symbols for vectors and tensors*: Special type fonts are recommended for these quantities but not for their components:

(a) Vectors should be printed in boldface type.

(b) Tensors of the second rank should be printed in sans serif type.

Simple Mathematical Operations. (1) *Addition and subtraction* of two physical quantities are indicated by

$$a + b \quad \text{and} \quad a - b$$

(2) *Multiplication* of two physical quantities may be indicated in one of the following ways:

$$ab \quad a\ b \quad a \cdot b \quad a \times b$$

REMARK: The various products of vectors and tensors may be written in the following ways:

Scalar product of vectors **A** and **B**: $\mathbf{A} \cdot \mathbf{B}$
Vector product of vectors **A** and **B**: $\mathbf{A} \times \mathbf{B}$

*UIP 11 (SUN 65-3), 1965.

Dyadic product of vectors **A** and **B**: **AB**
Scalar product of tensors S and T
($\Sigma_{ik} S_{ik} T_{ki}$) $\mathsf{S} : \mathsf{T}$
Tensor product of tensors S and T
($\Sigma_k S_{ik} T_{kl}$) $\mathsf{S} \cdot \mathsf{T}$
Product of tensor S and vector **A**
($\Sigma_k S_{ik} A_k$) $\mathsf{S} \cdot \mathbf{A}$

(3) *Division* of one quantity by another quantity may be indicated in one of the following ways:

$$\frac{a}{b} \quad a/b \quad a\,b^{-1} \quad a(1/b)$$

These procedures can be extended to cases where one of the quantities or both are themselves products, quotients, sums or differences of other quantities

If necessary, brackets have to be used in accordance with the rules of mathematics.

If the solidus is used to separate the numerator from the denominator and if there is any doubt where the numerator starts or where the denominator ends, brackets should be used.

EXAMPLES:

Expressions with a Horizontal bar	Same Expressions with a Solidus
$\frac{a}{bcd}$	a/bcd
$\frac{2}{9}\sin kx$	$(2/9)\sin kx$
$\frac{1}{2}RT$	$(1/2)RT$ or $RT/2$
$\frac{a}{b} - c$	$a/b - c$
$\frac{a}{b - c}$	$a/(b - c)$
$\frac{a - b}{c - d}$	$(a - b)/(c - d)$
$\frac{a}{c} - \frac{b}{d}$	$a/c - b/d$

REMARK: It is recommended that in expressions like:

$$\sin\{2\pi(x - x_0)/\lambda\}, \qquad \exp\{(r - r_0)/\sigma\},$$
$$\exp\{-V(r)/kT\}, \sqrt{(\epsilon/c^2)}$$

the argument should always be placed between brackets, except when the argument is a simple product of two quantities, e.g., sin *kx*. When the horizontal bar above the square root is used no brackets are needed.

Units—General Recommendations *Symbols for Units—General Rules.* (1) *Symbols for units* of physical quantities should be printed in *roman* (upright) *type.*

(2) *Symbols for units* should not contain a final full stop and should remain unaltered in the plural, e.g., 7 cm and *not* 7cms.

(3) *Symbols for units* should be printed in *lower case* roman (upright) type. However, the symbol for a unit, derived from a proper name, should start with a capital roman letter, e.g., m (meter); A (ampere); Wb (weber); Hz (hertz).

Mathematical Operations. (1) *Multiplication* of two units may be indicated in one of the following ways:

newton meter: $\mathrm{N \cdot m}$ (preferred), $\mathrm{N\ m}$

(2) *Division* of one unit by another unit may be indicated in one of the following ways:

$$\text{meter per second: } \frac{\mathrm{m}}{\mathrm{s}},\ \mathrm{m/s},\ \mathrm{m\,s^{-1}}$$

or by any other way of writing the product of m and $\mathrm{s^{-1}}$. Not more than one solidus should be used, e.g., not J/K/mol, but J/K · mol.

Numbers and Figures (1) *Numbers* should be printed in *upright type.*

(2) *Division* of one number by another number may be indicated in the following ways:

$$\frac{136}{273.15} \qquad 136/273.15$$

or by writing it as the product of numerator and the inverse first power of the denominator. In such cases, the number under the inverse power should always be placed between brackets.

REMARK: When the solidus is used and when there is any doubt where the numerator starts or the denominator ends, brackets should be used, as in the case of physical quantities.

(3) To facilitate the reading of large numbers, the figures may be grouped in *groups of three,* but no comma should be used, since European convention uses the comma as a decimal point.

EXAMPLE:

2 573 421 736.01

Symbols for Chemical Elements, Nuclides, and Particles (1) *Symbols for chemical elements* should be written in *roman* (upright) *type.* The symbol is not followed by a full stop.

EXAMPLES:

Ca C H He

(2) A nuclide is specified by the chemical symbol and the mass number, which should appear as a left superscript, e.g., $^{14}\mathrm{N}$. The atomic number may be shown too as a left subscript, e.g., $_7^{14}\mathrm{N}$, if needed. The right superscript position may be used to indicate a state of ioniza-

tion, e.g., Ca^{2+}, OH^-, or a state of excitation, e.g., $^{110}Ag^m$, $^4He^*$. The right subscript position is used to indicate the number of atoms of the specified nuclide or chemical element in a molecule, e.g., H_2SO_4.

(3) Symbols for particles and quanta

neutron	n
triton	t
leptons	e (electron), ν (neutrino), μ (muon)
mesons	π (pion), K, η
baryons	$\Lambda, \Sigma, \Xi, \Omega$
proton	p
helion	h
α-particle	α
deuteron	d
photon	γ

The charge of particles may be indicated by adding the superscript +, −, or 0.

EXAMPLES:

$$\pi^+, \pi^-, \eta^0, p^+, p^-, e^+, e^-$$

If in connection with the symbols p and e no charge is indicated, these symbols should refer to the positive proton and the negative electron respectively. The bar or tilde above the symbol of a particle is ofted used to indicate the antiparticle of that particle (e.g., $\bar{\nu}$ for antineutrino).

Quantum States (1) A symbol indicating the quantum state of a *system* such as an atom should be printed in capital roman (upright) type. The right subscript indicates the total angular momentum quantum number, and the left superscript indicates the multiplicity.

EXAMPLE:

$$^2P_{3/2}(J = \frac{3}{2}, \text{spin-multiplicity: } 2)$$

(2) A symbol indicating the quantum state of a single *particle* such as an electron should be printed in lower-case roman (upright) type. The right subscript may be used to indicate the total angular momentum quantum number of the particle.

EXAMPLE:

$$p_{3/2}(\text{electron state})$$

(3) The letter symbols corresponding to the *angular momentum quantum numbers* should be:

0	S, s	4	G, g	8	L, l
1	P, p	5	H, h	9	M, m
2	D, d	6	I, i	10	N, n
3	F, f	7	K, k	11	O, o

Nomenclature (1) *Use of the words specific and molar.* The word "specific" in English names for physical quantities should be restricted to the meaning "divided by mass."

EXAMPLES:

Specific volume	volume/mass
Specific energy	energy/mass
Specific heat capacity	heat capacity/mass

The word "molar" in the name of an extensive physical quantity should be restricted to the meaning "divided by amount of substance."

EXAMPLE

molar volume	volume/amount of substance

(2) *Notation for covariant character of coupling:*

S	Scalar coupling	A	Axial vector coupling
V	Vector coupling	P	Pseudoscalar coupling
T	Tensor coupling		

(3) *Abbreviated notation for a nuclear reaction.* The meaning of the symbolic expression indicating a nuclear reaction should be the following:

$$\begin{array}{c}\text{Initial}\\ \text{nuclide}\end{array}\left(\begin{array}{cc}\text{incoming} & \text{outgoing}\\ \text{particle} & \text{particle(s)}\\ \text{or} & \text{or}\\ \text{quantum} & \text{quanta}\end{array}\right)\begin{array}{c}\text{Final}\\ \text{nuclide}\end{array}$$

EXAMPLES:

$$^{14}N(\alpha, p)^{17}O \qquad ^{59}Co(n, \gamma)^{60}Co$$

$$^{23}Na(\gamma, 3n)^{20}Na \qquad ^{31}P(\gamma, pn)^{29}Si$$

(4) *Character of transitions.* Multipolarity of transition:

Electric or magnetic monopole	E0 or M0
Electric or magnetic dipole	E1 or M1
Electric or magnetic quadrupole	E2 or M2
Electric or magnetic octupole	E3 or M3
Electric or magnetic 2^n pole	En or Mn

(5) *Nuclide:* A species of *atoms*, with specified atomic number and mass number should be indicated by the word *nuclide*, not by the word isotope.

Different nuclides having the same atomic number should be described as *isotopes*.

Different nuclides having the same mass number should be described as *isobars*.

SI Units The General Conference on Weights and Measures, to which the United States adheres by treaty, has established the International System of Units, called SI units. The seven base quantities of this system and the corresponding units and their symbols are:

length	meter	m
mass	kilogram	kg

time	second	s
electric current	ampere	A
thermodynamic temperature	kelvin	K
luminous intensity	candela	cd
amount of substance	mole	mol

The coherent SI unit system consists of the above units plus all of the units derived from them by multiplication and division without introducing numerical factors. The units radian (rad) for plane angle and steradian (sr) for solid angle have historically been designated as supplementary units. In 1980, the International Committee for Weights and Measures determined that angle and solid angle are to be regarded as dimensionless derived quantities. The units radian and steradian are equivalent to the number one (1) and may be omitted in the expressions for derived units or used as a reminder of the role of angle or solid angle in the physical quantities.

A number of derived units have been given special names and symbols.

Quantity	Name of SI Derived Unit	Symbol	Expressed in Terms of SI Base or Derived Units
frequency	hertz	Hz	$1 \text{ Hz} = 1 \text{ s}^{-1}$
force	newton	N	$1 \text{ N} = 1 \text{ kg} \cdot \text{m/s}^2$
pressure and stress	pascal	Pa	$1 \text{ Pa} = 1 \text{ N/m}^2$
work, energy, quantity of heat	joule	J	$1 \text{ J} = 1 \text{ N} \cdot \text{m}$
power	watt	W	$1 \text{ W} = 1 \text{ J/s}$
quantity of electricity	coulomb	C	$1 \text{ C} = 1 \text{ A} \cdot \text{s}$
electromotive force, potential difference	volt	V	$1 \text{ V} = 1 \text{ W/A}$
electric capacitance	farad	F	$1 \text{ F} = 1 \text{ A} \cdot \text{s/V}$
electric resistance	ohm	Ω	$1\ \Omega = 1 \text{ V/A}$
electric conductance	siemens	S	$1 \text{ S} = 1\ \Omega^{-1}$
flux of magnetic induction, magnetic flux	weber	Wb	$1 \text{ Wb} = 1 \text{ V} \cdot \text{s}$
magnetic flux density, magnetic induction	tesla	T	$1 \text{ T} = 1 \text{ Wb/m}^2$
inductance	henry	H	$1 \text{ H} = 1 \text{ V} \cdot \text{s/A}$
luminous flux	lumen	lm	$1 \text{ lm} = 1 \text{ cd} \cdot \text{sr}$
illuminance	lux	lx	$1 \text{ lx} = 1 \text{ lm/m}^2$

Decimal multiples of the coherent base and derived SI units are formed by attaching to these units the following prefixes.

Factor by which the Unit is Multiplied	Prefix Name	Prefix Symbol
10^{18}	exa	E
10^{15}	peta	P
10^{12}	tera	T
10^{9}	giga	G
10^{6}	mega	M
10^{3}	kilo	k
10^{2}	hecto	h
10	deca	da
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f
10^{-18}	atto	a

The symbol of a prefix forms, with the unit symbol to which it is directly attached, a compound symbol which may have a positive or negative exponent, and which may be combined with other unit symbols. Thus:

$$1 \text{ cm}^3 = (10^{-2} \text{ m})^3 = 10^{-6} \text{ m}^3 \neq 10^{-2} \text{ m}^3$$

$$1 \text{ C} \cdot \mu\text{s}^{-1} = 1 \text{ C}(10^{-6} \text{ s})^{-1} = 10^6 \text{ C/s}.$$

Note 1. Because the base unit kilogram contains the prefix "kilo," the other prefixes are attached to the name "gram," e.g., milligram (mg) instead of microkilogram (μkg).

Note 2. Compound prefixes should not be used, e.g., use nanometer (nm) and not millimicrometer (mμm).

There are additional units, not part of the coherent system, which are generally accepted for use with the SI units or accepted for use in special fields.

The following units are accepted by the International Committee of Weights and Measures for use with the SI units for a limited transitional period: angstrom ($1 \text{ Å} = 10^{-10} \text{ m}$), barn ($1 \text{ b} = 10^{-28} \text{ m}^2$), bar ($1 \text{ bar} = 10^5 \text{ Pa}$), standard atmosphere ($1 \text{ atm} = 101\,325 \text{ Pa}$), curie ($1 \text{ Ci} = 3.7 \times 10^{10} \text{ s}^{-1}$), roentgen ($1 \text{ R} = 2.58 \times 10^{-4} \text{ C/kg}$), rad ($1 \text{ rad} = 10^2 \text{ J/kg}$).

Other Unit Systems The cgs system of units, based on the centimeter, gram, and second, as

Quantity	Name of Unit	Unit Symbol	Magnitude in SI Units
time	minute	min	60 s
	hour	h	3600 s
	day	d	86400 s
plane angle	degree	°	$\pi/180$ rad
	minute	′	$\pi/10\,800$ rad
	second	″	$\pi/648\,000$ rad
volume	liter	L	1 L = 1 dm^3
mass	tonne	t	1 t = 10^3 kg
energy	electronvolt	eV	approx. 1.60219×10^{-19} J
mass of an atom	atomic mass unit	u	approx. 1.66053×10^{-27} kg
length	astronomical unit	AU	$149\,600 \times 10^6$ m
	parsec	pc	approx. $30\,857 \times 10^{12}$ m

units in mechanics, is a metric system which continues to be used in some branches of physics. In daily life the customary units in the United States are those based on the foot, pound-force, and second, but these units are almost never used in physics except for the description of equipment, e.g., a 2-inch pipe.

Symbols and Units for Physical Quantities The table below provides an extensive but not exhaustive list of physical quantities with recommended symbols and with the symbol for the SI unit of each quantity. It is understood that deviations from the recommended quantity symbols may sometimes be necessary or desirable. On the other hand, the unit symbols are *standard* symbols for the units they represent, although other units with other symbols may, of course, be used.

Table of Symbols for Physical Quantities

Quantity	Symbol	International Symbol for Unit
SPACE AND TIME		
length	l	m
breadth	b	m
height	h	m
radius	r	m
diameter: $d = 2r$	d	m
path: $L = \int \mathrm{d}s$	L, s	m
area	A, S	m^2
volume	$V, (v)$	m^3
plane angle	$\alpha, \beta, \gamma, \theta, \vartheta, \phi$	rad
solid angle	ω, Ω	sr
wave length	λ	m
wave number: $\sigma = 1/\lambda$	σ	m^{-1}
circular wave number: $k = 2\pi/\lambda$	k	m^{-1}
time	t	s
period	T	s
frequency: $\nu = 1/T$	ν, f	Hz
circular frequency: $\omega = 2\pi\nu$	ω	s^{-1}
velocity: $v = \mathrm{d}s/\mathrm{d}t$	c, u, v	m/s
angular velocity: $\omega = \mathrm{d}\phi/\mathrm{d}t$	ω	rad/s
acceleration: $a = \mathrm{d}v/\mathrm{d}t$	a	$\mathrm{m/s}^2$
angular acceleration: $\alpha = \mathrm{d}\omega/\mathrm{d}t$	α	$\mathrm{rad/s}^2$
gravitational acceleration	g	$\mathrm{m/s}^2$
standard gravitational acceleration	g_n	$\mathrm{m/s}^2$
speed of light in vacuum	c	m/s
relative velocity: v/c	β	
MECHANICS		
mass	m	kg
density: $\rho = m/V$	ρ	$\mathrm{kg/m}^3$

Quantity	Symbol	International Symbol for Unit
MECHANICS (*Cont.*)		
reduced mass	μ	kg
momentum: $p = mv$	$\mathbf{p}, p$	kg · m/s
moment of inertia: $I = \int r^2 \, \mathrm{d}m$	I, J	kg · m^2
force	$\mathbf{F}, f$	N
weight	G, W	N
moment of force	$\mathbf{M}, M$	N · m
pressure	p	Pa
normal stress	σ	Pa
shear stress	τ	Pa
gravitational constant: $F(r) = Gm_1m_2/r^2$	G	N · m^2/kg^2
modulus of elasticity, Young's modulus: $\sigma = E\Delta l/l$	E	N/m^2
shear modulus: $\tau = G \mathrm{tg}\, \gamma$	G	N/m^2
compressibility: $\kappa = -(1/V)\mathrm{d}V/\mathrm{d}p$	κ	m^2/N
bulk modulus: $K = 1/\kappa$	K	N/m^2
viscosity	η	Pa · s
kinematic viscosity: $\nu = \eta/\rho$	ν	m^2/s
friction coefficient	f	—
surface tension	γ, σ	N/m
energy	E, U	J
potential energy	V, E_p	J
kinetic energy	T, E_k	J
work	W, A	J
power	P	W
efficiency	η	—
Hamiltonian function	H	J
Lagrangian function	L	J
relative density	d	—
MOLECULAR PHYSICS		
number of molecules	N	
number density of molecules: $n = N/V$	n	m^{-3}
Avogadro's constant	$N_0, (L)$	mol^{-1}
molecular mass	m	kg
molecular velocity vector with components	$\mathbf{c},(c_x, c_y, c_z)$	m/s
	$\mathbf{u},(u_x, u_y, u_z)$	m/s
molecular position vector with components	$\mathbf{r},(x, y, z)$	m
molecular momentum vector with components	$\mathbf{p},(p_x, p_y, p_z)$	kg · m/s
average speed	$\bar{c}, \bar{u}$	m/s
most probable speed	$\hat{c}, \hat{u}$	m/s
mean free path	l	m
molecular attraction energy	ϵ	J
interaction energy between molecules i and j	ϕ_{ij}, V_{ij}	J
velocity distribution function: $n = \int f \, \mathrm{d}c_x \mathrm{d}c_y \mathrm{d}c_z$	$f(c)$	—
generalized coordinate	q	—
generalized momentum	p	—
volume in γ phase space	Ω	—
Boltzmann's constant	k	J/K
$1/kT$ in exponential functions	β	J^{-1}
gas constant per mole	R	J/mol · K
partition function	Q, Z	—
diffusion coefficient	D	m^2/s
thermal diffusion coefficient	D_{T}	m^2/s
thermal diffusion ratio	K_{T}	—
thermal diffusion factor	α_{T}	—
characteristic temperature	Θ	K

Quantity	Symbol	International Symbol for Unit
MOLECULAR PHYSICS (*Cont.*)		
Debye temperature: $\Theta_D = h\nu_D/k$	Θ_D	K
Einstein temperature: $\Theta_E = h\nu_E/k$	Θ_E	K
rotational temperature: $\Theta_r = h^2/8\pi^2 Ik$	Θ_r	K
vibrational temperature: $\Theta_v = h\nu/k$	Θ_v	K
THERMODYNAMICS		
quantity of heat	Q	J
work	W, A	J
temperature	$t, (\vartheta)$	K
thermodynamic temperature	$T, (\Theta)$	K
entropy	S	J/K
internal energy	U	J
Helmholtz function: $F = U - TS$	F, A	J
enthalpy: $H = U + pV$	H	J
Gibbs function: $G = U + pV - TS$	G	J
linear expansion coefficient	α_l	K^{-1}
cubic expansion coefficient	α, γ	K^{-1}
thermal conductivity	λ	$W/m \cdot K$
specific heat capacity	c_p, c_v	$J/kg \cdot K$
heat capacity	C_p, C_v	J/K
Joule-Thomson coefficient	μ	$K \cdot m^2/N$
ratio of specific heats	γ, κ	–
ELECTRICITY AND MAGNETISM		
quantity of electricity	Q	C
charge density	ρ	C/m^3
surface charge density	σ	C/m^2
electric potential	V, Φ	V
electric field strength	$\mathbf{E}, E$	N/C, V/m
electric displacement	$\mathbf{D}, D$	C/m^2
capacitance	C	F
permittivity: $\epsilon = D/E$	ϵ	F/m
permittivity of vacuum	ϵ_0	F/m
relative permittivity: $\epsilon_r = \epsilon/\epsilon_0$	ϵ_r	–
dielectric polarization: $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$	$\mathbf{P}, P$	C/m^2
electric susceptibility	χ_e	–
polarizability	α, γ	$C \cdot m^2/V$
electric dipole moment	$\mathbf{p}, p$	$C \cdot m$
electric current	I	A
electric current density	j, J	A/m^2
magnetic field strength	$\mathbf{H}, H$	A/m
magnetic induction	$\mathbf{B}, B$	T
magnetic flux	Φ	Wb
permeability: $\mu = B/H$	μ	H/m
permeability of vacuum	μ_0	H/m
relative permeability: $\mu_r = \mu/\mu_0$	μ_r	–
magnetization: $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$	$\mathbf{M}, M$	A/m
magnetic susceptibility	χ_m	–
electromagnetic moment	$\boldsymbol{\mu}, \mu, \mathbf{m}, m$	$A \cdot m^2$
magnetic polarization: $\mathbf{B} = \mu_0 \mathbf{H} + \mathbf{J}$	$\mathbf{J}$	T
magnetic dipole moment	$\mathbf{j}, j$	$Wb \cdot m$
resistance	R	Ω
reactance	X	Ω
impedance: $Z = R + iX$	Z	Ω
admittance: $Y = 1/Z = G + iB$	Y	S
conductance	G	S
susceptance	B	S
resistivity	ρ	$\Omega \cdot m$

Quantity	Symbol	International Symbol for Unit
ELECTRICITY AND MAGNETISM (*Cont.*)		
conductivity: $1/\rho$	γ, σ	S/m
self-inductance	L	H
mutual inductance	M, L_{12}	H
phase number	m	–
loss angle	δ	rad
number of turns	N	–
power	P	W
Poynting vector	$\mathbf{S}, S$	W/m^2
magnetic vector potential	$\mathbf{A}$	Wb/m
LIGHT, RADIATION		
quantity of light	$Q(Q_v)$	lm · s
luminous flux	$\Phi(\Phi_v)$	lm
luminous intensity	$I(I_v)$	cd
illuminance	$E(E_v)$	lx
luminance	$L, (L_v)$	cd/m^2
luminous exitance	M	lm/m^2
radiant energy	$Q, W, (Q_e)$	J
radiant flux	$\Phi, (P, \Phi_e)$	W
radiant intensity	$I, (I_e)$	W/sr
irradiance	$E, (E_e)$	W/m^2
radiance	$L, (L_e)$	$W/sr \cdot m^2$
radiant exitance	$M, (M_e)$	W/m^2
absorptance	$\alpha(\lambda)$	–
reflectance	$\rho(\lambda)$	–
transmittance	$\tau(\lambda)$	–
linear attenuation coefficient	μ	m^{-1}
linear absorption coefficient	a	m^{-1}
refractive index	n	–
Stefan-Boltzmann constant: $M = \sigma T^4$	σ	$W/m^2 \cdot K^4$
luminous efficacy: Φ_v/Φ_e	K	lm/W
luminous efficiency: K/K_{max}	V	–
ACOUSTICS		
velocity of sound	c	m/sec
sound energy flux	P	W
reflection factor	ρ	–
acoustic absorption factor: $1 - \rho$	$\alpha, (\alpha_a)$	–
transmisssion factor	τ	–
dissipation factor: $\alpha - \tau$	δ	–
loudness level	$L_N, (\Lambda)$	–
reverberation time	T	s
specific acoustic impedance	$Z_s, (W)$	$N \cdot s/m^3$
acoustic impedance	$Z_a, (Z)$	$N \cdot s/m^5$
mechanical impedance	$Z_m, (\omega)$	$N \cdot s/m$
ATOMIC AND NUCLEAR PHYSICS		
atomic number, proton number	Z	–
mass number	A	–
neutron number: $N = A - Z$	N	–
elementary charge	e	C
electron mass	m, m_e	kg
proton mass	m_p	kg
neutron mass	m_n	kg
meson mass	m_π, m_μ	kg
atomic mass	m_a	kg
(unified) atomic mass constant: $m_u = m_a(^{12}C)/12$	m_u	u
magnetic moment of atom or nucleus	μ	$A \cdot m^2$

Quantity	Symbol	International Symbol for Unit
ATOMIC AND NUCLEAR PHYSICS (*Cont.*)		
magnetic moment of proton	μ_p	$A \cdot m^2$
magnetic moment of neutron	μ_n	$A \cdot m^2$
magnetic moment of electron	μ_e	$A \cdot m^2$
Bohr magneton	μ_B	$A \cdot m^2$
Planck constant $\left(\frac{h}{2\pi} = \hbar\right)$	h	$J \cdot s$
principal quantum number	n, n_i	–
orbital angular momentum quantum number	L, l_i	–
spin quantum number	S, s_i	–
total angular momentum quantum number	J, j_i	–
magnetic quantum number	M, m_i	–
nuclear spin quantum number	I, J	–
hyperfine quantum number	F	–
rotational quantum number	J, K	–
vibrational quantum number	v	–
quadrupole moment	Q	m^2
Rydberg constant	R_∞	m^{-1}
Bohr radius: $a_0 = 4\pi\epsilon_0\hbar^2/m_e e^2$	a_0	m
fine structure constant: $\alpha = e^2/4\pi\epsilon_0\hbar c$	α	–
mass excess: $m_a - Am_u$	Δ	kg
mass defect	B	kg
packing fraction: Δ/Am_u	f	–
nuclear radius	R	m
nuclear magneton	μ_N	$A \cdot m^2$
g-factor of nucleus: $\mu = gI\mu_N$	g	–
gyromagnetic ratio: $\gamma = \mu/I\hbar$	γ	$A \cdot m^2/J \cdot s$
Larmor (circular) frequency	ω_L	s^{-1}
cyclotron (angular) frequency	ω_c	s^{-1}
level width	Γ	J
mean life	τ	s
reaction energy	Q	J
cross section	σ	m^2
macroscopic cross section	Σ	m^2
impact parameter	b	m
scattering angle	$\vartheta, \theta, \varphi$	rad
particle flux density	φ	$s^{-1} \cdot m^{-2}$
particle fluence	Φ	m^{-2}
energy flux density	ψ	W/m^2
energy fluence	F	J/m^2
internal conversion coefficient	α	–
half-life	$T_{1/2}$	s
decay constant, disintegration constant	λ	s^{-1}
activity	A	s^{-1}
Compton wavelength; $\lambda c = h/mc$	λc	m
electron radius: $r_e = e^2/mc^2$	r_e	m
linear attenuation coefficient	μ, μ_l	m^{-1}
atomic attenuation coefficient	μ_a	m^2
mass attenuation coefficient	μ_m	m^2/kg
linear stopping power	S, S_l	J/m
atomic stopping power	S_a	$J \cdot m^2$
linear range	R, R_l	m
recombination coefficient	α	m^3/s
linear ionization by a particle	N_{il}	m^{-1}
total ionization by a particle	N_i	–
number of neutrons per fission	ν	–
number of produced neutrons per absorption	η	–
absorbed dose	D	J/kg
linear energy transfer	L	J/m

Quantity	Symbol	International Symbol for Unit
Chemical Physics		
amount of substance	n, ν	mol
molar mass of substance B	M_{B}	kg/mol
molar concentration of substance B	c_{B}	$\mathrm{mol/m^3}$
mole fraction of substance B	x_{B}	—
molar internal energy	$U_{\mathrm{m}}, (E_{\mathrm{m}})$	J/mol
mass fraction of substance B	w_{B}	—
molality of solute component B	m_{B}	mol/kg
chemical potential of component B	μ_{B}	J/mol
activity of component B	λ_{B}	—
relative activity	a_{B}	—
activity coefficient of component B	f_{B}	—
osmotic pressure	Π	Pa
osmotic coefficient	g, ϕ	—
stoichiometric number of component B	ν_{B}	—
affinity	A	J/mol
equilibrium constant	K_p	Pa
charge number of ion	z	—
Faraday constant	F	C/mol
ionic strength	I	mol/kg
fugacity of component B	f_{B}	Pa
electrolytic conductivity	σ, κ, γ	S/m
transport number	t	—
degree of dissociation	α	—

Letter Symbols and Letter Expressions for Mathematical Operations

These should be written in roman (upright) type

exponential of x	$\exp x$, e^x
base of natural logarithms	e
logarithm to the base *a* of *x*	$\log_a x$
natural logarithm of *x*	$\ln x$
common logarithm of *x*	$\lg x$, $\log x$
summation	Σ
product	Π
finite increase of *x*	Δx
variation of *x*	δx
total differential of *x*	$\mathrm{d}x$
function of *x*	$f(x)$, $\mathrm{f}(x)$
limit of $f(x)$	$\lim\limits_{x \to a} f(x)$

Trigonometric Functions

sine of *x*	$\sin x$
cosine of *x*	$\cos x$
tangent of *x*	$\tan x$
cotangent of *x*	$\cot x$
secant of *x*	$\sec x$
cosecant of *x*	$\operatorname{cosec} x$

REMARKS: (a) It is recommended to use for the *inverse trigonometric functions* the symbolic expressions for the corresponding trigonometric function preceded by the letters: arc.

EXAMPLES:

$$\arcsin x,\ \arccos x,\ \arctan x,\ \text{etc.}$$

(b) It is recommended to use for the *hyperbolic functions* the symbolic expressions for the corresponding trigonometric function, followed by the letter: h.

EXAMPLES:

$$\sinh x,\ \cosh x,\ \tanh x,\ \text{etc.}$$

(c) It is recommended to use for the *inverse hyperbolic functions* the symbolic expression for the corresponding hyperbolic function preceded by the letters: ar.

$$\operatorname{arsinh} x, \ \operatorname{arcosh} x, \ \text{etc.}$$

Complex Quantities

imaginary unit ($i^2 = -1$)	i, j
real part of z	$\mathrm{Re}\, z, z'$
imaginary part of z	$\mathrm{Im}\, z, z''$
modulus of z	$\lvert z\rvert$
argument of $z : z = \lvert z\rvert \exp i\varphi$	$\arg z, \varphi$
complex conjugate of z	$z^*, \tilde{z}$

Vector Calculus (see also p. 916)

absolute value of **A**	$\lvert\mathbf{A}\rvert, A$
differential vector operator	$\partial/\partial \mathbf{r}, \nabla$
gradient of φ	$\mathrm{grad}\, \varphi, \nabla\varphi$
divergence of **A**	$\mathrm{div}\, \mathbf{A}, \nabla \cdot \mathbf{A}$
curl of **A**	$\mathrm{curl}\, \mathbf{A}, \mathrm{rot}\, \mathbf{A}, \nabla \times \mathbf{A}$
Laplacian of φ	$\Delta\varphi, \nabla^2\varphi$
d'Alembertian of φ	$\Box\varphi$

Matrix Calculus

transpose of matrix A	$\tilde{A}_{ij} = A_{ji}$	$\tilde{A}$
complex conjugate of A	$(A^*)_{ij} = (A_{ij})^*$	A^*
Hermitian conjugate of A	$(A^\dagger{}_{ij}) = A_{ji}{}^*$	$A^\dagger$

Hugh C. Wolfe

SYNCHROTRON

The term synchrotron has come to mean "a ring shaped device for accelerating charged particles, e.g., electrons, protons, or heavier ions, to relativistic energies by the repeated passage of the particles, at essentially constant radius, through a time-varying electric field which alternates in direction at a fixed or variable frequency." Special examples are: (1) weak focusing synchrotrons, ie., constant gradient (CGS); (2) alternating-gradient synchrotrons (AGS); (3) fixed-field alternating-gradient synchrotrons (FFAG), or azimuthally varying-field synchrotrons (AVF); (4) separated-function, alternating-gradient synchrotron (SFAGS). All these machines have evolved from the early accelerators invented by E. O. Lawrence (cyclotron—1930), D. W. Kerst (betatron—1940), the synchronous acceleration principle discovered by E. M. McMillan and V. Veksler (1945), and the alternating-gradient strong focusing principle of Christofilos (1950), and Livingston, Courant and Snyder (1952); and the separated-function concept of M. G. White (1952) and T. Kitagaki (1953).

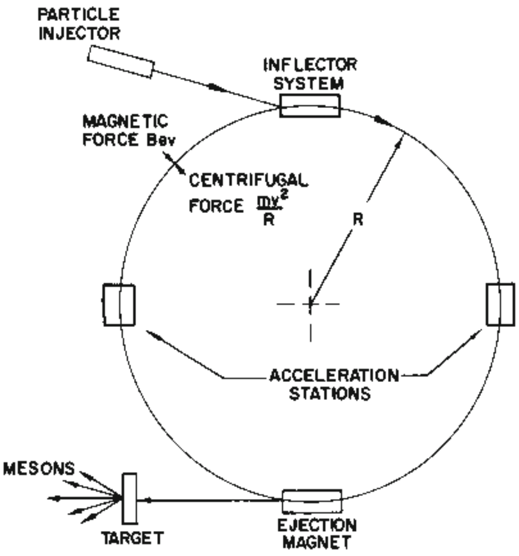

FIG. 1. Synchrotron.

There are basically six components or functions which a synchrotron must provide: (1) A source of particles, e.g., electrons or protons with energy and direction suitable for injection; (2) a vacuum chamber; (3) a magnet to bend particles in a circle; (4) focusing of particles; (5) acceleration of particles; (6) ejection of particles.

Ion Source Electrons or ions to be accelerated are generally produced in an external device by a hot cathode or a gaseous discharge and then, after being electromagnetically focused into a narrow pencil, they are accelerated up to several tens of MeV before injection into the synchrotron magnet gap. The optimum injector energy depends upon a number of factors, e.g., minimum magnet field strength at which the magnetic field shape will produce satisfactory focusing, space charge limitations, design of the radio-frequency acceleration system, and "inflection" problems associated with bending the particles into orbit. Generally speaking, a fairly high injector energy is preferred since most of the above problems are eased as the injector energy increases. Very close tolerances must be placed on the energy and angular spread of the injected beam; otherwise the particles will strike the walls of the vacuum chamber after only a few turns. Injector accelerators generally in use are: (1) Cockroft Walton (750 kV); (2) Van de Graaff (3 to 5 MeV); (3) linear accelerators (15 to 200 MeV).

Injection into extremely high energy synchrotrons, such as the 200/500 GeV National Accelerator Laboratory machine or the similar device now under design at CERN (Geneva, Switzerland), is accomplished in three steps: A 750 KeV Cockcroft-Walton, followed by a 200 MeV linear accelerator, followed by an 8 GeV, fast-cycling booster synchrotron which pulses at 15 Hz and injects into the final, separated-function synchrotron. The use of the intermediate booster synchrotron permits a smaller mag-

[a]Parameters listed for a given synchrotron do not necessarily occur simultaneously but represent maximum capabilities.

netic aperture in the final magnet and also raises the injection field to a level at which variations in remanent fields play no disturbing role.

Vacuum Chamber Since particles are scattered by collision with air molecules, it is necessary to provide a good vacuum over the entire region traversed by the particles while they are undergoing acceleration. The most critical period is when the particles are at low velocity, for then the Rutherford nuclear scattering and small angle atomic scattering are most probable. A vacuum of 10^{-6} mm of Hg is generally quite sufficient to reduce gas scattering losses to negligible proportions for electrons, protons, and deuterons.

For heavy ions, e.g., neon or heavier, the vacuum requirements are much more severe since the ion, if only partially ionized, can either lose or gain electrons by collisions with the residual gas and consequently be immediately lost to the walls. The dependence of beam attenuation on ion species, velocity, gas pressure, and synchrotron parameters is quite complex. As an example of the heavy ion vaccuum requirement, the Princeton Heavy Ion Synchrotron (see Table 1) successfully accelerated neon (Ne^{7+}) at a pressure of 4×10^{-8} Torr, but the beam was attenuated by a factor of 100. Calculations show that this synchrotron, at a pressure of 10^{-9} Torr, could accelerate any ion in any charge state with very little attenuation. A vacuum of even 10^{-10} Torr is now feasible.

In order that the vacuum chamber walls should not interfere with the magnetic field, or its space and time derivatives, it is necessary to employ either insulating walls of ceramic or laminated metal structures made vacuum tight by an outer skin of epoxy fibre glass. A thin-walled stainless steel pipe is satisfactory for slowly varying magnetic fields as in the Brookhaven synchrotron or the National Accelerator Laboratory final ring.

Bending A particle of rest mass m_0, charge $Z{\cdot}e$, and kinetic energy T, moving in a direction perpendicular to a magnetic field of B gauss, will move in a circle of radius R given by:

$$B \cdot R = \frac{1}{2.8Z}(T^2 + 2TE_0)^{1/2}$$

(kilogauss, meters, MeV)

where $E_0 = m_0c^2$, the rest energy of the particle. From this equation it can be seen that as the particle energy is increased from a very low initial energy to the final energy of several thousand MeV, the product $B \cdot R$ must increase manyfold. If B is held constant in time during the acceleration cycle and if the space average of B is also relatively constant, then R must increase with energy thus leading to the need for a very large radial aperture over which the field must be maintained. This is the case with cyclotrons. The radial aperture can be drastically reduced in either of two ways: (1) time modulate (e.g., pulse) the magnetic field so that it increases from a few tens or hundreds of gauss at ion injection time up to 10 to 20 kilogauss at which field the maximum particle energy is reached; (2) shape the magnetic field such that it increases sharply with increasing radius. The latter approach, while seemingly obvious, actually requires a very sophisticated angular and radial variation of the field in order to retain focusing in the direction parallel to the magnetic field. (It has been done by L. H. Thomas, 1938; Ohkawa, 1955; Kolomenskji, Petukhov, and Rabinovitch, 1955; Symon, 1955.) Accelerators .based on this time-independent but spatially varying field are generally referred to as FFAG or Spiral Sector Ring Accelerators. Their major utility appears to be in the field of high ion currents, which they can achieve by virtue of their non-pulsed character, but they appear to be practicable up to only a few thousand MeV of energy since they still require considerable radial aperture. By far the most widely exploited type of synchrotron is that first mentioned, i.e., the time-varying magnetic field, which holds the particles at an essentially constant radius while gaining energy. This technique, which leads to a simpler magnet design and a minimum of weight, will be described in detail in the remainder of this article.

Focusing A magnetic field which is perfectly uniform over the entire circular path of the particle and over the radial aperture leads to stable motion only for radial displacements of the particle. Particles displaced parallel to B (i.e., out of the orbit plane) are not refocused back on to the original circle and are quickly lost to the chamber walls. This can be readily understood by noting that motion parallel to B generates no $e\mathbf{V} \times \mathbf{B}$ force, and therefore such motion persists until the particle strikes the chamber walls. However, by deliberately introducing curved lines of force, it is possible to produce $e\mathbf{V} \times \mathbf{B}$ forces whose net effect results in restoring forces for all displacements from the ideal circular orbit. Oliphant's (1945) pioneering proton synchrotron in Manchester, England achieved weak focusing by employing a small, constant, radial *decrease* of magnetic field with *increasing* radius (constant-gradient synchrotron, GGS). Subsequent to the use of this principle in several large synchrotrons there has evolved a wide variety of field shapes which have a much stronger focusing action. All these strong-focusing fields are characterized by rapid spatial changes in the field strength, periodic reversal of sign of field gradients and even of the field itself. The most widely employed alternating gradient scheme is one in which a magnet sector that focuses *radially*, but defocuses *axially*, is followed by a sector which has the reverse property, i.e., *defocuses* radially and focuses axially. The net effect is strong focusing in *both* directions. There is a close analogy between alternating-gradient synchrotron focusing and an alternating series of convergent and divergent optical lenses whose net action is focusing. As a result of this arrangement of magnetic lenses, it is possible to use larger field gradients than in the weak-focusing case and thereby to achieve very strong focusing action. For example, an alternating-gradient 35 000-MeV accelerator, 560 feet in diameter, requires a vacuum chamber with a cross section of only 2.7 × 6 inches, whereas a weak-focusing, constant-gradient synchrotron would require at least ten times more aperture for equivalent performance.

The separated-function synchrotron (SFAGS) also employs alternating gradient focusing, but the bending function of the magnet is separate from the focusing. This is achieved by employing separate quadrupole and sextupole magnets for focusing only, while the bending magnets, having zero radial gradient, provide no focusing. The advantage of this separation lies in the possibility of achieving much higher bending fields than in a combined function magnet. For example, the National Accelerator Laboratory separated-function main ring is designed to operate at 22 kG whereas the usual AGS is limited to about 13 kG. The SFAGS principle also permits the exploitation of very high field, superconducting, iron-free bending magnets which do not lend themselves to the combined-function approach. Brookhaven National Laboratory is currently designing a superconducting, separated-function, combination intersecting storage ring and accelerator (ISA) which is to operate at 40 kG. Counter-rotating beams of 200 GeV protons will collide head-on releasing 400 GeV in the center-of-mass, or the equivalent of 80 000 GeV in a one-way machine with the target nucleus at rest.

Acceleration The increase in particle energy actually takes place when the circling charged particles pass through electric fields spaced around the circumference of the magnet. These fields must be time varying since a complete, repetitive traversal of a static field leads to zero energy gain. The usual arrangement is one in which the acceleration electrodes are excited by a sinusoidal voltage whose frequency is a harmonic (one to several thousand) of the particle rotation frequency and whose amplitude is such that particles can gain sufficient energy to match the rising magnetic field. Because of the principle of synchronous phase stability, discovered by McMillan and Veksler, particles with a wide spread in phase angle relative to the radio frequency are captured in stable "buckets" in phase space and are accelerated at just the correct rate, on the average, to stay in the middle of the vacuum chamber. Of course, the frequency of the accelerating field must be steadily and precisely increased as the particle rotation frequency increases. In some weak-focusing synchrotrons, this is one of the most difficult engineering tasks.

Electron synchrotrons pose special problems for the radio-frequency system. Because it is easy to inject electrons with a velocity very close to the velocity of light, the frequency of the required acceleration voltage is constant. This greatly simplifies the rf high voltage system and associated controls as compared with a proton synchrotron. However, a steep price is paid since relativistic electrons copiously radiate electromagnetic energy when traveling in a circle. [Radiation loss = $8.85 \times 10^4 (W^4/R)$ (eV/turn) where W is particle energy in GeV and R is magnet radius in meters.] For example, the Cornell electron synchrotron (see Table 1) radiates 20 MeV/turn at 12.0 GeV. This energy must be replaced by the rf cavities during each revolution in addition to increasing the kinetic energy of the electrons by a relatively small amount.

Ejection When the particles have been accelerated to full energy, they are caused either to run into an internal target or they are ejected by one of several schemes which usually involve exciting strong radial betatron oscillations with the last oscillation carrying the particles into an ejection magnet which deflects the beam clear of the synchrotron magnet structure.

In Table 1 are listed the important parameters of several typical existing synchrotrons. The principles discussed above for the separated-function, alternating-gradient synchrotron (SFAGS) are believed to be capable of extension to extremely high energy limited only by financial considerations. For protons and heavier particles, the electromagnetic radiation loss, which sets a practical limit for electron synchrotrons at about 60 GeV, will not be troublesome at any conceivable energy.

T

TELEMETRY

The terms telemetry and telemetering imply both distance and measurement, but beyond this there is not universal agreement regarding the use and meaning of the terms. The American Standards Association has defined telemetering as: "The measurement with the aid of intermediate means which permit the measurement to be interpreted at a distance from the primary detector." The distance involved may be anywhere from a few inches in the case of certain test projectiles to many millions of miles in the case of space probes to other planets. Other terms such as data transmission system or data link are frequently used. A distinction in terminology is sometimes made between the transmission of a measurement for observation and interpretation and the transmission of a measurement to directly govern a controlling action. In modern applications, the quantity transmitted may not be a measurement at all, but the result of some complex calculation based on numerous measurements over a time interval.

The dominant transmission means for telemetry has been electrical, and a few applications were already reported during the first half of the nineteenth century. During the latter half of the century, applications included regular transmission of meteorological and other measurements. During the early part of the twentieth century, there were extensive applications of telemetry in connection with the Panama Canal followed by applications in many other areas such as electrical power and pipeline distribution systems. Soon after 1930, telemetry through the transmission medium of radio links was in use for meteorological measurements from small unmanned balloons. Soon after 1940, the first radio telemetering systems for testing aircraft were being designed and used. This occurred in response to the need for more complete and reliable measurement during experimental flights of high-performance military aircraft than could be provided by onboard recorders and pilot's observations, sometimes lost. By 1945, radio telemetry was being used for measurements in the then small rockets, and before the end of the decade, telemetry carried by rocket vehicles was being used to investigate the upper reaches of the earth's atmosphere. In the 1950s, the development of advanced radio telemetering systems was spurred by the well-known rapid development of the field of rocket-propelled vehicles including, particularly, the development of ballistic missiles for military application.

In the 1960s there were developed and launched an increasing number of Earth satellites for both military and civilian application, all of which required radio telemetry. Civilian applications included communication, geophysics, meterology, oceanography, earth resources, and others. During this decade the manned space programs Mercury, Gemini, and Apollo came into being with their demanding radio telemetry requirements. Also during this decade came the first interplanetary probes with radio telemetry over distances measured in the hundreds of millions of miles. During the 1960s biomedical applications of radio telemetry developed rapidly, including "radio pills," implantable radio telemeters, and noninvasive patient monitoring.

It is sometimes convenient to divide telemetry applications into two areas which might be called operational and test. By operational we mean the application of telemetry as a permanent part of some system, in which case the telemeter must be compatible with the rest of the system in such aspects as cost, reliability, and maintainability. By test we mean the temporary application of telemetry to obtain test information during the developmental phase of some system, in which case the telemeter need not be completely compatible with the rest of the system.

Telemetry systems for industrial purposes tend to fall more under the operational area and formed the majority of applications before 1940. Industrial telemetering systems have been frequently characterized by modest requirements for speed of response and accuracy which fall well within the physical limitations of the transmission link (frequently wire circuits) and are therefore accomplished by rather straightforward and uncomplicated signal handling methods. On the other hand, these applications have been characterized by demanding requirements for low first cost and high reliability during long periods of unattended operation. Geophysical (including oceanographic) applications often have similar requirements. Industrial telemetry is well exemplified by the many thousands of telemeters in constant use by the electrical power industry throughout the world to measure electrical quantities and plant conditions.

The majority of aerospace telemetry during the 1940's and '50's was in the test area. Because of the destructive nature of tests and/or the difficulty in repeating them and because of the marginal nature of many of the aerospace systems, aerospace telemetry has been characterized by demanding requirements for speed of response, accuracy, and number of channels which are frequently not well within the physical limitations of the radio transmission link. This together with severe weight and space restrictions and difficult environmental conditions for equipment operation has resulted in a field of telemetry activity more or less separate from the industrial area. Much attention has been given to the statistical efficiency of signal processing in the presence of random errors of various kinds and to the specialized hardware techniques needed to satisfy space, weight, power supply, and environmental conditions. The advent of long-lived satellites and deep space probes, among many systems whose mission is wholly dependent on telemetered measurements, has greatly emphasized telemetry reliability considerations.

The deeper understanding of the nature of measurement and information that occurred shortly after World War II by application of statistical methods had its effect on the telemetering field even before the general communication field. In the beginning, the design and classification of telemetering systems tended to be in terms of the physical quantity measured, the physical quantities used for transmission and interpretation, and the transducers for conversion between these physical quantities, i.e., in terms of the hardware. Terms such as current, voltage, frequency, ratio, phase, impulse, etc., were and are used to describe some systems. Multiplexing (the transmission of many measurements over the same channel) was either frequency division (assignment of a frequency band to each measurement, non-overlapping with those of the others) or time division (assignment of a periodic time interval to each measurement, non-over-lapping with those of of the others).

The more recent statistical systems point of view in telemetry is concerned with *what* is done to the signal rather than *how* it is accomplished physically. From this point of view a telemetering system may do any or all of the following in logical sequence: (1) make a measurement; (2) abstract from the measurement in the form of a signal those characteristics which are needed for the eventual interpretation or decision; (3) store this signal; (4) code (modulate) this signal to give it greater immunity to the errors in the transmission link; (5) receive the signal; (6) store the signal; (7) decode (demodulate) the received signal to best preserve those characteristics which are needed for interpretation and decision; (8) store the result. A measurement is said to have been made on a system if after the measurement, the uncertainty regarding the quantitative state of the system is less than the uncertainty existing before the measurement. Uncertainty in the sense of information theory has an exact quantitative measure in terms of the probability distributions involved and can be replaced by a distortion or cost index when such a criterion is available. Similarly, a measurement is said to have been telemetered when there is a reduction in uncertainty or cost on the basis of the data produced by the telemetering system.

Radio telemetering systems use many methods of modulation in various combinations. These include amplitude, phase, frequency, pulse amplitude, pulse position, pulse duration, pulse frequency, and pulse code. Multiplexing is sometimes accomplished by more general orthogonal methods than frequency- and time-division. During the last decade aerospace telemetry has become predominantly digital, with the use of error-correcting block codes and convolutional codes in various combinations. The reason for this is twofold: (1) the very rapidly decreasing cost of electronic digital hardware, including microprocessors and dedicated designs; (2) the ease of encryption of digital signals to keep radio-telemetry transmissions private.

In the 1970s, although the applications of telemetry continued to grow rapidly and to embrace the rapidly developing electronic technology, the development of the general communications field caught up with the previously more sophisticated applications of communication principles by telemetry. The result has been a loss of visibility for telemetry as a special field; instead, it has tended to take a place as one of a number of applications in the communication field. For this reason, although a number of good books on telemetry appeared in the 1950s and '60s, there were none of general significance in the 1970s. An exception for a special area of application is given by Ref. 1. The most comprehensive of the books of the 1960s is probably Ref. 2. Many papers on telemetry and related matters up to the present time are to be found in the volumes of Ref. 3. Non-application-oriented communication theory and technology, although sometimes developed for telemetry, are now usually to be found in the general communication books and journals, often without reference to the telemetering application.

TEMPERATURE AND THERMOMETRY

Temperature is that attribute or state property which describes the thermodynamic state of a system and is a measure of the system's hotness, as expressed in terms of any of several arbitrary scales; it is an indicator of the direction in which energy will flow spontaneously when two bodies are brought into contact, i.e., from the hotter body (the one at a higher temperature) to the colder one (the one at a lower temperature). Temperature is not the equivalent of the total energy of a thermodynamic system; e.g., liquid water in thermal equilibrium with solid water (ice) has a greater energy per unit mass than the ice, although the two are at the *same* temperature. Temperature (like pressure and density) is an intensive property, i.e., it is independent of the quantity of matter, whereas properties such as mass and volume are extensive. Any device or system which has one or more physical properties (e.g., electrical resistance, electrical potential, pressure at constant volume or volume at constant pressure, length) that varies monotonically and reproducibly with temperature may be used to measure temperature; such a temperature measuring device is known as a *thermometer*. The science of temperature measurements is called *thermometry*. In the past, the science of the measurement of high temperature was known as pyrometry, but now that term usually refers to radiation thermometry at any temperature.

Temperature is one of the seven basic physical quantities of the International System (SI) of Units. All other physical quantities are defined in terms of these seven. Temperature measurement and control play a very important role in a wide variety of scientific, industrial, and domestic activities. Applications with which most people are familiar occur in medicine (patient and clinical laboratory), automobiles, heating and air conditioning, refrigeration, metallurgy, manufacturing, and electronics. Almost every household in the United States has at least one thermometer, whether it is a fever thermometer or is a thermostat on a furnace, air conditioner or kitchen range.

Temperature Scales A temperature scale is a system of assigning numerical values to temperatures. Scales are usually defined in terms of reproducible physical phenomena, such as the freezing and boiling points of water, to which temperature values are assigned, the subdivision of the interval between those defined points into units (e.g., degrees, kelvins), and by specifying the instruments for interpolating between the defining points.

Although sensitive thermometers were available by the middle of the 17th Century, no significant effort had been made to develop a universal temperature scale. Robert Hooke changed that situation in the 1660s, however, when he began divising a scale for his modified Florentine spirit thermometers. The scale he developed was based on equal increments of volume and used the freezing point of water as its starting point.

Gabriel Daniel Fahrenheit, a German instrument maker residing in Holland, was the first person to make reliable mercury-in-glass thermometers and the first to investigate the method of using two fixed points to construct a temperature scale, dividing the interval between the points into a convenient number of degrees. His scale (first proposed in 1714) was based on the lowest temperature obtainable with a freezing mixture of ice and salt as one fixed point, designated by him to be 0 degrees, and the temperature of the human body as the other, which he called 96 degrees. With this definition, he found the freezing point of water to be 32 degrees and its boiling point to be 212 degrees. Later, the freezing and boiling points of water became the defining fixed points of Fahrenheit's scale (as suggested by him in 1724).

The French physicist Guillaume Amontons proposed in 1688 that temperature could be defined as being directly proportional to the pressure of a fixed mass of gas contained in a constant volume, the lowest temperature which could exist corresponding to zero gas pressure. Only one fixed point (besides the absolute zero of temperature) would be needed then to define a scale.

Since the time of Amontons and Fahrenheit, there have been parallel developments of gas thermometry and of practical scales. The most common of these scales, which bear the name of their originators, were proposed by Fahrenheit in 1724, Rene Réaumur in 1730, Anders Celsius in 1742, William Thomson (later, Lord Kelvin; hence, the Kelvin scale) in 1848, and W. J. M. Rankine in 1850. Values on the Fahrenheit (°F), Réaumur (°Re), and Rankine (°R) scales are fixed by defining the freezing point of water as 32°F, 0°Re and 491.67°R and the boiling point of water (at one standard atmosphere) as 212°F, 80°Re, and 671.67°R, respectively. The Rankine scale is an absolute temperature scale with a degree of the same size as the degree on the Fahrenheit scale. The absolute zero is then 0°R or −459.67°F. The

Rankine (or absolute Fahrenheit) scale, defined by the relation $T(°\mathrm{R}) = t(°\mathrm{F}) + 459.67$, is one of the many possible thermodynamic scales. The Kelvin scale is a thermodynamic temperature scale and, as Thomson showed, is the same as the absolute scale based on the ideal-gas laws. In 1954, a thermodynamic temperature scale, with as unit the Kelvin (°K), was adopted by assigning a value of 273.16°K to the triple point of water. (The zero of the thermodynamic Celsius scale had already been adopted in 1948 as being 0.0100°C below that of the triple point of water.) The magnitude of the unit of temperature was thus defined as 1/273.16 of the thermodynamic temperature of that point. The choice of 273.16°K was made from a consideration of the results of measurements of the mean expansion coefficient of gases between 0°C and 100°C which led, after suitable correction for nonideal behavior, to an absolute zero of −273.15°C. For those measurements, the interval between the ice point and the steam point of water was taken to be 100°C exactly. Having made those measurements and defined the unit of temperature, the interval of exactly 100°C between the ice point and the steam point is no longer required or defined as such. In fact, recent primary gas thermometry results indicate that the Celsius thermodynamic temperature, in terms of this temperature unit, for the steam point is about 99.975°C. As suggested by Celsius, values on the Centigrade (°C) scale were based on the freezing point of water as 0°C and the boiling point of water as 100°C, an interval of 100°C exactly (hence, the term centigrade). The Celsius scale is defined in terms of the Kelvin scale: $t(°\mathrm{C}) = T(\mathrm{K}) - 273.15$ K. (The degree symbol ° was dropped from the symbol for Kelvin in 1968.) The size of the units of the Celsius and the Kelvin scales are the same.

For the scales named, the temperature interval between the freezing and the boiling points of water are divided into degrees, the number of them being 180°F, 80°Re, 180°R, 100°C and 100 K. The Fahrenheit scale has been discontinued everywhere except in the United States where its use is being phased out as the metric system is being adopted. The Rankine scale is still used to some extent in some aspects of engineering, e.g., in the calculation of the theoretical efficiency of engines. Apart from the limited use of these two scales, the only ones in use today are the Celsius and the Kelvin scales. The latter have been widely used in scientific work for many years.

Scale Conversions To convert a value of temperature on a given scale to that on another scale involves consideration of the size of the degree of each scale and of the temperature values of the scales' zeros. Some examples of conversions follow.

To convert a temperature value on the Celsius scale to that on the Kelvin scale, add 273.15. Conversely, to convert a temperature value from the Kelvin scale to the Celsius scale, subtract 273.15 from the value in kelvins. ($t(°\mathrm{C}) = T(\mathrm{K}) - 273.15$).

To convert a temperature value on the Fahrenheit scale to that on the Celsius scale, subtract 32 and multiply by $\frac{5}{9}$. Conversely, to convert a temperature value from the Celsius scale to that on the Fahrenheit scale, multiply by $\frac{9}{5}$ and then add 32. ($t(°\mathrm{F}) = \frac{9}{5}\,t(°\mathrm{C}) + 32$).

To convert a temperature value on the Kelvin scale to that on the Rankine scale, multiply by $\frac{9}{5}$. Conversely, to convert a value from the Rankine scale to that on the Kelvin scale, multiply by $\frac{5}{9}$. ($T(\mathrm{K}) = \frac{5}{9}\,T(°\mathrm{R})$).

To convert a temperature value on the Fahrenheit scale to that on the Rankine, add 459.67. Conversely, to convert a temperature value from the Rankine scale to that on the Fahrenheit scale, subtract 459.67. ($t(°\mathrm{F}) = T(°\mathrm{R}) - 459.67$).

To convert a temperature value on the Celsius scale to that on the Réaumur scale, multiply by $\frac{4}{5}$. Conversely, to convert a value on the Réaumur scale to one on the Celsius scale, multiply by $\frac{5}{4}$. ($t(°\mathrm{C}) = \frac{5}{4}\,t(°\mathrm{Re})$).

Other conversions among the scales can be performed by similar methods, or one can use the methods given above to convert a temperature value on one scale to that on a second scale, and then from that scale to a third scale, and so forth until the value on the desired scale is obtained.

The Ideal-Gas Temperature Scale Although there had been very little work on the properties of gases prior to about 1800, considerable progress was made in understanding gases in the 19th Century and the methods of gas thermometry continued to be improved during that period. It was found that the laws of the expansion of gases were much simpler than those of liquids and that very high precision was required to detect any difference in the expansion behavior of gases, excluding the easily condensable vapors. In 1847, H. Regnault showed that a gas thermometer could provide high precision in the range from 0°C to 100°C. Using such a thermometer, he showed that, although he could detect differences in the expansion coefficients of the easily condensable gases, he was unable to detect any difference in the expansion behavior of hydrogen and nitrogen, each having an expansion of about one part in 273 per degree *centigrade* (the constant-volume hydrogen thermometer later became the basis for a practical temperature scale). Later it was found that all gases at low pressures and at temperatures well above their critical temperatures had identical thermal behavior to within their accuracy of measurement, the pressure at constant volume and the volume at constant pressure for a given quantity of gas varying linearly with temperature (e.g., $v = v_0(1 + \alpha t)$, where v is the volume at temperature t°C, v_0 is the volume at 0°C, and α is the coefficient of thermal expansion). A mercury-in-glass thermometer calibrated on the Centigrade scale was generally used for the indication of temperature in those measurements. The coefficient of thermal expansion was determined to have a best value of $(1/273.15)°C^{-1}$, so that by extrapolation, the lowest possible temperature would be −273.15°C (the temperature at which the gas would have no volume). Consequently, −273.15°C is called the *absolute zero* of temperature. One should not take the statement of zero volume literally; it just means that at −273.15°C, all systems are in their ground states and no energy can be extracted from them. Some systems at or near absolute zero have what is referred to as *zero-point motion*. This is not a reservoir of energy which can be extracted, but is just a manifestation of the Heisenberg uncertainty principle.

By introducing the concept of *absolute temperature*, we may set up a new temperature scale based upon the behavior of ideal gases and avoid negative temperatures. Temperatures θ on that scale are given by $\theta = t(°C) + 1/\alpha = t(°C) + 273.15°C$. Through the use of θ, the general gas law (the law obeyed by an ideal gas) becomes

$$\frac{PV}{\theta} = \text{constant}.$$

This is the basis of the gas thermometer, and the scale on which the temperature θ is defined is the ideal-gas or absolute temperature scale. If either the pressure or the volume of a fixed quantity of gas is held constant, then the measurement of the other determines the temperature. No gas is ideal, however, so the gas thermometer is actually based on an approximately ideal gas and the assumption that the departures from ideality can be accurately measured and taken into account. By this means, the thermometer is made to be independent of the properties of real gases and becomes effectively ideal.

Thermodynamic Temperature Scale Since real gases don't behave *exactly* as ideal gases, gas thermometers using different principles of operation (constant volume or constant pressure) or different gases gave early experimenters somewhat different scales. Consequently, the need remained for a fundamental scale independent of the properties of the particular substance being used. In 1848, W. Thomson (later, Lord Kelvin) proposed such a scale based on the efficiency of an ideal reversible heat engine, which is dependent only on the limits of temperature between which it works. S. Carnot had described the ideal heat engine in 1824; its cycle consists of two isothermal and two adiabatic paths. Thomson's scale of thermodynamic temperature T was defined by the relation

$$-\frac{Q_1}{Q_2} = \frac{T_1}{T_2}$$

where Q_1 refers to the quantity (joules) of heat extracted from the hot reservoir at a temperature of T_1 and Q_2 refers to the quantity of heat returned to the cold reservoir at a temperature of T_2. T_1 and T_2 are the temperatures on the thermodynamic scale. If a perfect (ideal) gas (internal energy restriction is that $(\partial U/\partial V)_\theta = 0$, and equation of state is $PV = nR\theta$, where n is the number of moles of gas and R is the universal gas constant) is considered as the working substance in a Carnot cycle, then

$$-\frac{Q_1}{Q_2} = \frac{\theta_1}{\theta_2}.$$

Thus, the thermodynamic and the absolute, ideal gas, temperature scales are the same if the values are selected to be identical at one finite temperature. It is noteworthy that the universal gas constant R forms the link between energy and thermodynamic temperature; given Avogadro's number, the value of R has been determined solely by the arbitrary choice of the magnitude of the unit of temperature, the kelvin.

Statistical Mechanical Temperature Scale In the statistical mechanics of a many-particle system at equilibrium, there is a parameter that defines the state of the system which, when assumed to be temperature, permits the derivation of the laws of thermodynamics and, hence, confirms the validity of the assumption. The definition of the kelvin then determines the value of the Boltzmann constant, k (which with Avogadro's number, gives the gas constant R), and the statistical mechanical temperature is by definition equal to the thermodynamic temperature. Consequently, any temperature-dependent phenomenon, which can be exactly described by statistical mechanics, can be used (as a thermometer) to determine the thermodynamic temperature of the system. Four well-known examples of such phenomena are the distribution of radiant energy from a surface (obeying Planck's radiation law), the magnetic susceptibility of weak paramagnets (nuclear and electronic, obeying the Curie law) at temperatures high compared to their critical (magnetic ordering) temperatures, nuclear orientation (γ-ray anistropy being the most widely used technique) of magnetically (electronic) ordered systems at ultralow temperatures, and electrical noise in a resistor (obeying the Nyquist relation).

The Need for a Practical Temperature Scale Precision thermometry based on the thermodynamic temperature scale had its beginnings with the work of P. Chappuis and of H. L. Callendar during the period from the late 1880s to the early 1900s. Chappuis transferred the hydrogen (Centigrade thermodynamic) scale in the range from 0°C to 100°C, provided by his constant-volume hydrogen gas thermometer, to several carefully made mercury thermometers, constructed of French hard glass. These were then used to calibrate many other mercury thermometers which in turn were to be used in many countries to put temperature measurements on the same scale. The probable inaccuracy of those thermometers was stated to be 0.002°C. Callendar also developed a constant-volume gas thermometer which he used to calibrate a platinum resistance thermometer up to about 550°C. (W. Siemens had previously proposed the use of the electrical resistance of platinum as a thermometer.) The choice of platinum as a sensor was excellent as it has turned out to be the most stable and accurate thermometer available; indeed, it is now a standard instrument of the International Practical Temperature Scale (IPTS). Using the equations which he developed for expressing the relationship between the resistance of platinum and the temperature, Callendar determined the melting points of silver and gold by extrapolation.

In 1887, the Comité Internationale des Poids et Mesures (International Committee on Weights and Measures) (CIPM) adopted a resolution stating that the standard thermometric scale for the international service of weights and measures was to be the Centigrade scale of the hydrogen gas thermometer, having for fixed points the temperature of melting ice (0°C) and that of the vapor of boiling distilled water (100°C) under a pressure of one standard atmosphere.

Although gas thermometers could provide thermodynamic temperatures, they were cumbersome and unsuited for many applications. The more practical thermometers were mercury and platinum resistance thermometers, which were much more reproducible, simple to use, and generally provided a greater range of operation. Since thermodynamic temperatures are so difficult to measure accurately by gas thermometry and because of the increasing demands of science and technology, discussions, which were designed to lead to an agreement on an international practical scale covering as wide a temperature range as possible, were begun before World War I, discontinued during the war, and then held again in the 1920s. Some desired features of such a scale were that temperatures on the scale should agree as closely as possible with thermodynamic temperatures, that it should be precisely reproducible, and that it should be conveniently and accurately realizable. This would then give the users a single, internationally accepted basis for measurements which was in close agreement with the thermodynamic scale. The deliberations eventually led to the adoption of the first international temperature scale.

International Temperature Scales The needs as given above for a practical scale of temperature and the work on practical thermometry eventually led to the adoption of the International Temperature Scale of 1927 (ITS-27) by the 7th General Conference on Weights and Measures. That scale was based on the freezing point of water (0°C) and the boiling point of water (100°C), a fundamental interval of 100°C exactly, and on some fixed points outside this range. In the range of −190°C to 660°C of that scale, the platinum resistance thermometer was specified as the interpolation instrument; a Pt–10% Rh/Pt thermocouple was specified as the interpolation instrument for the range 660°C to 1063°C; for higher temperatures, an optical pyrometer was specified. As a consequence of improvements in measurements and techniques, the scale was revised and the revision adopted in 1948 by the 9th General Conference. The revised scale (called the ITS-48) was almost identical with the ITS-27 in form. The value of only one fixed point, the freezing point of silver, was changed, and that merely to make the scale more uniform. The zero of the thermodynamic Centigrade scale was adopted as being 0.0100°C below the triple point of water. Planck's radiation formula instead of Wien's formula was specified to make the scale consistent with the thermodynamic scale above the freezing point of gold. A new value of the second radiation constant, C_2, closer to that derived from atomic constants was also specified. Other changes were the specification of higher purity platinum for the standard resistance thermometers and thermocouples, and the recommendations for methods of realizing the fixed points. Additionally, the designation of the unit of temperature, the degree Centigrade, was replaced by the degree Celsius. By so doing, all temperature scales were then named after their originators.

Accepting the 1854 recommendation of Lord Kelvin that when a single fixed point was sufficiently stable, it would be preferable to define the scale using that one point, a redefinition of the Kelvin thermodynamic scale, unit of temperature being °K, was adopted in 1954 by the 10th General Conference, as already mentioned. The redefinition of the scale was accomplished by assigning a value of 273.16°K to the temperature of the triple point of water. The unit, °K, was defined as 1/273.16 of the thermodynamic temperature of that triple point. The zero of the thermodynamic Celsius scale was defined to be 0.01°C below the triple point.

In 1960, the 11th General Conference changed the name of the ITS-48 to the International Practical Temperature Scale of 1948 (IPTS-48); this was not a revision of the 1948 scale but merely a revision of its text. A list of the defining fixed points of the IPTS-48 is given in Table 1.

In order to have a scale that gave tempera-

TABLE 1. DEFINING FIXED POINTS OF IPTS-48*

Fixed Points	Temperature, °C
Temperature of equilibrium between liquid oxygen and its vapor (oxygen point)	−182.97
Temperature of equilibrium between ice, liquid water, and water vapor (triple point of water)	+0.01
Temperature of equilibrium between liquid water and its vapor (steam point)	100
Temperature of equilibrium between liquid sulfur and its vapor (sulfur point)	444.6**
Temperature of equilibrium between solid silver and liquid silver (silver point)	960.8
Temperature of equilibrium between solid gold and liquid gold (gold point)	1063

*Exact values assigned. The pressure is 101,325 Pa (1 standard atmosphere), except for the triple point of water.

**In place of the sulfur point, it is recommended to use the temperature of equilibrium between solid zinc and liquid zinc (zinc point) with the value 419.505°C. The zinc point is more reproducible than the sulfur point and the value which is assigned to it has been so chosen that its use leads to the same values of temperature on the International Practical Temperature Scale as does the use of the sulfur point.

ture as close as possible to thermodynamic temperature, a completely revised and extended version of the IPTS was adopted in 1968. The result was the IPTS-68. That is the present version of the international temperature scale and it is defined by: (1) assigning values to the temperatures of eleven fixed points, extending from the triple point of hydrogen (13.81 K) to the freezing point of gold (1337.58 K); (2) specifying interpolation formula for the specified standard instruments, namely, the platinum resistance thermometer between 13.81 K and 630.74°C, and the platinum-10% rhodium/platinum thermocouple for the range from 630.74°C to 1064.43°C; and (3) specifying the Planck law of radiation for temperatures higher than 1064.43°C, with 1064.43°C (1337.58 K) as the reference temperature and the value 0.014388 m · K for the second radiation constant C_2. The IPTS-68 recognizes the thermodynamic temperature as the basic temperature and defines its unit (the kelvin, K) to be 1/273.16 of the thermodynamic temperature of the triple point (equilibrium among the solid, liquid, and vapor phases) of water. The IPTS-68 is not defined below −259.34°C. The 11 fixed points of the IPTS-68 and their assigned temperatures are listed in Table 2.

The major difference between the IPTS-48 and the IPTS-68 is that on the IPTS-68, the temperature range was extended from the boiling point of oxygen, −182.97°C (90.18 K), (the lowest temperature of IPTS-48) to the triple point of hydrogen, 13.81 K. The IPTS-68 extended the scale to lower temperatures in order to unify the existing national scales in the region 10 K to 90 K and brought the values measured on the scale into agreement with thermodynamic temperatures within the limits of the accuracy of measurement at that time. The equations specified for the interpolating instruments were modified also. The IPTS-68 distinguishes between the International Practical Kelvin Temperature, symbol T_{68}, and the International Practical Celsius Temperature, t_{68}.

$$t_{68} = T_{68} - 273.15 \text{ K}.$$

The units of t_{68} and T_{68} are the same as for t and T, respectively, where T is the thermodynamic temperature (unit is the kelvin, K) and t is the Celsius thermodynamic temperature (unit is the degree Celsius, °C). The degree Celsius is by definition equal in magnitude to the kelvin.

An amended version of the IPTS-68 was adopted in 1975. Any measured temperature, T_{68}, is unchanged by that amended version. It differs from the 1968 version only in that an alternative fixed point was introduced (the argon triple point as an alternative to the oxygen boiling point), the specified natural isotopic composition of neon was changed slightly, the reference function for the standard platinum thermometer was given in an improved form, the criteria for selection of thermocouples were changed, the values of some of the secondary reference points were changed, a table of estimated uncertainties of the assigned values of the defining fixed points was deleted, and some inconsistencies and deficiencies were removed from and additional information added to the section on supplementary information.

An important but subtle point regarding practical temperature scales should be noted. By definition, the unit for thermodynamic temperatures is the same size in all temperature regions; this however, is not necessarily true for the IPTS-68 and the other practical scales. Even if the temperatures assigned to the fixed points are their true thermodynamic values, it has not been established that the specified interpolating formulas will exactly reproduce thermodynamic temperatures, except above the gold point. Consequently, the unit on the practical scale may not be constant; a unit of temperature (K or °C) in one temperature region may be of different size from that in

TABLE 2. DEFINING FIXED POINTS OF THE IPTS-68.[a]

	Assigned Value of International Practical Temperature	
Fixed Points	T_{68}(K)	t_{68}(°C)
Equilibrium between the solid, liquid, and vapor phases of equilibrium hydrogen (triple point of equilibrium hydrogen)[b]	13.81	-259.34
Equilibrium between the liquid and vapor phases of equilibrium hydrogen at a pressure of 33 330.6 Pa (25/76 standard atmosphere)[b,c]	17.042	-256.108
Equilibrium between the liquid and vapor phases of equilibrium hydrogen (boiling point of equilibrium hydrogen)[b,c]	20.28	–252.87
Equilibrium between the liquid and vapor phases of neon (boiling point of neon)[c]	27.102	–246.048
Equilibrium among the solid, liquid, and vapor phases of oxygen (triple point of oxygen)	54.361	–218.789
Equilibrium between the liquid and vapor phases of oxygen (condensation point of oxygen)[c,d]	90.188	–182.962
Equilibrium among the solid, liquid, and vapor phases of water (triple point of water)[e]	273.16	0.01
Equilibrium between the liquid and vapor phases of water (boiling point of water)[e,f]	373.15	100
Equilibrium between the solid and liquid phases of zinc (freezing point of zinc)	692.73	419.58
Equilibrium between the solid and liquid phases of silver (freezing point of silver)	1235.08	961.93
Equilibrium between the solid and liquid phases of gold (freezing point of gold)	1337.58	1064.43

[a] Except for the triple points and the equilibrium hydrogen point at 17.042 K, the assigned values of temperature are for equilibrium states at a pressure of 101,325 Pa (1 standard atmosphere). If differing isotopic abundances could significantly affect the fixed point temperatures, the abundances are specified.

[b] Equilibrium hydrogen means that the hydrogen has its equilibrium *ortho-para* composition at the relevant temperature. *Ortho* and *para* are the designations for the molecular configurations (nuclear spin arrangements) of hydrogen.

[c] Fractionation of isotopes or impurities dictates the use of boiling points (vanishingly small vapor fractions) for hydrogen and neon and condensation point (vanishingly small liquid fraction) for oxygen.

[d] The equilibrium state among the solid, liquid and vapor phases of argon (triple point of argon) at T_{68} = 83.798 K (t_{68} = −189.352°C) may be used as an alternative to the condensation point of oxygen.

[e] The water used should have the isotopic composition of ocean water.

[f] The equilibrium state between the solid and liquid phases of tin (freezing point of tin) has the assigned value of T_{68} = 505.1181 K (t_{68} = 231.9681°C) and may be used as an alternative to the boiling point of water.

another. As a result, the accurate determination of thermodynamic temperatures in all temperature regions is the principal task of thermometry today.

Future Improvements and Extensions of the IPTS In view of the elaborate experimental techniques usually required to make accurate thermodynamic temperature measurements, the need for a practical scale above about 0.5 K that is close to the Kelvin thermodynamic temperature scale remains great. There are several modifications which can be anticipated for a future IPTS. They include assigned values of fixed points which are in closer agreement with thermodynamic temperatures (as determined by recent experiments), extension of the range covered to lower temperature (0.5 K would seem to be a reasonable choice for the lower end of a practical scale), improved standard instruments for interpolation between the defining fixed points, and improved interpolation procedures. It is expected that there will be a scale revision, that it will encompass the above, and that the new scale will be adopted by about 1987.

A new (provisional) scale, the 1976 Provisional 0.5 K to 30 K Temperature Scale (EPT-76), was approved in 1976 by the CIPM. It is based on low temperature gas thermometry, on magnetic thermometry, and on fixed points to which temperature values have been assigned. The defining fixed points of the EPT-76 and their assigned temperatures are given in Table 3. This scale is expected to provide the information on which to base the downward extension of the future IPTS. Gas thermometry has recently been completed in certain regions and is in progress in others to provide refined thermodynamic temperatures throughout the entire range from about 2 K to about 1337 K. The standard thermocouple will probably be replaced with high temperature platinum resistance thermometers, which appear to be superior in sensitivity and stability. It is possible that the radiation scale will be extended downward, perhaps to the silver point (961.93°C) or even the aluminum point (660.37°C). Previously, it was thought this was unlikely, but recent developments in instrumentation now appear to make this more feasible.

Practical Thermometry Since temperature measurements are required over such a wide range and diversity of situations, a large number of different types of thermometers with varying levels of accuracy and convenience have been developed over the years. Those most frequently used are based on the expansion of gas, liquid or solid; on changes in electrical resistance; on the thermoelectric effect; on changes in the thermal radiation of a system; on changes in the thermal (Johnson) noise of electrical resistors; on changes in the resonant frequency of some materials; on spectroscopic changes; on changes in voltage of semiconductor *p-n* junction diodes; and on changes in the magnetic susceptibility of paramagnets.

The most familiar thermometer, the mercury-in-glass thermometer, is based on the fact that mercury expands much more rapidly than its glass container. Liquid-in-glass thermometers, other than mercury-filled ones, are used for measurements at temperatures below the freezing point of mercury. Usually a dye is put in the liquid to improve readability. Liquid-in-glass thermometers may be designed for partial-immersion, total-immersion, or complete-immersion operation. These thermometers can be made as maximum and/or minimum-indicating devices. One maximum-indicating thermometer is the clinical or fever thermometer. It contains a narrow constriction in the capillary just above the bulb which breaks the mercury column and prevents the mercury from retreating into the bulb when the thermometer is re-

TABLE 3. REFERENCE POINTS OF THE EPT-76.

Reference Point	Assigned Temperature, T_{76}(K)
Superconducting transition point of cadmium	0.519
Superconducting transition point of zinc	0.851
Superconducting transition point of aluminum	1.179 6
Superconducting transition point of indium	3.414 5
Boiling point of ^{4}He[a]	4.222 1
Superconducting transition point of lead	7.199 9
Triple point of equilibrium hydrogen[b]	13.804 4
Boiling point of equilibrium hydrogen at a pressure of 33,330.6 Pa (25/76 standard atmosphere)[b]	17.037 3
Boiling point of equilibrium hydrogen[a,b]	20.273 4
Triple point of neon[c]	24.559 1
Boiling point of neon[a,b,c]	27.102

[a] Boiling point under a pressure of 101 325 Pa (1 standard atmosphere).

[b] These are the four lower defining points of the IPTS-68. (NOTE: the values of temperature assigned to these points in EPT-76 are not the same as those assigned in IPTS-68.) The term equilibrium hydrogen means here that the hydrogen should have its equilibrium *ortho-para* composition at the relevant temperature.

[c] The two neon points are for neon with the natural isotopic composition of 2.7 mmol of ^{21}Ne and 92 mmol of ^{22}Ne per 0.905 mol of ^{20}Ne.

moved from the body and the temperature of the thermometer begins to decrease; this leaves the column above the constriction to indicate the maximum temperature reached by the thermometer.

There are many types of dial thermometers, including liquid, liquid-vapor, or gas filled, and their use is very widespread, particularly in industry. These thermometers usually consist of a bulb connected via a capillary tube to a Bourdon tube, mounted in a case and attached through some mechanism to a rotatable pointer on a scale. The usual liquid used in dial thermometers is mercury.

The principle of the expansion of a solid is employed in bimetallic-strip thermometers, which are comprised of strips of two different metals bonded together, side by side. If the metals have different coefficients of expansion, then the bimetallic strip will bend with a change in temperature; this can be used to move an indicator along a scale or to open and close electrical contacts, the latter operation forming a thermostat for a furnace, oven, or air conditioning system.

The most frequently and conveniently used gas thermometer is the constant-volume one which utilizes the changes in pressure to indicate changes in temperature. Another type of gas thermometer is the dielectric-constant gas thermometer. Measurements in this case depend on the change of the dielectric constant with gas density and, thus, are intensive in their nature, in contrast to the extensive quality of regular gas thermometry. A reference temperature is required for the operation of gas thermometers.

Saturation vapor-pressure thermometry is commonly used for the measurement of temperature in the liquid helium (^{4}He and ^{3}He) and liquid hydrogen regions, and to a lesser extent in the regions of other cryogenic fluids, because of the sensitivity and convenience of this type of measurement.

There are many different types of resistance thermometers, with each type being most suited for use in a particular temperature region. In all cases, however, a circuit for measuring resistance with change in temperature is required. Included among the resistance thermometers are the platinum, copper, and nickel resistance thermometers, the rhodium-iron resistance thermometers, and the semiconductor, thermometers (arsenic-doped germanium, thermistors, carbon).

Thermocouples are used for measurements of temperature from a few millikelvins to above 2800°C. The basic thermocouple consists of two wires of different materials which, when joined together at one end (the hot junction) and connected to a voltage measuring instrument at the other end (the cold junction), will produce a voltage as a smooth function of the temperature difference between the two junctions. Various pure elements and alloy combinations can be used to form couples which are best suited to particular temperature regions. Thermocouples are probably the most widely used industrial thermometers because they are inexpensive, rugged, long-lasting, and suitable for continuous recording and/or control of temperature. Since thermocouples can be made very small, they can respond very rapidly to fast changes in temperature.

Radiation thermometers were developed for measuring high temperatures (greater than 1064°C) and they have the advantage that they are noncontact thermometers. Optical pyrometers measure apparent temperatures of objects by comparing the radiation from the objects over a narrow wavelength band with that of a standard, preferably using a photoelectric detector for the comparison. Corrections for the emissivity of the source must be made to determine the temperature. Total-radiation pyrometers measure the whole spectrum of energy radiated by the source and that is used to determine the temperature. They are less accurate than optical pyrometers but can measure much lower temperatures (of the order of 100°C). This type of pyrometer also requires emissivity corrections. Also utilizing radiation from an object to measure its temperature is the technique of thermography (mapping of surface temperature distributions over extended areas). This is widely used in the medical field for the detection of tumors near the surface of the skin, and in industrial applications for detection of hot spots (defective insulators on power lines, furnace walls, areas of heat leaks in buildings, etc.).

Another noncontact technique for measuring high temperatures involves Raman spectroscopy, in particular the nonlinear process known as coherent anti-Stokes Raman spectroscopy (CARS). This technique is finding practical applications in measurements of temperatures of flames, in internal combustion engines, in jet engines, and of hot gases.

Johnson-noise thermometers, based on the measurement of the Johnson-noise power or voltage, are now commercially available. Johnson (thermal) noise voltage is the small fluctuating voltage generated in any electrical conductor by the random motion of the electrons (charged particles). The extent of the motion of the electrons is a function of temperature and, thus, the voltage is related to thermodynamic temperature. Noise thermometers are suitable for use from a few mK to over 1000°C.

Thermometers which are based on the temperature-dependent resonant frequency of a material are very attractive since the quantity measured is frequency. One such thermometer is the nuclear quadrupole resonance (NQR) thermometer. An excellent feature of the NQR thermometer is that the thermometric property involved is a fundamental property of a substance, a unique frequency-temperature relationship which need be established only once and is forever after applicable for that substance. A commercial NQR thermometer is available; it is based on the NQR of ^{35}Cl in $KClO_3$, which has been the substance most studied. NQR thermometers are suitable for use over the range from about 50 K to 450 K.

Another resonant-frequency thermometer is the quartz crystal resonator, which, if the crystal is properly cut, is quite linear from about 190 K to 525 K. Although this thermometer has excellent resolution, it does exhibit hysteresis and drift.

Semiconductor *p-n* junction diode thermometers are becoming widely used throughout the range from liquid helium temperatures (~1 K) to about 200°C. The diodes are currently made of germanium, silicon or gallium arsenide. These thermometers are based on the principle that for forward-biased *p-n* junction diodes, the current varies approximately exponentially with V/T, where V is the voltage. At constant current, then, the junction voltage decreases approximately linearly with increasing temperature. The emitter-base junction diodes of transistors have been used also as thermometers.

Liquid-crystal thermometers have come into fairly widespread use in recent years. In their operation, they rely on the change in wavelength of reflected light with a change in temperature. The liquid crystals or their mixtures are selected such that the wavelengths of the reflected light are in the visible region, giving rise to a change in color with a change in temperature. To serve as thermometers, the liquid crystals are in their cholesteric phase and their temperature range of operation is from about 0°C to about 70°C.

In the cryogenic temperature region, magnetic thermometers are very useful and widely used. They employ the temperature dependence of the magnetic susceptibility χ of weak paramagnets (nuclear and electronic) far above their critical temperatures. χ is a parameter that indicates the extent to which a substance (paramagnetic salt or nuclear spin system) is susceptible to magnetization and which for "weak" paramagnets is given by the Curie law ($\chi = C/T$).

Each type of thermometer has its particular advantages and disadvantages, and the selection of a thermometer for a given application must be based on the requirements of that application. Among the considerations which influence the choice of the thermometer are accuracy, sensitivity, reproducibility, size, temperature range, speed of response, durability, and cost.

TENSORS AND TENSOR ANALYSIS

Introduction Tensors and tensor analysis represent a powerful and useful part of mathematical physics. Tensors include such familiar objects of physical interest as ordinary scalars and vectors. They also include more complicated objects and are basic to a full understanding of advanced subjects such as electromagnetic theory and general relativity. Consequently, tensors often possess an aura of mystery and a special mystique that they do not always deserve. The reader is referred to the articles of VECTOR ANALYSIS, ELECTROMAGNETIC THEORY, and RELATIVITY appearing elsewhere in this encyclopedia.

The concept of tensor can be traced back to such men as Karl Gauss, George Riemann, and Elwin Christoffel in the last century. The algebra and calculus of tensors can be traced back to Gregorio Ricci and his pupil Tullio Levi-Civita early in this century. Their names appear frequently in connection with specific concepts or special tensors. The books by Levi-Civita[1] and Eisenhart[2] in the general references at the end of this article will provide a more complete history of this subject.

The word *tensor* means "to stretch" and thus is related to the concepts of stress and strain appearing in the theory of elasticity and deformable bodies. Dyadics, which were used more frequently in the last century, may be considered to be almost synonymous with the more modern concept of tensors and to be superseded by them. Tensors and tensor analysis are important in both mathematics and physics and are gaining importance in many fields of engineering and technology. See the excellent book by Sommerfeld[3] for applications to the mechanics of deformable bodies, and the book by Page[4] for more information about dyadics.

Tensors, Rank, and Dimensionality Before wondering about the physical interpretation of a tensor, which depends entirely on the problem at hand, consider its mathematical description. The number of components in a given tensor depends on both its rank R and on its tensor dimensionality D. The lowest rank R that a tensor may have is 0. The number of components possessed by a tensor of rank 0 is always 1, no matter what the dimensionality D of the tensor may be. A common name for such a tensor is "scalar." So, an n-dimensional scalar is a one-component tensor of rank zero. One example of a scalar quantity is a thermometer reading representing temperature. A second example is ordinary mass–but not the gravitational weight associated with the mass which is, in fact, a downward-pointing force vector.

The next rank that a tensor may have is 1. The number of components possessed by a tensor or rank 1 is always n, the dimensionality of the tensor. Thus, in two-dimensional space, a tensor of rank 1 has 2 components; in three-dimensional space, 3 components; and so on. Again, a common name for such a tensor is "vector." So an n-dimensional vector is an n-component tensor of rank 1. The first example of a vector that comes to mind is velocity.

The next rank that a tensor may have is 2. The number of components possessed by a tensor of rank 2 is always n^2, the square of the dimensionality of the tensor. Thus in two-dimensional space a tensor of rank 2 has 4 components; in three-dimensional space, 9 components, and so on. A tensor of rank 2 is the first that normally would be called a true tensor.

These facts may be summarized. For what are called complete tensors the general result is that the number of components in a tensor of rank R and dimensionality D is given by the formula $Z = D^R$.

One kind of incomplete tensor is called an "antisymmetric tensor." Such a tensor always has some zero components. The number of independent nonzero components in an antisymmetric tensor in n-dimensional space is given by $\frac{1}{2}n(n-1)$.

It is convenient that in three dimensions an antisymmetric tensor of rank 2 has only three nonzero components. This coincidence gives rise to this tensor's interpretation as a kind of vector or "pseudovector." A familiar example of an antisymmetric tensor that may be thought of as a vector is magnetic field strength **H** and the associated magnetic induction **B**. A second example is angular momentum **L**. It is this last association that has given the name axial vector to this general class of pseudovector. The coincidence is related to the fact that in three dimensions the number of planes (defined by pairs of coordinates x, y; x, z; y, z) is the same as the number of coordinates x, y, z. In any other dimension this does not happen, but the number of independent planes still is equal to the number of tensor components. Thus, in two dimensions, there is only one plane (1,2) and one tensor component, while in four dimensions, there are six independent planes (1,2; 1,3; 1,4; 2,3; 2,4; 3,4) and six components. Finally, Table 1 summarizes the number of components of simple tensors for spaces with dimensions up to five. Notice that the number of components of the symmetric and antisymmetric tensors of a given rank sum up to the maximum number for that rank. For more details on the elementary properties of vectors and tensors the reader is referred to the book by Lass[5] in the general references.

Algebra of Tensors As a general rule, the algebra that has been developed for matrices may be used with tensors. In fact, second-rank tensors look like square matrices; first-rank tensors (vectors) look like 1 by n matrices. In any given situation, tensors and matrices may be multiplied together to achieve a purpose such as transforming the tensor by a linear operator. In these instances the tensor components may express the physical aspects of the problem and the matrix components the more mathematical aspects of the problem. The reader may find more information on this subject in the article on MATRICES appearing elsewhere in this encyclopedia.

All vectors are tensors, but not all tensors are vectors. A vector $\mathbf{A}_i$ has the transformation law:

$$\mathbf{A}'_j = \ell_{ij}\mathbf{A}_i,$$

whereas a tensor $\mathbf{K}_{ik}$ has a transformation law:

$$\mathbf{K}'_{jl} = \ell_{ij}\ell_{kl}\mathbf{K}_{ik}.$$

Here the symbol ℓ_{ij} or ℓ_{kl} represents the transformation matrix taking $\mathbf{A}_i$ or $\mathbf{K}_{ik}$ from the

TABLE 1. NUMBER OF COMPONENTS OF A TENSOR

	Dimensions				
	1	2	3	4	5
Scalar	1	1	1	1	1
Vector	1	2	3	4	5
Axial vector	1	2	3	4	5
Tensor–second rank	1	4	9	16	25
Symmetric tensor	1	3	6	10	15
Antisymmetric tensor	0	1	3	6	10
Tensor–third rank	1	8	27	64	125

unprimed to the primed coordinate system. The n^2 elements of the matrix ℓ_{ij} are derived from the direction cosines of the unit vectors in one system of coordinates with respect to the unit vectors in the other.

A tensor $\mathbf{K}_{ik}$ or $\mathbf{K}'_{jl}$ represents a physical object. The double index ik or jl, while similar to ij or kl for the matrix ℓ, refers to the axes in one system of coordinates. Accordingly, they are different in nature even though they may have the same form.

Covariance and contravariance refer to the transformation properties of vectors and tensors. These concepts are essential to a complete understanding of vector and tensor analysis. The rules of manipulation of the vector or tensor indices, which designate whether a vector is covariant or contravariant or whether a given tensor is covariant, contravariant, or mixed in its transformation properties, are well documented along with other mathematical and formal aspects in many textbooks. One of the best of these is Sokolnikoff[6] listed in the general references. An approach that emphasizes the relationship between the concept of reciprocal lattices (long familiar to solid-state physicists and crystallographers) and the fact that the covariant and contravariant versions of the same vector reside in different coordinate systems is explained in Stratton[7] and illustrated in Eisele and Mason[8]. In many problems the value of retaining the distinction between covariance and contravariance vanishes because, for cartesian coordinates, a coordinate lattice and its reciprocal lattice are one and the same. It follows that the covariant and contravariant components of a vector or tensor will be identical in magnitude and direction.

Calculus of Tensors Numerous applications of tensor analysis can be found in texts dealing with special and general relativity. In fact, it would not be too inaccurate to say that the subject of tensor calculus grew up with general relativity. The small book by Einstein[9], and another by Møller[10] provide further background on the subject of relativity. Deserving special consideration as an extremely simple introduction to the manipulation of tensors and their calculus is the book by Lieber and Lieber.[11]

The concepts of covariance and contravariance reappear in tensor calculus in a new and more general form than previously mentioned in connection with reciprocal lattices. The archetype contravariant vector is taken as the position vector $\mathbf{r} = (x^1 \cdots x^n)$ or differential components of $d\mathbf{r}$. It obeys the transformation:

$$dx'^i = M^i{}_j dx^j = \frac{\partial x'^i dx^j}{\partial X^j},$$

or $\mathbf{A}'^i = M^i{}_j \mathbf{A}^j$. Contravariant tensors of higher rank follow a similar pattern of index and prime placement. The archetype covariant vector is taken as a vector generated by the gradient operator and obeys the transformation

$$\frac{\partial \phi}{\partial x'^i} = N^j{}_i \frac{\partial \phi}{\partial x^j} = \frac{\partial x^j}{\partial x'^i} \frac{\phi}{\partial x^j},$$

or $\mathbf{B}'_i = N^j{}_i \mathbf{B}_j$. Covariant tensors of higher rank follow a similar pattern of index and prime placement. A mnemonic device "co-lo-prime-below" has been introduced by Lieber and Lieber[11] to aid in remembering the difference between the two classes of tensors.

The metric tensor $\mathbf{g}_{ij}$ or $\mathbf{g}^i{}_j$, which has a special meaning in relativity, is introduced in differential geometry in connection with the definition of differential line element:

$$ds^2 = \mathbf{g}_{ij} dx^i dx^j.$$

Its forms for three-dimensional cartesian and spherical coordinates respectively, are:

$$\begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{vmatrix} \qquad \text{and} \qquad \begin{vmatrix} 1 & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & r^2 \sin^2\theta \end{vmatrix}$$

The Kronecker delta and the Levi-Civita symbols are defined as:

$$\delta_{ij} = \begin{matrix} 1 \text{ if } i = j \\ 0 \text{ if } i \neq j \end{matrix}$$

and

$$\epsilon_{ijk} = \begin{matrix} +1 \text{ if } i, j, k = 1, 2, 3 \text{ or a cyclic permutation} \\ -1 \text{ if } i, j, k = 3, 2, 1 \text{ or a cyclic permutation} \\ 0 \text{ if any two or three of } i, j, k \text{ have the same value.} \end{matrix}$$

The delta symbol is useful in discarding cross-product terms that vanish under conditions of orthogonality and in indicating unity in the normalization process. The epsilon symbol is useful in simplifying multiple vector products and revealing their true tensor nature. Thus for example in tensor component form:

$$\mathbf{C} = \mathbf{A} \times \mathbf{B} \quad \text{becomes} \quad C_i = \epsilon_{ijk} A_j B_k,$$

$$\mathbf{A} \cdot (\mathbf{B} \times \mathbf{C}) \quad \text{becomes} \quad \epsilon_{ijk} A_i B_j C_k, \text{ and}$$

$$\mathbf{A} \times (\mathbf{B} \times \mathbf{C}) \quad \text{becomes} \quad \epsilon_{ijm} \epsilon_{klm} A_j B_k C_l.$$

Tensors and Quadratic Forms In classical mechanics, tensors arise naturally in the study of rotating objects. The moment of inertia tensor associated with an object is of rank 2 and can be represented by an ellipsoid of rotation. Many important and useful properties of the system can be obtained by applying matrix transformations to this tensor. A particularly lucid development of this subject may be found in the excellent textbook by Goldstein,[12] where eigenvalues and eigenvectors are obtained through the reduction to principal axes (i.e., diagonal form).

In quantum mechanics, a similar application exists in which it is required to diagonalize simultaneously two Hermitian quadratic forms with real eigenvalues. For the general case, a principal axis transformation can be found. However, the resulting principal axes need not be an orthogonal set. This is illustrated in Eisele and Mason.[8]

For a modern general treatment of the subject of tensors see Krogdahl.[13] A more specific treatment may be found in Goodbody.[14]

THEORETICAL PHYSICS

As knowledge increases and becomes more diversified, a process of arborization of subject matter ensues—various branches of knowledge branch again into new specializations; for example, natural philosophy, which embraced a general curiosity about phenomena occurring in Nature, branched into the physical and natural sciences, and these in turn into specific sciences such as physics, chemistry, and biology. Physics, in turn, has branched into many subject areas, such as nuclear physics, laser physics, hydrodynamics, and statistical physics. Another kind of branching, which is related to personality and aptitude rather than to subject matter, is the division of activity in physics into experimental and theoretical physics. A similar division has developed in chemistry and is in an early period of infancy in the biological and social sciences.

The branching of activity in physics between experiment and theory is both convenient and natural. Experiment has to do with the design of a measuring apparatus, the taking of measurements, and the comparison of these measurements with expectation. Theoretical physics has largely to do with providing a conceptual and explanatory background in the form of equations and their solutions with predictive value. The language of physics is interpreted mathematics; mathematical symbols are used to represent quantitative physical concepts and the mathematical equations provide relationships between them. For example, Robert Boyle, in 1660, found that for an enclosed mass of air, the pressure, volume, and temperature (each measurable quantities) are not independent; in fact, Boyle showed that if the temperature is held fixed, the volume varies inversely as the pressure applied. This was an empirical result which found "explanation" later in the kinetic theory of gases based on Newton's laws of particle motion. The kinetic theory, in turn, predicts that Boyle's law represents only ideal behavior and that deviations from the ideal should be measurable. This going back and forth between experiment and theory is characteristic of physics and provides a powerful process for improving and extending experimentation on the one hand, and of developing and testing theoretical hypotheses on the other.

The breadth and diversity of the human interest and intellect is such that some physicists prefer the earthy experience of designing apparatus and using it in a sophisticated measuring situation, while others prefer to work abstractly with ideas and their mathematical expression. This concrete-to-abstract spectrum extends from architects and engineers at one limit, through practical experimenters, theoretical physicists, to mathematicians or philosophers at the other. Theoreticians themselves divide into fuzzy categories, some in close and immediate contact with experiment, some relating general theoretical developments to an overall philosophic view, and some (the so-called applied mathematicians) engaging largely in the mathematics of very practical problems, such as calculating heat loss in steam pipes or the optimal shape of airfoils for maximum lift in an air stream.

The success of theoretical physics in the modern, post-industrial era (exemplified, for example, in the large proportion of theoretical physicists among the winners of Nobel prizes) arises out of the power of the human mind to conceptualize beyond the limits imposed by everyday experience. Although we live in a world of three space dimensions, the physicist and mathematician conceive of and explore imagined or abstract worlds of other dimensions, including worlds of infinite dimension and even worlds of fractional dimensionality. In the early scientific era this power of the human concept was employed to do the seemingly impossible—to measure the radius of the earth without penetrating its depths or sailing around it; to measure the height of inaccessible mountains by triangulation; to weigh the moon without touching it or leaving the earth. The concept and design of a modern nuclear power plant is based on fantastic abstractions—theoretical nuclear physicists talking about Einstein's mass-energy conversion inside countless nuclei so tiny that no one has ever seen or touched, tasted or heard them; but the plant itself is built with metal, concrete, and other common materials by skilled and unskilled tradesmen of a variety not basically different from those employed on any construction site. Yet the day comes when the switches are thrown and the houselights come on in obscure towns a thousand miles distant from the slowly disintegrating uranium fuel rods embedded in the moderator of the nuclear pile.

Just as the discipline of physics as a whole is divided into subdisciplines or subject areas, so it is with theoretical physics. One roughly defined division is between so-called h-bar physics ($\hbar$ is Planck's constant divided by 2π) and non-h-bar physics, depending on whether the phenomenon in question can be explained on the basis of the so-called classical or prequantum laws, such as those of Newton or Maxwell, or whether one must resort to the new mechanics devised in the 1920s to take account of the quantized nature of matter in its microscopic form. Examples of non-$\hbar$ physics would be much of geophysics, hydrodynamics, thermodynamics and biophysics. Generally, non-$\hbar$ physics has to do with the description of rather large-scale, long-term phenomena. Even these phenomena, however, generally have a microscopic basis which requires the quantum theory for more detailed understanding or explication.

Theoretical physics as it has been practiced in the post-Renaissance period has been at once both intensely reductionistic and grandly holistic. The extrapolation by Newton of a very limited experience with planetary motions to universal gravitation between all material bodies is an example of grand holism; the behavior of one piece of matter is related to the behavior of all other matter in the universe. Pauli's exclusion principle and associated antisymmetrization of the wave function is another. Nonetheless, theoretical physicists are primarily reductionistic—looking for explanations by conceptually taking things apart and assuming that a better understanding of macroscopic phenomena will follow from an understanding at a finer, more microscopic level of description. A fundamental question today is whether there is a natural limit to this procedure of explanation of a phenomenon in terms of its "parts." One looks to the behavior of liquids, solids, and gases in terms of their atomic constituents and the interactions among them; the atomic constituents are explicable in terms of electrons and nuclei; nuclei are explicable in terms of protons and neutrons, and these in terms of the modern "elementary particles" like quarks and gluons. Do the quarks also have subworlds for their explication? or is one then pushing the concept of explanation by reduction too far? These are open and fascinating questions in contemporary physical theory.

Another division of activity in theoretical physics is the division of phenomena into relativistic and nonrelativistic categories. Loosely speaking, relativity has to do with high-velocity phenomena, that is, with relative motions of matter reaching nearly to the velocity of light. Because of Einstein's general theory and the close association between inertial and gravitational mass, relativity becomes essentially inseparable from gravitation. Special relativity is the domain of high-velocity phenomena in regions of space which have an extremely small density of matter. The so-called theory of special relativity is basically an algorithm by which observers in rapid relative motion to one another can establish overall consistency between their apparently different observations on presumably the same natural phenomenon.

In the presence of strong gravitational fields Einstein showed that the laws of physics take on their simplest form in coordinate systems which have been warped by the gravitational fields. This brilliant concept that one can replace kinematics by geometry went a long way to fulfilling ancient speculations about the essentially geometric structure of the universe. The details of Einstein's theory may yet require modification, but its essential conceptual correctness seems to be beyond question.

It is fascinating that the two successful, modern paradigms about the ultimate structure and nature of our universe, to both of which Einstein contributed in an essential way, seem at some basic level in contradiction to one another. This presents the theoretical physicist with one of the great paradoxes of our time. On the one hand the quantum theory seems to deal efficiently and successfully with the "other" basic forces of the universe—electromagnetic forces, nuclear forces, the "weak" forces associated with beta decay—but not with gravitational forces. Grand unification theories have not been successful so far, despite many sophisticated assaults on the problem. On the other hand, general relativity deals in an inherent way only with the gravitational force, its other aspect being the intimate relationships between space, time and matter and how these relationships affect our observations.

A second aspect of the apparent conflict between quantum mechanics and relativity has to do with Bell's theorem, which shows that either quantum mechanics does not obey the ordinary rules of logic and reason, or that it is inherently non-local in a sense which must be carefully defined. Non-locality would imply that information is transmitted essentially instantaneously, whereas special relativity states that no signal can travel faster than light. Bell's inequality is still under test, though many scientists would take the view that it has, in essence, already been tested.

One of the most intriguing problems in quantum mechanics, which also relates to Bell's inequality, is to define the interface between quantum phenomena and classical measurement. Schrödinger's equation gives a rather strange description of microscopic phenomena (strange because the dynamical quantity, the wave function Ψ, is a probability amplitude and cannot be measured or observed directly); it seems essential to the understanding of the results of measurements. Yet the measurements themselves are made with, and the values read from, classical instruments. Even more intriguing is the interface between the measuring apparatus and the human consciousness. From a more specific point of view, one can raise the question whether large macromolecules (e.g., enzymes) of the kind involved in living systems are essentially classical objects, essentially quantum objects, or perhaps interesting interface systems between the classical and quantum limits.

The most specific divisions of activity in theoretical physics are those relating to subfield. For example, one has the following broad areas: condensed matter, nuclear physics, elementary particle physics, field theory, quantum optics, biophysics, geophysics, plasma physics, upper atmospheric physics, astrophysics, relativity, gravitation, and cosmology. In general these areas parallel counterparts in experimental physics and reflect a division of interest and activity on the basis of size of objects considered, degree of accessibility, degree of abstraction required, etc., or some combination of these factors. Often one is influenced to enter a particular specialization through the interests of a gifted teacher or colleague; sometimes a researcher develops a peculiar, absorbing, and lifetime interest in a certain specific area such as stellar evolution in much the same way that a person might develop a special yen to visit Australia or Tanzania. Whatever factors induce the theoretician to enter a certain specialized area of teaching or research, subject sophistication and mathematical and conceptual complexity generally serve as effective trapping mechanisms. Although it is easier for the theoretician to cross subject areas than for the experimenter (who is burdened with specialized equipment and techniques), it is nonetheless difficult in practice; and this despite a great unity in theoretical physics of conceptual ideas and supporting mathematics. (For example, the concept of space-time fields and the mathematics of differential equations are common to almost all specialized areas of physical theory.)

One important technical development affecting modern theoretical physics is the high-speed computer. Most theoreticians do at least some calculations, and many do a lot. The kinds of problems that are being tackled today would have been inconceivable even 15 years ago. Computations are now done overnight that would have then involved a lifetime. Whether reliance on the computer has become the tail wagging the dog of theoretical inquiry is a question widely debated and largely unanswered. Evidence can be adduced to support the claim that computers enhance concept development; but evidence can also be adduced to argue that computers get in the way of creative thinking, perhaps largely via the illusion that numbers constitute understanding. Whatever the implication, the fact is that computers play an important, almost dominant role in modern theoretical inquiry.

In some sense physical theory is model building. All but the simplest experiments are too difficult for a complete mathematical description. Idealization and abstraction based on knowledge and driven by curiosity and interest lead to sets of equations which attempt to model experimental reality. The hallmarks of the good theorist are first the ability to see the forest as well as the trees, that is, not to get lost in detail before a perspective is developed; then to be clever at manipulating equations so that justifiable and revealing approximations can be made. The ultimate test of a theory is its ability to account for present experimental results and to give guidance as to useful new experiments. A theory may refer to a schema or a paradigm of broad scope and wide application like quantum mechanics or Maxwell's equations; but the term can also be used narrowly for some interesting detail within the paradigm, such as scattering theory, or the Landau theory of second-order phase transitions.

Theoretical physics is especially rich in models and metaphors, so that people trained in this area can make imaginative contributions to other fields of human endeavor where the tradition of using mathematics is less highly developed. Dramatic examples are the contribution of physicists such as Francis Crick and Max Delbruck to the recent dramatic advances made in molecular biology.

References

Many modern scientific magazines carry articles bearing on major advances in modern physical theory, notably Scientific American and Physics Today. Bohm's book, listed below, deals with some interesting philosophical questions relating to the interpretation of quantum theory, relativity and the nature of human consciousness. Although the work of Prigogine is not without its strong critics, nonetheless, he deals in an interesting way with some fundamental problems bearing on time, irreversibility and the nature of living systems. Kuhn's views on the existence of scientific paradigms and their revolutionary modification has become a classic work in the philosophy of science. The Einstein-Infeld book is an old classic with contemporary value. Finally, the book by Trainor and Wise develops a perspective as to how the mathematical structures used in physical theory arise naturally out of our perception of the world and the phenomena we are trying to explain.

THERMIONICS

Thermionics is the study of electron emission from solids occurring at elevated temperatures (1000–2500°C). The effect is of primary importance with vacuum tubes, x-ray tubes, microwave tubes, electron microscopes, and other devices which depend on a continuous supply of electrons. With such a device electrons are provided by heating a filament of an appropriate material such as BaO, SrO, thoriated tungsten, etc., as discussed below.

Among the early workers with currents from hot electrodes were Hittorf (1869–1883) and Goldstein (1885), both drawing quite large currents, and Elster and Geitel (1882–1889) who worked with very small currents, both positive and negative, in their research on the phenomenon. Edison (1883) in his work on the incandescent lamp discovered current emitted from the hot carbon filament and proposed a use for it in a patent granted to him. This emission became known as the "Edison effect." None of these men, however, knew what they had, supposing that they dealt with ions such as occur in electrolysis or gas discharges. It was not until 1897–1899 that the work of J. J. Thomson showed that the negative carriers of cathode rays were a new species of particle with mass about 1700 times smaller than that of the hydrogen ion. This was the electron. Drude (1900) suggested that electrons rather than metallic ions are the carriers of current in metals, and Thomson proposed that they are also the negative charges emitted by hot metals. O. W. Richardson made a study on this basis (1901) and derived equations relating the current density to the absolute temperature. The theory was subsequently extended by W. Schottky (1919) and S. Dushman (1923). Latter developments utilized the Fermi-Dirac statistics, introduced by Sommerfeld (1928) to analyze electronic conduction in solids.

The theory of thermionic emission from metals will now be briefly outlined. The energy relationships are shown in Fig. 1, where μ is the Fermi level and ϕ the work function (the energy required to remove an electron, at the Fermi level, from the metal). In the following we consider electrons to be emitted only in the positive x direction taken to be perpendicular to the surface. For electrons to be emitted they must have sufficient energy, directed in the positive x direction, to overcome the barrier W $(\mu + \phi)$. Assuming that all of the electron's energy is kinetic, this condition may be stated as

$$\tfrac{1}{2} m v_x{}^2 > \mu + \phi$$

or

$$v_x > \left[\frac{2(\mu + \phi)}{m}\right]^{1/2} \qquad (1)$$

where m is the mass of the electron and v_x is the velocity component along the positive x direction.

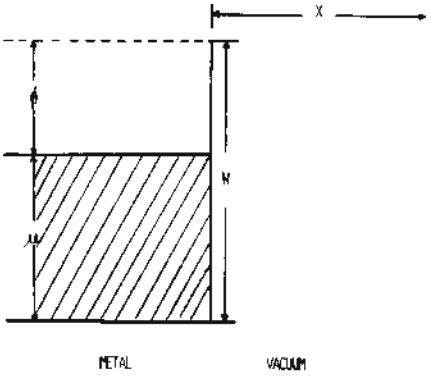

FIG. 1.

The problem now is that of calculating the number of electrons at a given temperature, which have the required velocities. In general, the number of electrons dn with a velocity in the interval v to $v + dv$ is given by the product obtained by multiplying the number of available quantum states by the probability that the states will be occupied, i.e.,

$$dn = \rho(v) f(v)\, dv_x\, dv_y\, dv_z \qquad (2)$$

where $\rho(v)$ is the density of states, $f(v)$ is the Fermi-Dirac occupancy probability and v_x, v_y, v_z refer to the velocity components in the direction signified by the subscripts. For electrons we have

$$\rho(v) = \left(2\frac{m}{h}\right)^3 \qquad (3)$$

where h is Planck's constant and

$$f(v) = \frac{1}{e^{(E-\mu)/kT} + 1} \qquad (4)$$

where

$$E = \frac{m}{2}\left(v_x{}^2 + v_y{}^2 + v_z{}^2\right),$$

k is the Boltzmann constant and T the absolute temperature.

The thermionic current in the positive x direction is obtained by multiplying Eq. (2) by qv_x, where q is the charge per electron, integrating the result over the intervals

$$\left[\frac{2(\phi + \mu)}{m}\right]^{1/2} < v_x \leqslant \infty$$

$$-\infty \leqslant v_y \leqslant \infty$$

$$-\infty \leqslant v_z \leqslant \infty,$$

and using the assumption that the exponential term in (4) is large compared to unity.

The result is the so-called Richardson-Dushman equation for the thermionic current density I:

$$I = \left(\frac{4\pi q m k^2}{h^3}\right) T^2 e^{-\phi/kT} \qquad (5)$$

or representing the term in the brackets by A

$$I = AT^2 e^{-\phi/kT}. \qquad (6)$$

Evaluation of A gives

$$A = 120 \text{ amperes cm}^{-2}\ \text{K}^{-2}.$$

The equation is based on the assumption that all the emitted electrons will be drawn to a collector. Actually, the current will be slightly less than that given by the above equation, since there is a probability that an electron approaching the metal surface will be reflected back into the metal even though it has enough energy to escape.

TABLE I

Material	A (amp cm^{-2} K^{-2})	ϕ (eV)
Tungsten	60–100	4.5
Tantalum	120	4.3
Thorium on tungsten	3–5	2.7
BaO, SrO	0.01–0.1	0.45
Thorium carbide	550	3.5

From D. G. Fink, "Electronic Engineer Handbook," New York, McGraw-Hill, 1975.

Some values of A and ϕ are given in Table 1. As may be seen, the values of A are different from the theoretical value. The primary reason is the temperature dependency of the work function. This may be seen by considering a linear temperature dependency

$$\phi(T) = \phi_0 + \alpha T.$$

Substituting into (6) gives

$$I = Ae^{-\alpha/T}\, T^2 e^{-\phi_0/kT}$$

or

$$I = A' T^2 e^{-\phi_0/kT}.$$

If $\alpha > 0$, as is often the case, then A' will be smaller than A.

The exponential term of the expression has been amply verified over a large temperature range. The work function ϕ is known for a large number of metals. It depends on the orientation of the crystal and tends to be larger for metals in which the atoms are packed closely together, smaller for open lattice metals, the range being about 1.5–6 volts. It is slightly higher on dense crystal faces than on open ones. The pure metal that is most often used as a thermionic emitter where ruggedness and high voltage are involved is tungsten, because of its strength and high melting point. For it, the values of ϕ and apparent A are about 4.5 volt and 100 amperes/cm^2 deg^2. Molybdenum, tantalum, and niobium are others used in special applications.

The thermionic properties of a metal surface are profoundly changed by thin films of foreign materials. This is the basis of the thoriated tungsten emitter used in small and medium-size vacuum tubes by Langmuir and Rodgers in 1914. The filament is made of tungsten having a small additive of thorium. In the heat treatment, some of the thorium diffuses to the surface, where it forms a quite stable deposit that is less than one atom deep. The work function of this surface is less than that of either thorium or tungsten, about 2.6 volts, and A is about 3 ampere/cm^2 deg^2. Where the tungsten filament is normally operated near 2700 K the thoriated tungsten yields a comparable emission current density at 1800–2000 K, with a very considerable saving in heating power. The surface is less rugged than that of pure tungsten.

By far the larger number of vacuum tubes use the oxide-coated filament, described by Wehnelt (1904). On nickel alloy base is deposited a relatively thick coating of the mixed oxides of barium, strontium, and calcium. Certain activation processes yield a surface with work function ϕ in the region of 1 volt. In spite of the small and variable value of the factor A, in the range of 0.01, the low work function provides a surface of high emission so that it can be used at the temperature of near 1000 K, giving still higher thermal efficiency than the thoriated tungsten. The mechanism of electron emission from this surface is considerably different from that of the pure metal. The oxide layer is normally an insulator at room temperature that becomes a semiconductor at the operating temperature. The oxides are partly dissociated so that there are metal atoms, particularly of barium, in the body of the layer and on its surface. The surface barium probably contributes to the low work function. The body barium is presumably ionized so that it contributes conduction electrons in the semiconductor. At the metal-oxide interface, there is another low-work-function surface so that electrons can pass from the metal base into the oxide, to be available for emission at the outer surface. With this modified mechanism, the emission equation still essentially holds. The reason is largely that the Boltzmann factor $\exp(\phi/kT)$ varies so rapidly with temperature that it renders other factors of little consequence experimentally.

It has been assumed that there is another electrode nearby with high enough positive voltage on it so that all of the emitted electrons are drawn to it. The current is then said to be saturated. In this condition, the current can still increase slowly with increasing voltage. The reason is that the strong electric field at the surface of the metal penetrates between the surface atoms and helps the electrons escape. The actual current then is increased above the saturation current by a factor $\exp 4.40(F^{1/2}/T)$ determined by Schottky in 1914, where F is the field strength in volts per centimeter, as verified with the refractory metals. With thoriated tungsten, the increase is more rapid than this, and with the oxide cathodes, the increase is so rapid that it is hard to say when saturation sets in.

At still higher surface fields, of the order 10 million volts/cm, another emission effect sets in, whereby the electrons are drawn out of even the cold metal. This is FIELD EMISSION, q.v.

At voltages below that required for saturation, the repulsion between the negatively charged electrons tends to limit the current. This is the space charge region, the condition in which most thermionic devices work. The current then is fairly insensitive to temperature and other conditions at the cathode so long as the anode voltage is well below the saturation value. In this condition, the current can be controlled by grids and other means. The space-charge-limited current between a plane emitting cathode and an anode at distance d from it and at voltage V, each of area 1 cm^2, is given fairly closely by the expression

$$i = 2.33 \times 10^{-6} V^{3/2}/d^2 \text{ amperes}$$

derived by Child (1911) and by Langmuir (1913). The equation is modified for a cylindrical structure, but the $V^{3/2}$ factor applies to any structure.

When the potential between emitter and plate is reversed so as to become retarding for electrons, the current is limited to the number of electrons with enough energy to overcome the retarding potential and is not limited by space charge. The current i_r is then related to the saturation current i_s by the expression

$$i_r = i_s \exp\left(-11{,}600\frac{V_r}{T}\right)$$

T being the temperature of the emitter and V_r the retarding potential. This may be written

$$\log i_r = 5030\frac{V_r}{T} + \log i_s.$$

Besides giving a means of determining the temperature of the emitter as shown by Germer (1925), the formula also is the basis of electronic devices with logarithmic response.

THERMODYNAMICS

Classical Thermodynamics is a theory which on the basis of four main laws and some ancillary assumptions deals with general limitations exhibited by the behavior of macroscopic systems. Phenomenologically it takes no cognizance of the atomic constitution of matter. All *mechanical* concepts such as kinetic energy or work are presupposed. Thermodynamics is motivated by the existence of dissipative mechanical systems. A *thermodynamic system* K may be thought of as a collection of bodies in bulk; when its condition is found to be unchanging in time (on a reasonable time scale) it is *in equilibrium*. It is then characterized by the values of a finite set of say n physical quantities, it being supposed that none of these is redundant. Such a set of quantities constitutes the *coordinates* of K, denoted by $x(=x_1, \cdots, x_n)$. Any set of values of these is a state $\mathfrak{S}$ of K. In virtue of these definitions, K is in a state only when it is in equilibrium. The passage of K from a state $\mathfrak{S}$ to a state $\mathfrak{S}'$ is a *transition* of K. A transition is *quasi-static* if in its course it goes through a continuous sequence of states, and if the forces which do work on the system are just those which hold it in equilibrium. A transition is *reversible* if there exists a second transition which restores the initial state, the final condition of the surroundings of K being the same as the initial condition. Reversible transitions are assumed to be quasi-static.

An enclosure which is such that the equilibrium of a system contained within it can only be disturbed by mechanical means is *adiabatic*, otherwise it is *diathermic*. For instance, stirring, or the passage of an electric current, constitute "mechanical means." A system K_0 in an adiabatic enclosure is *adiabatically isolated* but this does not preclude mechanical interactions with the surroundings. Its transitions are then called adiabatic.

For the time being, the masses of all substances present will be supposed fixed, and to achieve simplicity it will be given that (1) there are no substances present whose properties depend on their previous histories; (2) capillary forces as well as long-range interactions are absent. Further it will be supposed that of the n coordinates of K just $n - 1$ have geometrical character (*deformation coordinates*, e.g., volumes of enclosures), so that the work done by K in a quasi-static transition is

$$\int dW = \int \sum_{k=1}^{n-1} P_k(x) dx_k \tag{1}$$

Such a system will be called a *standard system* ($n - 1$ enclosures in diathermic contact, each containing a simple fluid, may serve as example, x_n being any one of the pressures).

The Zeroth Law Suppose two systems $K_A(x)$ and $K_B(y)$ to be in mutual diathermic contact. Experience shows that the states $\mathfrak{S}_A$ and $\mathfrak{S}_B$ cannot be assigned arbitrarily, but that there exists a necessary relation of the form

$$f(x;y) \equiv f(x_1, \cdots, x_n; y_1, \cdots, y_m) = 0 \tag{2}$$

between them. If K_C is a third system, its diathermic equilibrium with K_B on the one hand, or with K_A on the other, is governed by conditions

$$g(y;z) = 0 \tag{3}$$

and

$$h(z;x) = 0 \tag{4}$$

respectively. That these three functions are not independent is expressed by the *Zeroth Law*: *If each of two systems is in equilibrium with a third system then they are in equilibrium with each other.* It follows that any two of Eqs. (2) through (4) imply the third, i.e., they must be equivalent to equations of the form

$$\xi(x) = \eta(y) = \zeta(z) \tag{5}$$

Thus with each system there is now associated a function, its *empirical temperature function*, such that two systems can be in equilibrium if and only if their *empirical temperatures* (i.e., the values of their empirical temperature functions) are equal. Write $t = \xi(x)$ so that one has the *equation of state* of K_A. Also, t may be introduced in place of any one of the x_k. Note that the empirical temperature is not uniquely determined since $t_A = t_B$ may be replaced by $\phi(t_A) = \phi(t_B)$ where the function ϕ is monotonic but otherwise arbitrary: one has a choice of *temperature* scales. For a system not in equilibrium, temperature is not defined.

The First Law It is obvious that one can do mechanical work upon a system (say by stirring) while its initial and final states are the same. (Nothing is being said about the surroundings!) In this sense mechanical energy is not conserved. One might however hope that it is conserved at least in a restricted class of transitions. That this is so is asserted by the *First Law: The work W_0 done by a system* K_0 *in an adiabatic transition depends on the terminal states alone.* Thus if $\mathfrak{S}'(x')$, $\mathfrak{S}''(x'')$ are the terminal states

$$W_0 = F(x'; x'')$$

If $\mathfrak{S}'''(x''')$ is a third state, and the previous transition proceeds via $\mathfrak{S}'''$, W_0 must not depend on x''', i.e.,

$$F(x'; x''') + F(x'''; x'') \equiv F(x'; x'')$$

It follows that there must exist a function $U(x)$, defined to within an arbitrary additive constant, such that

$$F(x';x'') = U(x') - U(x'')(= -\Delta U \text{ say})$$

$U(x)$ is the *internal energy function* of K. (To make sure that U is in fact defined for all states, one assumes that *some* adiabatic transition always exists between any pair of given states.) The energy of a compound standard system is the sum of the energies of its constituent standard systems. Further, U must be a monotonic function of t, and it is convenient to choose the scale of t such that $\partial U/\partial t > 0$.

When the transition from $\mathfrak{S}'$ to $\mathfrak{S}''$ is adiabatic, $W_0 + \Delta U$ vanishes by definition of U. If the transition is not adiabatic and W is the work done by K, the quantity

$$\Delta U + W(=Q, \text{say}) \qquad (6)$$

will in general fail to vanish. Q is then called the *heat absorbed* by K. Every element of a quasi-static adiabatic transition is subject to $dQ = 0$, i.e., by Eqs. (1) and (6), to the differential equation

$$\sum_{k=1}^{n-1}\left(P_k(x) + \frac{\partial U(x)}{\partial x_k}\right)dx_k + \frac{\partial U}{\partial t}\,dt = 0 \qquad (7)$$

The Second Law Experiment shows that if $\mathfrak{S}'$ and $\mathfrak{S}''$ are arbitrarily prescribed states, then it may be that no adiabatic transition from $\mathfrak{S}'$ to $\mathfrak{S}''$ exists. When this is the case one says that $\mathfrak{S}''$ is inaccessible from $\mathfrak{S}'$, but $\mathfrak{S}'$ is then accessible from $\mathfrak{S}''$, as has been already assumed. The states may of course happen to be mutually accessible. The existence of states adiabatically inaccessible from a given state is asserted precisely by the *Second Law: In every neighbourhood of any state* $\mathfrak{S}$ *of an adiabatically isolated system, there are states inaccessible from* $\mathfrak{S}$. (This formulation of the Second Law is known as the *Principle of Carathéodory*.) *A fortiori* this law applies to quasi-static transitions, i.e., those which satisfy Eq. (7). It asserts there are states $\mathfrak{S}''$ near $\mathfrak{S}'$ such that no functions $x_k(t)$ exist which satisfy Eq. (7) and whose values when $t = t''$ are just x_k'', $(k = 1, \cdots, n - 1)$. It is merely a mathematical problem (the Theorem of Carathéodory) to prove that this is the case if and only if there exist functions $\lambda(x)$ and $s(x)$, $(x_n \equiv t)$ such that the left-hand member is identically equal to λds, where ds is the total differential of s. Thus, the Second Law entails that

$$dQ = dU + dW = \lambda\, ds \qquad (8)$$

(dQ is of course not a total differential). s is called the *empirical entropy function of* K. It is not uniquely determined, since it may be replaced by any monotonic function of s. If two standard systems K_A and K_B in diathermic contact make up a compound system K_C, $dQ_C = dQ_A + dQ_B$, i.e., because of Eq. (8),

$$\lambda_A ds_A + \lambda_B ds_B = \lambda_c ds_c$$

By including s_A, s_B and the common empirical temperature t among the coordinates of K_C, one infers that

$$\lambda_A = T(t)\theta_A(s_A), \quad \lambda_B = T(t)\theta_B(s_B), \quad \lambda_C = T(t)\theta(s_A, s_B)$$

The common function $T(t)$ is called the *absolute temperature function*, while

$$S_A(s_A) = \int \theta_A(s_A) ds_A$$

is the *metrical entropy* of K_A. The "element of heat" dQ of any standard system thus splits up into the product of a universal function of the empirical entropy and the total differential $dS(x)$ of the metrical entropy function:

$$T\,dS = dU + dW \qquad (9)$$

By multiplying T by a constant and dividing S by the same constant, T can be arranged to be positive.

If one now chooses $x_n = S$ and recalls that the $x_k (k < n)$ are freely adjustable, the Second Law would be violated if S were also adjustable at will (by means of non-static adiabatic transitions.) Taking continuity requirements into account, it follows that S can either never decrease or never increase. The single example of the sudden expansion of a real gas shows that it can never decrease. One has the *Principle of Increase of Entropy: The entropy of an adiabatically isolated system can never decrease.*

So far the first three principal laws have been brought in in their traditional order. This has the disadvantage that one comes to grips with the heart of thermodynamics, namely, the existence of irreversible processes and its consequences, only after one has encountered certain laws and concomitant concepts, such as temperature, heat, and energy, which are largely irrelevant to it. It is, in fact, possible to begin with the Second Law provided one adopts an appropriate formulation, e.g., *there exists an ordering of the states of any standard system K, reflected in the existence of a function* $s(x)$ *such that if* s', s'', *are the values of* $s(x)$ *for arbitrarily selected states* $\mathfrak{S}'$, $\mathfrak{S}''$ *of K then* $\mathfrak{S}''$ *is adiabatically inaccessible from* $\mathfrak{S}'$ *if and only if* $s'' < s'$. Then $s(x)$ is the empirical entropy function already encountered. On bringing in the First Law now it follows at once that $dQ = \lambda\, ds$ for quasi-static transitions. The Principle of Increase of Entropy now follows trivially from the Second Law in the revised formulation. Further, one recognizes immediately that the First and Second Laws are independent of each other: the Second could remain valid even if the First were found to be false.

The Third Law It is known from experiment that for given values of the deformation coordinates, the energy function has a lower bound U_0. The question arises whether the entropy S has an analogous property. It is found in practice that the specific heats $\partial U/\partial T$ of all substances appear to go to zero at least linearly with T as $T \to 0$. This ensures that the function S goes to a finite limit S_0 as $T \to 0$. Experiment shows however further that as $T \to 0$, the derivatives of S with respect to the deformation coordinates also go to zero. In contrast with U_0, S_0 has therefore the remarkable property that it is independent of the deformation coordinates. One thus arrives at the *Third Law: The entropy of any given system attains the same finite least value for every state of least energy.* One immediate consequence of this is that the so-called *classical ideal gas* (the product of whose volume V and pressure P is proportional to T) cannot exist in nature. Further, no system can have its absolute temperature reduced to zero. The Third Law is therefore a statement about the properties of functions, not of systems, at $T = 0$.

The practical applications of the theory just outlined divide themselves into two broad classes: (1) those which are based on the existence and properties of the functions U and S and some others related to them—all "thermodynamic identities" being merely the integrability condition for the total differentials of these functions; and (2) those which are based on the Principle of Increase of Entropy: the entropy of the actual state of an adiabatically enclosed system being greater than that of any neighbouring "virtual" state.

The most important of the auxiliary functions just mentioned are
the *Helmholtz Function:*

$$F = U - TS \tag{10}$$

the *Gibbs Function:*

$$G = U - TS + \sum_{k=1}^{n-1} P_k x_k \tag{11}$$

the *enthalpy:*

$$H = U + \sum_{k=1}^{n-1} P_k x_k \tag{12}$$

sometimes called *thermodynamic potentials.* Then, e.g.,

$$dF = -S\,dT - dW$$

F therefore contains all available quantitative information about K, since

$$S = -\frac{\partial F}{\partial T}, \quad \text{and} \quad P_k = -\frac{\partial F}{\partial x_k} \tag{13}$$

The same is true of G for instance, since

$$S = -\frac{\partial G}{\partial T}, \quad \text{and} \quad x_k = \frac{\partial G}{\partial P_k}$$

F and G are naturally taken as functions of $x_1, \cdots, x_{n-1}, T$ and of $P_1, \cdots, P_{n-1}, T$, respectively. At times one speaks of F as the "Helmholtz free energy" and of G as the "Gibbs free energy." In an *isothermal* reversible transition, the amount W of work done by a system is equal not to the decrease of its energy U but to the decrease $-\Delta F$ of its (Helmholtz) free energy. In the presence of internal sources of irreversibility

$$W < -\Delta F$$

In considering physicochemical equilibria, that is to say, if one is interested in the internal constitution of a system in equilibrium when changes of phase and chemical reactions are admitted, one introduces the *constitutive coordinates* n_i^α; this being the number of moles of the ith constituent C_i in the αth phase. The definitions of Eqs. (10) through (12) remain unaltered, for the n_i^α do not enter into the description of the interaction of the system with its surroundings. Let an amount dn_i^α of C_i be introduced quasistatically into the αth phase of the system. The work done on K shall be $\mu_i^\alpha dn_i$. The quantity μ_i^α so defined is the *chemical potential* of C_i in the αth phase. It is in general a function of all the coordinates of K. Then, identically,

$$dG = \sum_{k=1}^{n-1} x_k dP_k - S\,dT + \sum_i \sum_\alpha \mu_i^\alpha dn_i^\alpha$$

Integrability conditions such as

$$\partial \mu_i^\alpha / \partial T = -\partial S / \partial n_i^\alpha$$

are applications of the first kind. On the other hand, the minimal property of G, derived from the maximal property of S, requires that

$$\sum_i \sum_\alpha \mu_i^\alpha dn_i^\alpha = 0$$

when all virtual states differ only in the values of the constitutive coordinates. If the system is chemically inert, the dn_i^α are subject only to the requirements of the conservation of matter. One then concludes that if there are c constituents and p phases, i.e., $n + pc$ coordinates in all, then the number f of these to which arbitrary values may be assigned is

$$f = c - p + n$$

This typical application of the second kind is the Gibbs PHASE RULE (for inert systems.) This rule is often stated merely for systems with only two external coordinates ($n = 2$, e.g., $x_1 = P$, $x_2 = T$). There must then be no internal partitions within the system nor may it, for instance, contain magnetic substances in the presence of external magnetic fields.

The beauty and power of phenomenological thermodynamics lies just in the generality and paucity of its basic laws which hold independently of any assumptions concerning the microscopic structure of the systems which they govern. Its quantitative content is limited to conditions of equilibrium. Its conceptual framework is too narrow to permit the description of the temporal behavior of systems, except in as far as it makes it possible to decide which one of any pair of states of an adiabatically enclosed system must have been the earlier state.

Statistical thermodynamics seeks to remedy these deficiencies by making specific assumptions about the microscopic structure of the system K, and relating its macroscopic behaviour to that of its atomic constituents. K is then to be regarded as an *assembly* of a very large number of particles, which, on a nonquantal level, is a mechanical system with, say, N degrees of freedom. A *microstate* of K is a set of values of its N coordinates and its N conjugate momenta. It is out of the question to measure all these at a given time. One therefore constructs a *representative ensemble* $\mathcal{E}_{\mathrm{K}}$ of K, which is an abstract collection of a very large number of identical copies of K. At any time t, the members of $\mathcal{E}_{\mathrm{K}}$ will be in different microstates. Let the fractional number of members of the ensemble whose microstates lie in the range dp, dq about p, q be $\phi\, dp\, dq$. Then ϕ is the *probability-in-phase*, and with $d\Gamma = dp\, dq$

$$\int \phi\, d\Gamma = 1 \qquad (14)$$

The reason for this terminology is implicit in the *Postulate: The probability that a given assembly* K *will, at time t, be in a microstate lying in the range* $d\Gamma$ *about p,q, is equal to the probability* $\phi\ d\Gamma$ *that the microstate of a member of* $\mathcal{E}_{\mathrm{K}}$*, selected at random at time t, lies in the same range.*

The mean value $\langle f\rangle$ of a dynamical quantity f is defined to be

$$\langle f\rangle = \int f\phi\, d\Gamma$$

If N is sufficiently large, fluctuations about the mean will usually be negligible.

When K is in equilibrium ϕ must be constant in time, and this will be the case if it is a function of the (time-independent) Hamiltonian H of K. Ensemble averages are now assumed to coincide with temporal averages. When, in particular, K is in diathermic equilibrium with its surroundings one can show that ϕ must have the form

$$\phi = \exp[(\Phi - H)/\theta] \qquad (15)$$

where Φ and θ are independent of p,q. Then

$$\theta\langle \ln \phi\rangle = \Phi - \langle H\rangle \qquad (16)$$

and, because of Eq. (14)

$$d\int \exp[(\Phi - H)/\theta]\, d\Gamma = 0 = \langle d[(\Phi - H)/\theta]\rangle$$

where d refers to a variation of the macroscopic coordinates of K. Using Eq. (16) and its variation, the relation

$$-\theta d\langle \ln \phi\rangle = d\langle H\rangle - \langle dH\rangle \qquad (17)$$

follows. Now $\langle H\rangle$ ($=\bar{U}$, say) is the total energy of the assembly, while $\langle dH\rangle$ is the average of the change of the potential energy, i.e., the work $-dW$ done by the external forces on K. If one writes

$$\bar{S} = -k\langle \ln \phi\rangle$$

where k is a constant, Eq. (17) becomes

$$k^{-1}\theta\, d\bar{S} = d\bar{U} + dW$$

This is identical with the phenomenological relation of Eq. (9) if one formally identifies S with $\bar{S}$, U with $\bar{U}$ and θ with kT. In this way, contact with the phenomenological theory has been established, and the quantities characteristic of the one theory have been *correlated* with that of the other. With this correlation, or interpretation, Φ becomes F. However, because of Eqs. (14) and (15)

$$F = -kT \ln \int \exp(-H/kT) d\Gamma$$

so that if only H is known, the integral on the right (the *partition function*), and thus F, can be calculated. The equation of state of a real gas can thus in principle be obtained from a knowledge of the forces operating within the assembly. This illustrates how the additional information put into the theory yields a correspondingly greater output. Phenomenologically such an equation of state might be written as

$$PV = \sum_{n=1}^{\infty} B_n(T)\, V^{1-n}$$

but here each of the *virial coefficients* B_1, B_2, $\cdots$ must be measured separately.

If the quantum mechanical behavior of matter is taken into account, the fact that one cannot assign precise simultaneous values to canonically conjugate quantities must produce modifications of the details of the statistical theory. However, it is not necessary to consider these here.

THERMOELECTRICITY

Thermoelectricity is the subject dealing with the relation between electrical effects (potential differences, current flow) and thermal effects (temperature differences, heat flow) in a conducting material. The conducting material is not limited to solids in which the charge carriers are electrons. For example, thermoelectric effects can be observed in ionic conductors, where the carriers are ions, or in semiconductors where the carriers may be holes or electrons.

1. Macroscopic Observations (a) *Seebeck Effect*. Suppose we take two conducting wires (of different chemical composition) A and B joined together as in Fig. 1, and maintain junction d at a temperature T_1 different from the temperature T_2 of junction c. Then a difference of potential $V_B - V_A$ is observed at the terminals a and b (both at the same temperature), or, if a and b are connected through a sensitive current meter a current will be observed to flow. The effect was observed by Seebeck in 1826 and has carried his name thereafter. This combination of conductors is called a *thermocouple*. Now suppose that $T_2 = T_1 + \Delta T$, where ΔT is a small increment in T, and a voltage ΔV is observed at terminals a and b, then the thermopower of the thermocouple is defined by

$$S_{AB} = \lim_{\Delta T \to 0} (\Delta V/\Delta T). \qquad (1)$$

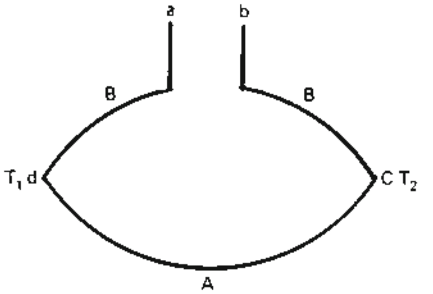

FIG. 1. A circuit consisting of two different conductors A and B. If $T_1 \neq T_2$, then a voltage $V_b - V_a$ appears between terminals a and b.

Although the appearance of the Seebeck voltage requires the presence of two disimilar conductors, the thermoelectric effects are determined by intrinsic properties of the individual conductors, and indeed

$$S_{AB} = S_B - S_A \qquad (2)$$

where S_B and S_A are termed *absolute thermopowers* of the individual conductors A and B. Both S_B and S_A will generally be temperature dependent, and the total voltage observed at a and b for a finite difference in T_1 and T_2 is

$$V_b - V_a = \int_{T_1}^{T_2} (S_B - S_A)\, dT. \qquad (3)$$

If T_1 is constant then $V_b - V_a$ is a function of T_2. If this function is determined by calibration against a standard thermometer, then the voltage of the thermocouple can be used to measure temperature, or it may be used to control a switch. These are the bases of thermocouple thermometers and thermostatic controls which are the two main practical uses of the Seebeck effect.

(b) *Peltier Effect*. In the same Fig. 1 suppose that a battery is connected across terminals a and b so that an electrical current density (current divided by cross section) J flows in the circuit. Then it is observed that heat is evolved at one of the junctions and absorbed at the other. This effect is different from Joule (I^2R) heating in that, when the current is reversed, the junction which previously evolved heat absorbs heat, and vice versa, whereas the Joule heat is independent of current direction. Mathematically

$$Q = \Pi_{AB} J \qquad (4)$$

where Q is the Peltier heat absorbed per unit time and unit cross-sectional area. Π_{AB} is the Peltier coefficient of the thermocouple, but again it can be written as

$$\Pi_{AB} = \Pi_B - \Pi_A \qquad (5)$$

where Π_A and Π_B are intrinsic properties of materials A and B. By using semiconductors which have high Peltier coefficients the Peltier effect can be used in a refrigerator with no moving parts.

From the above description it is clear that S_{AB} can easily be measured experimentally. Π_{AB} can also be measured but with somewhat more difficulty. It is not obvious, however, how one separates S_{AB} and Π_{AB} into parts characteristic of A and B individually. The third thermoelectric effect is important in this respect.

(c) *Thomson Effect.* This involves one conductor only. If we pass a current density J through a homogeneous wire then the heat production per unit volume is

$$Q = \rho J^2 - \mu J \, dT/dx \qquad (6)$$

where ρ is the resistivity of the material, dT/dx is the temperature gradient along the wire, and μ is called the *Thomson coefficient.* The first term is just the Joule I^2R term which does not reverse on heating; the second term is the Thomson heat, whose measurement depends on the fact that it changes sign when J changes directions.

Using techniques of irreversible thermodynamics it is possible to show rigorously that the three effects are connected by the Kelvin relations:

$$\mu = T \, dS/dT \qquad (7)$$

and

$$\Pi = TS. \qquad (8)$$

Hence if μ_A is measured as a function of T then S_A and Π_A can be obtained from

$$S_A = \int \frac{\mu_A(T)}{T} \, dT \qquad (9)$$

and

$$\Pi_A = TS_A. \qquad (10)$$

The measurement of $\mu(T)$ is a difficult experiment. Fortunately it only has to be performed on one material and S_A is then obtained from Eq. (9). Thereafter S_{AB} can be measured in a much simpler experiment and S_B derived from Eq. (2). Recently, first-class measurements of μ_A for Pb and Cu have been made by Roberts.[4] The derived values of S_A are now the accepted standards for use in thermocouples to derive the thermopowers of any other material. There is one other important family of standard materials, namely superconductors, which have zero thermopower. At low temperatures ($T < 22$ K) it is possible to make a thermocouple where A and B are normal and superconducting materials, respectively. Then $S_A = S_{AB}$ which can be more or less easily measured .

In Fig. 2 we show the thermopower of a simple metal–aluminum.[5,6] It is typical in the sense that at low temperature there is a large dip (or peak) which arises from a mechanism called *phonon drag.* It is superimposed on a more slowly varying background arising from a diffusion mechanism. Simple free electron theory indicates that for negative charge carriers (electrons in this case) the sign of both of these quantities should be negative. For more complicated metals (e.g., the noble metals, Fig. 3) they are frequently positive. In semiconductors the sign of the thermopower has frequently been used to decide whether the charge carriers were electrons or positive holes.

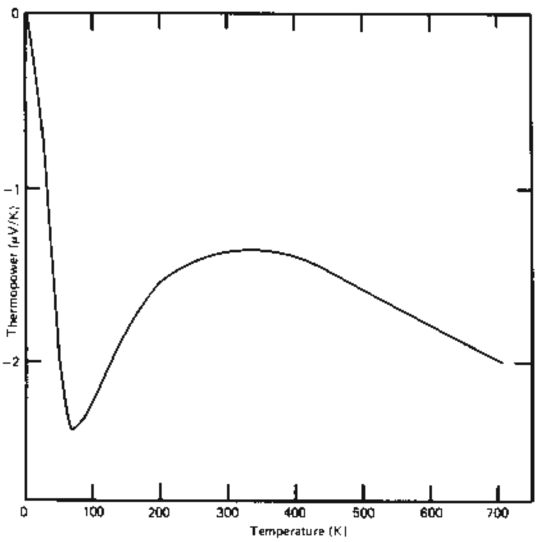

FIG. 2. Thermopower of pure aluminum.[5,6]

2. Microscopic Theory The thermopower can frequently be divided into two components, diffusion thermopower and phonon drag thermopower.

(a) *Diffusion Thermopower.* Consider a bar of metallic conductor with its ends at temperatures T and $T + \Delta T$ as in Fig. 4. Electrons at G will on the average be "hotter," i.e., have higher energies and velocities than those at F. The hot electrons at E will tend to diffuse toward F where the density of hot electrons is smaller. The cold electrons at F will tend to diffuse toward E where the density of cold electrons is smaller. If these two effects were the same they would cancel and there would be no thermopower. However, the diffusion process involves scattering of electrons from impurities, imperfections, and lattice vibrations (phonons). If the scattering is energy dependent—suppose hot electrons are scattered more than cold ones, for example—then the cold ones diffuse more rapidly than the hot ones. As a consequence the density of electrons increases at the hot end. But increased density means that an electrostatic field will be produced in the material. This field opposes further increase in electron density at the hot end. An equilibrium is reached when the net number of electrons diffusing in one direction is equalled by the number returning under the action of the electric field. Thus in a single material a thermoelectric field is set up. Its magnitude is determined by the rate of change of electron scattering cross section with energy. This can be positive or

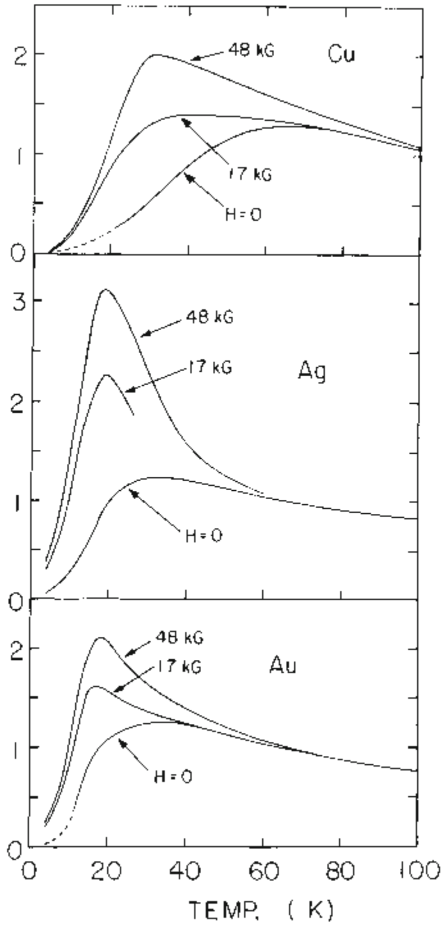

FIG. 3. Thermopower of the noble metals in a series of magnetic fields.[8]

negative, resulting in thermoelectric fields of either sign. To measure the thermoelectric field one attaches a voltage probe at each end and connects these to a sensitive voltmeter. This is just the circuit of Fig. 1 again. But if there is a temperature gradient along A there must also be one along B and therefore there is a thermoelectric field set up in B. The voltage measured is the consequence of these fields in the two conductors. That is, S_{AB} rather than S_A or S_B is measured.

The significant feature of this simple analysis is that, in contrast to resistivity, which is proportional to scattering cross section, thermopower depends critically on the rate of change of scattering cross sections with energy. This property makes it very sensitive to impurities, crystal imperfections, structural changes, etc. For example, we show in Fig. 5 how the thermopower changes at two phase changes, at 38 and 54 K, of the one-dimensional organic conductor tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ).[7]

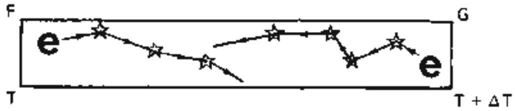

FIG. 4. Electron diffusion in a bar of metal with a temperature gradient.

(b) *Phonon Drag.* The simplest picture of diffusion thermopower assumes that the phonons (lattice vibrations) are always in local thermal equilibrium. In fact this will never be the case exactly and phonons will move along the temperature gradient. They will lose their momentum by interaction with crystal imperfections and with electrons. If the phonon-electron interaction predominates then the phonons will lose momentum to the electrons, pushing the electrons to one end of the conductor and thereby setting up an added contribution to the thermoelectric field. This contribution produces phonon drag thermopower. (The reason for the name phonon drag is more apparent in a parallel treatment of the Peltier effect, where the current of electrons "drag" the phonons with them.) The phonon drag contribution is most important in the temperature region where phonon-electron scattering predominates. This is for $T \sim \frac{1}{5}\theta_D$, where θ_D is the Debye temperature. At lower temperatures the number of phonons available for phonon drag decreases rapidly, and at higher temperatures the phonons tend to lose their momentum by phonon-phonon scattering rather than by phonon-electron scattering processes.

Measurements in a magnetic field (Fig. 3) indicate that the thermopower is highly field

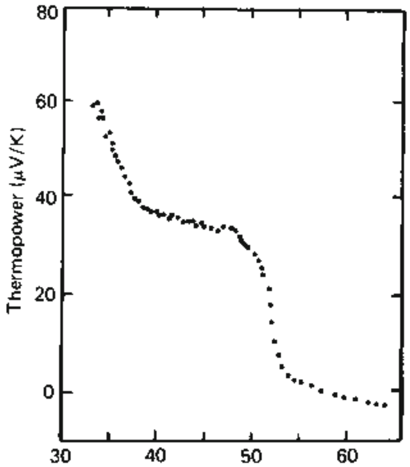

FIG. 5. Thermopower of TTF-TCNQ in the vicinity of phase transitions at 38 and 54 K.[7]

dependent in this region, but the definitive separation of the field effect into diffusion and phonon drag components has not been achieved.

THIN FILMS

General The term "thin films" is used for a wide variety of physical structures. Self-supporting solid sheets usually are called foils when thinned from thicker material by such methods as rolling, beating, or etching; and films, when obtained by stripping a deposited layer from its substrate. Supported thin films are deposited on planar or (in special cases) curved substrates by such methods as vacuum evaporation, cathode sputtering, electroplating, electroless plating, spraying, and various chemical surface reactions in a controlled atmosphere or electrolyte. Thicknesses of such supported films range from less than an atomic monolayer to a few microns ($1\mu = 10^{-4}$ cm). A frequently used thickness measure is the angstrom ($1Å = 10^{-8}$ cm). Thin films not forming a continuous sheet are called "island films." Particularly, noble metals may condense as islands of considerable thickness (up to ~ 10^2 Å).

In scientific studies and technical applications, the use of well-controllable deposition methods such as vacuum evaporation and cathode sputtering are generally preferred. The film structure is markedly influenced by such deposition parameters as substrate composition and surface structure, source and substrate temperatures, deposition rate, and composition and pressure of the ambient atmosphere (where applicable). In general, the structure of films is more disordered than the corresponding bulk material. Smaller grains, higher dislocation concentrations, and deviations from stoichiometry are typical, and films approach bulk structure only as a limiting case. Under certain growth conditions, films exhibit preferential crystal orientations or even epitaxy. (Epitaxy means that the film structure is determined by the crystal structure and orientation of the underlying substrate.)

Solid thin films are common study objects in most phases of solid-state physics. They supply the samples for the study of general structural and physical properties of solid matter where special beam methods require small quantities of material or extremely thin layers, as for instance in transmission electron microscopy and diffraction, NEUTRON DIFFRACTION, UV spectroscopy, and X-RAY DIFFRACTION and SPECTROSCOPY. Thin films represent the best means for studying physical effects, where these effects are caused by the extreme thinness of the material itself. Examples are the rotational switching of ferromagnetic films, electron tunneling phenomena, electromagnetic skin effects of various kinds, and certain optical interference phenomena (see FERROMAGNETISM, SKIN EFFECT and TUNNELING). Films also are convenient vehicles for the investigation of nucleation and crystal growth, and for states of extremely disturbed thermodynamic equilibrium.

Presently, films find three major industrial uses: the decorative finishing of plastics, optical coatings of various kinds (mainly antireflection coatings, reflection increasing films, multilayer interference filters, and fluorescent coatings), and in electronic components from transistors or resistor-capacitor networks to such specialized devices as magnetic storage bits, photosensors, and cryotrons. The restricted space only permits the discussion of a few selected research and application areas.

Nucleation, Growth and Mechanical Properties of Films In vacuum evaporation, molecules or atoms of thermal energy are deposited at a uniform angle of incidence and under well-defined environmental conditions. Most nucleation and growth studies, therefore, have been made on evaporated films. A particle approaching the substrate enters close to its surface a field of attracting short-range London forces with an exchange energy proportional to $-1/r^6$. At a still shorter distance r, repulsive forces proportional to $e^{-r/\text{constant}}$ resist the penetration of the electron clouds of the surface atoms. Due to the atomic or crystalline structure of the substrate, this potential field exhibits periodicity or quasiperiodicity in the substrate plane. The freshly condensed particles migrate over the surface with a jump frequency $i_D \propto \exp(-Q_D/kT)$, or desorb with a frequency $i_{ad} \propto \exp(-Q_{ad}/kT)$, where the activation energy Q_D is often approximately one-fourth of Q_{ad}. Permanent condensation occurs in most cases at distinct nucleation centers which may consist of deep potential wells of the substrate, clusters of condensed particles, or previously deposited "seed" particles of a different material. The number of nuclei formed in the second case is strongly temperature and rate dependent.

Most metals always condense in crystalline form, but the grain size is extremely small at low temperatures (on the order of a few angstroms) and increases markedly with increasing substrate temperatures. Grain size decreases with increasing deposition rates. The condensation of amorphous or quasi-liquid phases at low temperatures has been observed for such metals as antimony and bismuth and a few dielectrics. Some of these materials, on annealing, pass through otherwise unobserved, and probably metastable, phases.

Stresses of considerable magnitude are often observed in deposited films. The main causes of these stresses are a mismatch of expansion coefficients between substrate and film, enclosed impurity atoms, a high concentration of lattice defects and, in very thin films, a variety of surface effects. Often, the stresses resulting from lattice defects can be minimized by the choice of a higher substrate temperature during deposition, or they can be reduced by a post-deposition anneal. Metal films frequently exhibit tensile strengths which are considerably larger than those of the corresponding bulk materials.

Thin-film Optics Deposited metal mirrors probably represent the oldest optical application of films. High-quality mirrors usually are produced by the vacuum evaporation of aluminium on an appropriately shaped glass substrate. Often, a glow-discharge cleaning of the substrate or a chromium undercoat is first applied to increase the adhesion of the aluminium. After deposition, the aluminium is protected by anodic oxidation or an evaporated overcoat of SiO, SiO_2, or Al_2O_3.

For SiO, maximum reflectance in the visible spectral region is achieved at a thickness of about 1400Å. Rapid SiO evaporation reduces the reflectance at shorter wavelengths.

Single or multilayer coatings find increasing use as optical interference filters. These film stacks may consist solely of transparent films of different refractive indices n_f, or a combination of absorbing and nonabsorbing layers. Common low-index materials for glass coatings in the visible region of the spectrum are MgF_2(n_f = 1.32 to 1.37), and cryolite Na_3AlF_6(n_f = 1.28 to 1.34); high-index materials are SiO (n_f = 1.97), ZnS ($n_f \approx 2.34$), TiO_2(n_f = 2.66 to 2.69) and CeO_2 (n_f = 2.2 to 2.4). The indices are given for the sodium D line. Various semiconductors are used for infrared coatings.

At each air-film, film-film, or film-substrate interface, the incident light amplitude is split into a reflected and a transmitted fraction according to the Fresnel coefficients

$$f_{j-1} = (\hat{\mathfrak{n}}_{j-1} - \hat{\mathfrak{n}}_j)/(\hat{\mathfrak{n}}_{j-1} + \hat{\mathfrak{n}}_j) \text{ and}$$
$$g_{j-1} = 2\hat{\mathfrak{n}}_{j-1}/(\hat{\mathfrak{n}}_{j-1} + \hat{\mathfrak{n}}_j)$$

where j and $j - 1$ denote the number of the optical layer counted from the side of the incident beam. $\hat{\mathfrak{n}}_j = \mathfrak{n}/\cos\Theta_j$ for p polarization or $\hat{\mathfrak{n}}_j = \mathfrak{n}_j \cos\Theta_j$ for s polarization is the effective refractive index, and $\mathfrak{n}_j = n_j - ik_j$ the refractive index of the j layer.

$$\cos\Theta_j = \sqrt{(\sqrt{p_j^2 + q_j^2} + p_j)/2}$$
$$-i\sqrt{(\sqrt{p_j^2 + q_j^2} - p_j)/2}$$

$$p_j = 1 + (k_j^2 - n_j^2)\,[n_0 \sin\theta_0/(n_j^2 + k_j^2)]^2$$
$$q_j = -2n_jk_j\,[n_0 \sin\theta_0/(n_j^2 + k_j^2)]^2$$

The symbol θ_0 is the angle of incidence in the incident medium.

For nonabsorbing film stacks ($k_i = 0$; $i = 1, 2 \cdots, m + 1$), the over-all reflectance and transmittance may be obtained by summing the multiple coherent reflections between the film boundaries. A more general treatment based on electromagnetic theory yields for amplitude reflectance and transmittance the recursion formulas

$$r_{(j-1)-} = (f_{j-1} + r_{j-} \exp(-2i\hat{\Phi}_j))/$$
$$(1 + f_{j-1}r_{j-} \exp(-2i\hat{\Phi}_j))$$

and

$$t_{(j-1)-} = (g_{j-1}t_{j-} \exp(-i\hat{\Phi}_j))/$$
$$(1 + f_{j-1}r_{j-} \exp(-2i\hat{\Phi}_j))$$

$\hat{\Phi}_j = \Phi_j \cos\Theta_j$ is the effective phase thickness. $\Phi_j = (2\pi/\lambda)\mathfrak{n}_j l_j$ where λ is the wavelength in vacuo and l_j is the geometrical film thickness. The recursion is started on the side of emergence, using the initial conditions $r_{m-} = f_m$ and $t_{m-} = g_m$. Intensities are given by $R = |r_{0-}|^2$ and $T = (\Re\,\mathfrak{n}_{m+1}/n_0)\;|t_{0-}|^2$ where $\Re$ denotes "real part of." If A_j is the absorption in the layer j, $R + T + \Sigma_j A_j = 1$.

A single antireflection coating of $\lambda/4$ optical thickness $n_f l_f$ yields zero reflectance at $n_f = \sqrt{n_{glass}}$. A double layer coating of $\lambda/4$ films requires $n_2/n_1 = \sqrt{n_g}$. The transmission of a Fabry-Perot interference filter consisting of a dielectric spacer layer between two partially reflecting metal films is given by $I/I_0 = [(1 + A/T)^2 + (4R/T^2)\sin^2(\delta - \Phi)]^{-1}$ where $\Phi = 2\pi nl\cos\theta/\lambda$. R, T, and A are the reflection, transmission and absorption coefficients of the reflecting layers. The refractive index and thickness of the spacer film are n and l. θ is the angle of refraction in the spacer, and δ the phase change for reflections at the spacer-metal film interfaces. $(I/I_0)_{\max} = (T/(1-R))^2$ and $(I/I_0)_{\min} = (T/(1+R))^2$. The band pass half-width is $\Delta\lambda_{1/2} \simeq \lambda\,(1-R)/m\pi R^{1/2}$ for the interference order m ($m\pi = \Phi$). More complex coatings and filters, and their various applications, cannot be discussed here. It should be mentioned, however, that films play a very important role today in the accurate determination of the optical constants of many materials, but particularly of metals (see REFLECTION).

Film Electronics Deposited dielectric film materials in common use are SiO_2, Al_2O_3, Si_3N_4, and various glasses. Thin capacitive layers in the 100 to 500 Å thickness region are often produced by the anodization of tantalum and aluminum to Ta_2O_5 or Al_2O_3, respectively. The breakdown strength and dielectric constant of films approach bulk values, but might be reduced by surface roughness, structural faults, and lower density. According to the Lorentz-Lorenz formula, the dielectric constant D changes with reduced density ρ as $dD/d\rho = 3C/(1-C\rho)^2$, where C is a constant depending on the material. On metal-dielectric-metal films, quantum mechanical tunneling through the dielectric film becomes observable below a dielectric thickness of about 100 Å. For applied voltages less than the metal-insulator work function ϕ, the tunneling current density J is proportional to the applied voltage V, demonstrating that the low-voltage tunneling resistance is ohmic. $J = (qV/h^2s)(2m^*\phi)^{1/2}\ \exp\ [-(4\pi s/h)(2m^*\phi)^{1/2}]$. At high applied voltages ($qV > \phi$), the current increases very rapidly: $J = (q^2V^2/8\pi h\phi_s{}^2)\exp[-(8\pi s/3hqV)(2m^*)^{1/2}\phi^{3/2}]$. s is the insulator thickness, m^* the electronic effective mass, and q the electron charge. Thicker dielectric films may exhibit in high fields appreciable Schottky or avalanche currents when they are greatly disordered.

Polycrystalline metal films generally show, due to their low structural order, a larger resistivity than the bulk material. According to Matthiessen's rule, the total resistivity can be expressed as $\rho = \rho(t) + \rho(i)$ where $\rho(t)$ is the temperature-dependent resistivity associated with scattering by lattice vibrations, and $\rho(i)$ is a temperature-independent resistivity caused by impurity or imperfection scattering. Very thin specimens with a thickness comparable to the electron mean free path show a $\rho(i)$ rapidly increasing with decreasing thickness. This increase is caused by an increasing contribution of non-specular electron scattering at the film surfaces. By annealing a metal film, $\rho(i)$ might be reduced permanently. A large $\rho(i)$ results in a small temperature coefficient α.

Many known superconductors can be deposited as super-conductive films (see SUPERCONDUCTIVITY). Through thin-film experiments, the energy gap in semiconductors can be measured, and material parameters, such as the penetration depth of magnetic fields, can be studied at dimensions less than the coherence range.

Studies of semiconductor films have shown many facets. The properties of epitaxial films have mainly been investigated on Ge and Si, and to a lesser degree on III-V compounds. Much work has been done on polycrystalline II-VI films, particularly with regard to the stoichiometry of the deposits, doping and post-deposition treatments, conductivity and carrier mobility, photo-conductance, fluorescence, electroluminescence, and metal-semiconductor junction properties. Among other semiconductors, selenium, tellurium, and a few transition metal oxides have found some interest.

Film resistors, capacitors, and interconnected R-C net-works on planar glass or ceramic substrates are finding widespread industrial use. Common resistor materials are carbon, nichrome and tin oxide in individual components; and nichrome, tantalum nitride, SiO-chromium cermet and cermet glazes in planar networks. Gold, copper, aluminum, or tantalum are used for termination lands, connection leads, and capacitor plates. SiO_2, Al_2O_3 and Si_3N_4 serve as film capacitor dielectrics and crossover insulation. The geometrical configuration of the desired component or circuit pattern is obtained either by deposition through mechanical masks or by removing from a continuous sheet the undesired portions after the deposition process is completed. This removal is frequently accomplished by a combination of photolithographic and etch processes.

The minimum length l and width w of a resistor are calculated from the given resistance R, the sheet resistance $\mathfrak{R}$ in ohms per square, dissipated power P, and permissible power dissipation per square inch $\mathcal{P}$ by use of the formulas $w = \sqrt{(P \cdot \mathfrak{R})/\mathcal{P} \cdot R}$ and $l = wR/\mathfrak{R}$. The capacitance of film capacitors is given by $C = 0.225\,D(N-1)A/t$, where C is the capacitance in picofarads, D the dielectric constant, N the number of plates, A the area in square inches, and t the dielectric thickness in inches.

Thin-film semiconductor devices have been slow to reach the production stage, mainly due to difficulties in controlling the film surface and interface properties. Various barrier layer diodes have exhibited impressive rectification ratios, but limited breakdown strength and low speed due to their large specific capacitance. Of the many film TRANSISTOR concepts proposed, the insulated gate field effect device looks the most promising and manufacturable. Its structure consists of a minute metal-dielectric-semiconductor capacitor. The semiconductor strip carries current between two terminals called source and drain. A field applied between metal "gate" and source modulates the semiconductor conductance and consequently the source-drain current. Usable semiconductor materials with a sufficiently low concentration of interface states are CdS, CdSe, and tellurium. These devices exhibit pentode-like characteristics with voltage gains ranging from 2.5 at 60 MHz to 8.5 at 2.5 MHz. The gain band width product G.B., which is equal to the transconductance divided by 2π times the gate capacitance, reaches values of about 20 MHz. It is determined by G.B. $= \mu_d V_D / 2\pi L^2$, where μ_d is the effective drift mobility of the electrons, V_D the source-drain potential, and L the source-drain spacing which is usually chosen between 1 and 5μ. Special film semiconductor devices in industrial use are various types of photodetectors.

Magnetic Films Magnetic thin films of nickel-iron (usually deposited at an 80:20 composition by weight) exhibit a number of unusual properties, which have led to many experimental and theoretical studies, as well as to important applications in binary storage and switching, magnetic amplifiers, and magneto-optical Kerr-effect displays.

Such "Permalloy" films have two stable states of magnetization, corresponding to positive and negative remanence. When deposited in a magnetic field or at an oblique angle, they exhibit uniaxial anisotropy. In practice, this anisotropy shows some dispersion, since it results from the alignment of local lattice disturbances. The stable states result from the minimization of the free energy $E = MH_L \cos\theta - MH_T \sin\theta + K \sin^2\theta$, where the last term represents the anisotropy energy, and θ is the angle between the magnetization M and the easy axis. From an inspection of the derivatives of this equation follows the hard-direction straight-line and the easy-direction square hysteresis loops of anistropic films. In the latter case, the magnetization is always either $+M$ or $-M$, and the change occurs at $H_L = \pm H_K$. The transitions from unstable to stable states occur at $\partial^2 E/\partial\theta^2 = 0$, resulting in a critical curve $H_L{}^{2/3} + H_T{}^{2/3} = H_K{}^{2/3}$ which has the form of an asteroid enclosing the origin (see MAGNETISM).

An important feature of magnetic films is the high speed with which the state of magnetization can be reversed. Dependent on film properties and magnetic fields, three modes of magnetization reversal occur: Domain wall motion, incoherent rotations, and the extremely fast coherent rotation of the magnetization. Wall-motion switching is expected when the driving fields are smaller than the critical values.

More recently, various magnetic garnet films have gained importance in research and industrial applications.

During the last decade, progress in thin film technology has been promoted to a large extent by the development of solid state devices, and especially integrated circuits. The requirements for defect-free epitaxial growth, extreme chemical purity, multilayering of different materials, and complex patterning of films at feature sizes at or below one micrometer have led to the development of vastly improved methods and highly automated equipment for thin film deposition, optical x-ray and electron lithography, plasma and ion beam etching, and chemical and structural analysis.

Some of the important newer deposition methods are chemical gas transport reactions, low temperature chemical vapor deposition (LTCVD), high pressure epitaxial growth, and molecular beam epitaxial growth (MBE). MBE in particular has been instrumental in the development and optimization of many novel device structures and has made possible the deposition of modulated semiconductor films consisting of stacks of thin alternating epitaxial layers ($\leqslant 100$ Å per layer) of two different semiconductor compounds. These III-V/III-V or IV/III-V structures exhibit superlattice character with very large carrier mobilities and other interesting electronic properties.

These processing methods are complemented by such analytical tools as the scanning electron microscope (SEM) for topological studies, low energy electron diffraction (LEED) for surface crystal structure, Auger analysis (AES) for elemental composition, x-ray photoelectron spectroscopy (XPS) for chemical bonds, secondary ion mass spectroscopy (SIMS), electron induced desorption (EID), photoelectron spectroscopy, and surface voltage spectroscopy.

The improved processing and analysis methods for thin films together with advances in theoretical solid state physics have led to the development of important new classes of solid state devices such as: very large scale integrated circuits (VLSI), various microwave device types and microwave integrated circuits, planar solid state opto-electronics, thin film transducers of various kinds, charge coupled devices (CCD's), magnetic bubble memories, surface acoustic wave (SAW) delay lines and filters, and many others. Further progress—albeit slower—has also been made in the technology of optical coatings, especially in the areas of transparent conductive films and metal-dielectric interference filters.

TIME

Too many interpretations of the concept of time are based on one of the following two kinds of oversimplification. Philosophers have speculated about time on the premise that it is a primary notion and can be abstractly defined without bothering about the implementation of the definition. Conversely, the physicists, before Einstein, had a tendency to take time for granted and to use it as a parameter without further questioning its definition. Phychologists may have been the first to make a step in the right direction by trying to relate the concept of time to actual perceptions.

Nowadays, the physicist has become aware of the necessity of providing operational definitions of the concepts he uses, and it is generally acknowledged that the very concept of time depends upon the possibility of the repetition of events that may be considered identical or, at least, that have a common recognizable feature. However, the far-reaching implications of this idea are seldom realized, and it is not infrequent to read otherwise respectable discussions based on a notion so "obvious" that its vagueness remains completely unsuspected, namely, the notion of a "clock."

Assigning to time the character of a self-contained concept and assuming the existence of appropriate "clocks" showing the flow of this "time" is putting the cart before the horse. In a more refined approach, an a priori time concept is accepted and principles are formulated by virtue of which a motion taking place in some specified conditions is uniform. But even such a procedure amounts to a self-deception, as the actual definition of time is then camouflaged behind those "principles." (For example, the essential of the definition of time in classical mechanics lies in Newton's first law). In brief, the true primary operation is the *arbitrary choice* of a repeatable phenomenon that may be used in the definition of a clock. The rate of flow of "time" is then implied by this choice, that is, the choice of the fundamental clock *is* the definition of time.

For practical purposes, it is appropriate to limit the freedom inherent in the choice of a clock by specifying convenient properties to be imposed on the resulting time scale. The main such properties are the availability of a sufficiently perennial master "clock" and the possibility of devising wieldy secondary clocks, for everyday use, that give reproducible and consistent readings endowed with a property of additivity. The first master clock that suggested itself to mankind was provided by the rotation of the earth on its axis and around the sun. The unit of time thus defined and its aliquot parts gave birth to the first astronomical time scales (mean solar day, tropical year), which served as a background for the development of classical mechanics and astronomy. A large number of phenomena were discovered (e.g., the beats of a good watch) that bear a linear relationship to that time scale. Any of the "linear systems" involved could be used as a secondary clock. Then, when the measuring techniques improved, it appeared that the mutual linearity of those phenomena was only an approximation. This discovery brought about a mild crisis of the metrology of time. The crisis was readily dismissed by stating that the rotation of the earth was not really uniform (as compared to "more accurate" clocks). In fact, the situation had a deeper purport: two descriptions of the fundamental master clock, that had been hitherto considered equivalent, appeared to be inconsistent, and the question of the *choice* of the clock was brought to the foreground again. The difficulty was temporarily settled in 1955 by relating the astronomical time scale to one particular period (tropical year 1900.0 = 31 556 925.975 seconds), and the following new permanent definition was adopted at the October, 1967, meeting of the 13th General Conference on Weights and Measures: "The second is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the fundamental state of the atom of cesium 133." This definition, which is in full agreement with the preceding one, has two advantages: It can readily be implemented by a so-called atomic clock, and it yields a standard which is reproducible to 1 part in 10^{11} or better.

Newtonian time, a basic feature of the whole body of classical mechanics, is practically the astronomical time, operationally defined as above, complemented by the following extra postulate. Let any single observer, standing still on earth, determine the (improved as above) astronomical time scale; the time scale so obtained is then to be used by every "observer," whatever his motion with respect to the first one. This postulate expresses, for each "observer," one choice of the master clock among infinitely many possible choices and as such it is legitimate. When it was stated, it was also consistent with the contemporaneous physical knowledge. Later on, the physicists grew accustomed to certain properties derived from the choice of Newtonian time and space and from other postulates of mechanics and electromagnetism, until a calamity happened which was similar to what has befallen astronomical time: the improvement of the measuring techniques showed that one empirical fact (namely, that the velocity of light in the laboratory frame of reference is independent of the motion of the emitter) was not compatible with all of those properties. Again a choice was necessary. The analysis of special relativity disclosed which of the properties at stake were incompatible. The decision as to which to drop was largely a matter of convenience. Einstein's choice (justified by strong operational reasons) was to drop the universality of time and space in order to retain more physical postulates. From then on, time and space ceased to be absolute concepts (see RELATIVITY). It is worth mentioning that the presence of such a fundamental choice at the basis of the special-relativistic theory of time is not always recognized.[1]

As the choice of the master clock may not be made any more by one "observer" on behalf of another one, the choice has to be decided upon for each "observer" separately. Special relativity's specification is that each inertial "observer" shall use the time scale defined by means of a conventional atomic "clock" at rest with respect to himself. This procedure leads to the concept of proper time, which enjoys a mathematically invariant character and plays, for inertial systems, the part formerly played by the universal time (see RELATIVITY).

When it comes to comparing the descriptions of the universe as made by "observers" whose motions relative to an inertial frame involve an acceleration, use is generally made of "general covariance," which permits a straightforward generalization of proper time. The relevant mathematical framework is that of general RELATIVITY. However, the interpretation of the general-relativistic proper time in terms of everyday experience involves instantaneous inertial frames, which are not embodied by any material system in this kind of problem. Therefore, the explicit relationship between proper time and the time actually measured by a material device called a clock is by no means clear.[2] In fact, the use of proper time in accelerated systems again implies a choice of the master clock, and in the present instance the choice has the drawback of being fairly abstract. Notwithstanding the largely widespread opinion, general covariance may not be the most convenient tool for the study of time in noninertial frames of reference. The problem of time measurements in such frames is an open problem, on which practically everything remains to be done.

Editor's Note: For space-time see section entitled "Einstein's Theory of Gravitation" in the article GRAVITATION, and for quantization of gravitational field and space-time, see the section entitled "Quantum Theory" in that article.

TRANSFORMER*

In elementary form, a transformer consists of two coils wound of wire and inductively coupled to each other. When alternating current at a given frequency flows in either coil, an alternating electromotive force (emf) of the same frequency is induced in the other coil. The value of this emf depends on the degree of coupling and the magnetic flux linking the two coils. The coil connected to a source of alternating emf is usually called the primary coil, and the emf across this coil is the primary emf. The emf induced in the secondary coil may be greater than or less than the primary emf, depending on the ratio of primary to secondary turns. A transformer is termed a step-up or a step-down transformer accordingly.

Most transformers have stationary iron alloy cores, around which the primary and secondary coils are placed. Because of the high permeability of iron alloys, most of the flux is confined to the core, and tight coupling between the coils is thereby obtained. So tight is the coupling

*Figures 1, 2, 4, and 5 and information contained in this article are based on the book "Electronic Transformers and Circuits" by Reuben Lee, New York, John Wiley & Sons, Inc., and are used with permission of the publisher.

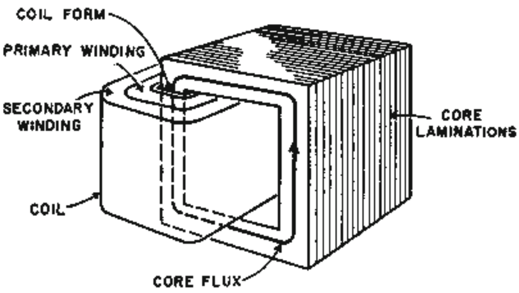

FIG. 1. Transformer coil and core.

between the coils in some transformers that the primary and secondary emf's bear almost exactly the same ratio to each other as the turns in the respective coils or windings. Thus, the turns ratio of a transformer is a common index of its function in raising or lowering potential.

A simple transformer coil and core arrangement is shown in Fig. 1. The primary and secondary coils are wound one over the other on an insulating coil tube or form. The core is laminated to reduce eddy currents. Flux flows in the core along the path indicated, so that all the core flux links both windings. In a circuit diagram, the transformer is represented by the symbol of Fig. 2.

In order for a transformer to deliver secondary emf, the primary emf must vary with respect to time. A dc potential produces no voltage in the secondary winding or power in the load. If both varying and dc potentials are impressed across the primary, only the varying part is delivered to the load. This comes about because the electromotive force e in the secondary is induced in that winding by the core flux ϕ according to the equation

$$e = -\frac{N\,d\phi}{dt}$$

This equation may be stated in words as follows: The voltage induced in a coil is proportional to the number of turns and to the time rate of change of magnetic flux linking the coil. This rate of change of flux may be large or small. For a given potential, if the rate of change of flux is small, many turns must be used. Conversely, if a small number of turns is used, a large rate of change of flux is necessary to produce a given potential.

Without transformers, modern industry could not have reached its present state of development. The highest potentials which are economically feasible in ac generators are of the order of 20 kV. Transmission of power over long distances is most economical at high potentials which have reached levels of 750 kV and over. The higher the potential of the transmission line, the greater is the amount of power that can be transmitted over a given line conductor. The upper limit of potential is determined by insulation. Insulation research and development have resulted in completely surge-proof transformers, and have made possible power systems which are capable of withstanding lightning surges. At the utilization end of power systems, potential is successively lowered by means of step-down transformers to make power available in safe, useful form. Instrumentation and control of electrical power also require special forms of transformers.

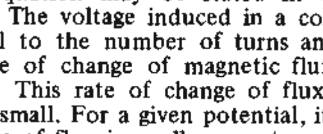

FIG. 2. Simple transformer.

An ideal transformer is defined as one which neither stores nor dissipates energy. Departures from the ideal transformer are caused by:

(1) Winding resistance and capacitance,
(2) Leakage inductance (due to flux which does not link both windings),
(3) Core hysteresis and eddy current losses,
(4) Magnetizing current.

Factors (1) and (2) above contribute to regulation, or the difference between secondary emf at no-load and full-load. This property is most important with variable load. Although no actual transformer is ideal, some transformers very nearly approach it. For example, in a 50-kVA rectifier transformer winding resistance amounts to 1 per cent, and leakage reactance 3 per cent, of the applied emf; core loss is 0.6 per cent of rated power, and magnetizing current is 2 per cent of rated current. Efficiency (output power divided by input power) is 98.4 per cent for this transformer.

Transformers are needed in electronic apparatus to provide the different values of potential for proper vacuum, gas or solid-state device operation, to insulate circuits from each other, to furnish high impedance to alternating current but low impedance to direct current, to change from one impedance level to another, to connect balanced lines to unbalanced loads, and to maintain or modify wave shape and frequency response at different potentials. Electronic transformers differ from power frequency transformers in the range of impedance levels, frequencies, size and weight. Categories of electronic transformers are: (1) Power, (2) frequency range, and (3) pulse.

Electronic power transformers are generally used to supply rectifiers at potentials ranging from 150 volts to 750 kV. Recent years have seen the widespread use of inverter transformers which convert dc potentials to higher dc potentials in conjunction with semiconductor or gas-filled devices. A simplified circuit is that of Fig. 3. Here the transformer output is a rectangular alternating wave which is often rectified again to produce dc output at increased potential.

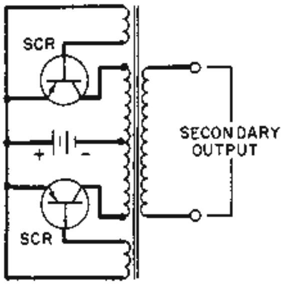

FIG. 3. Solid-state controlled rectifier and transformer for dc to ac inverter.

Frequency range transformers are used in applications where the frequency varies, including audio, video, carrier and control frequencies. Such frequencies vary from a fraction of 1 Hz to uhf (300 to 3000 MHz). Transformers may be wide-band or narrow-band in frequency response, and the core material changes accordingly. In wide-band transformers, the ratio of lowest frequency to highest frequency may be as great as 10^5. For such a wide band, the core material consists of nickel alloy laminations of high permeability which maintain uniform secondary voltage at the lowest frequency; also, this material makes possible low leakage inductance and winding capacitance, both of which are essential to good response at the highest frequency.

Narrow-band applications use mostly high frequencies and operate over a small percentage of the carrier frequency (e.g., 50 to 55 MHz). At radio frequencies, air-core transformers are used. Primary and secondary windings may be coaxial or concentric, with provision for adjusting the coupling between them. A circuit often used at radio frequencies is shown in Fig. 4. Primary and secondary circuits are tuned to resonance at the carrier frequency, and the response is shown in Fig. 5 for three conditions of coupling. Here

L_1 = self-inductance of primary coil
L_2 = self-inductance of secondary coil
L_m = mutual inductance between coils
k = coefficient of coupling = $L_m/\sqrt{L_1 L_2}$
f = carrier frequency
ω = $2\pi f$

It can be shown that maximum output occurs when

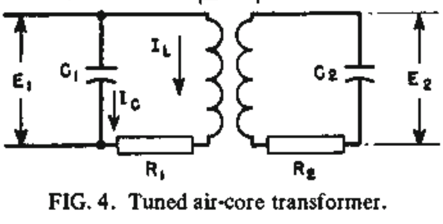

FIG. 4. Tuned air-core transformer.

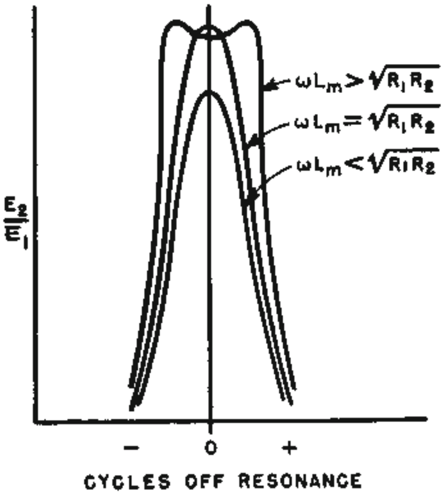

FIG. 5. Response curves for circuit of Fig. 4.

$$2\pi f L_m = \sqrt{R_1 R_2}$$

and the value of the coupling coefficient that produces this output at resonance is known as the critical value. Undercoupling produces less output than critical. A certain degree of overcoupling may be advantageous, in that it causes a broad-nosed response curve such as the slight double hump in the response marked $\omega L_m > \sqrt{R_1 R_2}$. With modulated carriers, this response would offer very little attenuation to sidebands formed by the carrier and audio frequencies; yet the circuit would reject unwanted signals in adjacent carrier channels.

In tuned circuits like these, cores of powdered iron or ferrites are often used to tune the coils, minimize size, and obtain better performance than would be possible with air-core coils. The kind of core material used depends upon the frequency and Q (= $2\pi f L_1/R_1$) required. In general, the higher the frequency, the lower the permeability of the core material. Ferrites are available that range in permeability from $\mu = 10^4$ for use at low frequencies to $\mu = 10$ for use at 60 MHz.

Pulse transformers are used in radar modulators and computers. In radar applications, the pulses are usually rectangular and occur repetitively. Pulse widths range from 0.1 to 200 μsec. Peak ratings are large, from 100 to 50 000 kW. Secondary emf may range up to 300 kV for operation of high-power magnetrons and klystrons. Computer transformers are usually small, have ferrite cores and operate from current pulses to drive core matrices.

Advances in transformer technology depend largely on development of new core and insulation materials, conductor arrangements, measuring techniques and methods of application. By these means, transformers come into use at higher frequencies, with better balance, smaller size or higher power than formerly thought possible.

TRANSISTORS

There are two generic types of transistor, the bipolar transistor and the field effect transistor. In the bipolar transistor, minority carriers are injected across a forward biased space charge region, at the emitter, diffuse across an essentially field free base region, and are collected across a high field space charge region, at the collector.* The minority carriers transit the base with little loss through recombination. Since they are emitted across a low impedance junction and collected across a high impedance junction, this results in power gain. The field effect transistor employs a channel, either built in or induced, which is modulated by a transverse gate region. This is somewhat analogous to the modulation of the plate current in a vacuum tube by the grid.

The bipolar transistor was discovered in 1947 by Bardeen and Brattain at Bell Laboratories while doing basic research on germanium surfaces which was motivated by failure to make a field effect transistor. The invention was rapidly exploited by a group at Bell under William Shockley. The field effect transistor had been patented in 1930 by Lilienfeld, but apparently was not reduced to practice, also at Bell Laboratories, until after the bipolar transistor. Had the field effect transistor preceded the bipolar transistor, the application of bipolar transistors would probably have proceeded more slowly, since circuit engineers would have found the field effect transistor more akin to their previous experience.

The transistor has influenced almost all phases of human activity. It is prevalent in consumer goods, in industrial control, and, particularly, it has made possible the large scale computer, thus increasing the capability of the human mind. It may possibly have an even larger effect on the future than nuclear fission or space travel.

Various basic types of transistors are given in Table 1. Typical structures are shown in Figs. 1(a)-1(d).

Of the bipolar transistors, probably the original point contact transistor is the least understood. Shockley,[1]* in a classical example of applied physics, predicted almost completely the characteristics of junction transistors prior to any experimental results. To achieve the junction transistor structure it was necessary to form two *pn* junctions in close proximity. Attempts were made to do this by adding dopants during crystal growth, by alloying and regrowing junctions, and by vapor phase epitaxy. The first two resulted in commercial germanium devices. The vertical structure of the grown junction transistor was complete after crystal growth. It was then necessary to cut the transistors from this material and make emitter, base, and collector contacts, the base contact being difficult because of the thin base structure. The grown junction transistor had poor high frequency characteristics and excessive base resistance and was soon displaced. The alloy junction transistor was developed further. The original devices had base widths of the order of 50 μm and were limited to not much more than the audio frequency range. However, extremely clever junction formation techniques, including the jet etched surface barrier transistor and the microalloy diffused transistor, resulted in transistors which pushed performance up into the middle radio frequencies. These devices were widely incorporated in entertainment products, computers, and military electronics. However, they had the disadvantage that the transistors were fabricated essentially one at a time. The use of a solid state diffusion, in which a multiplicity of transistors could be

*Computer simulations have shown this to be an oversimplification, but it is helpful conceptually. This assumption is widely used in transistor design.

*Due to the huge number of publications in the semiconductor field, only this paper, general texts, and data shown will be referenced.

fabricated at the same time in a wafer of germanium or silicon, produced structures of tighter geometrical control, greater uniformity, and increased performance. In silicon devices, silicon dioxide was used as a mask to localize the diffusions.

Photolithographic technique borrowed from the printing industry was used to form localized cuts in the silicon dioxide, and then the silicon dioxide was used as a mask to localize the diffusion. It became possible to decrease base widths to $\frac{1}{4}$ μm. This made possible the fabrication of transistors useful to over 100 MHz. Through the early stages of this work, although the silicon dioxide is an excellent dielectric, it was thought to be contaminated and was removed as one of the processing steps. The Fairchild group realized the usefulness of this material to passivate junctions and developed the planar transistor. This group then made use of this extra level of insulation to extend the contacts and decrease lateral active device dimensions. This not only made possible much higher performance discrete devices, but also laid the groundwork for integrated circuits.

The choice of material has always been an emotionally debated issue in semiconductors. The original work was done on germanium partly because the surface of germanium could be treated chemically to insure low surface recombination velocity and because zone melting made possible the fabrication of high purity single crystals. Silicon offered higher performance plus the outstanding qualities of silicon dioxide as an insulator. However, the melting temperature of this material was higher

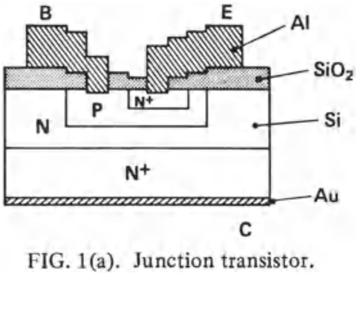

FIG. 1(a). Junction transistor.

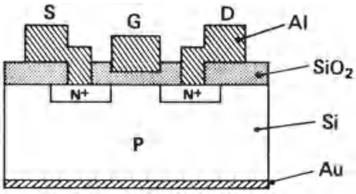

FIG. 1(c). MOS transistor.

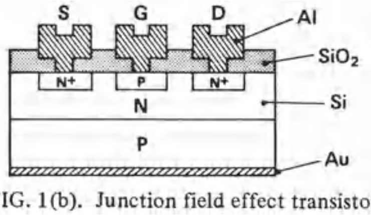

FIG. 1(b). Junction field effect transistor.

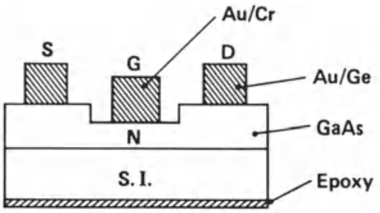

FIG. 1(d). Metal semiconductor transistor (MESFET).

and it took considerable work to produce single crystals of adequate perfection for semiconductor use. In distinction to the physical methods used with germanium, progress in silicon came through the purification of $SiCl_4$ in the gas phase prior to its reaction to elemental silicon. Once the technology of silicon had been mastered, it rapidly displaced germanium because of its better high temperature operation, the ubiquitous usefulness of silicon dioxide, and its higher saturation drift velocity. At present, gallium arsenide and silicon are vying for applications requiring the highest performance. At coarser geometries, the higher mobility of gallium arsenide is attractive. However, at very small geometries, which are now attainable through electron beam lithography, the differences tend to wash out as the ultimate scattering limited velocity of the two materials are similar. The properties of the three materials are summarized in Table 2.

Junction field effect transistors were originally fabricated in germanium. However, using the same technology developed for silicon bipolar transistors, JFETs were soon fabricated in silicon. It had been proposed that metal oxide field effect (MOS) transistors with an induced rather than a defined channel and with an insulated gate would give superior performance. However, instabilities in the oxide charge made these devices impractical due to threshold voltage shifts until it was determined that the instabilities were caused by the drift of sodium in the SiO_2. By eliminating sodium in the silicon dioxide through meticulous processing and by using mixed SiO_2-P_2O_5 glass as a sodium barrier, stable MOS field effect transistors were fabricated and this type of transistor has more and more become the predominant active device for integrated circuits. This is for three reasons. First, the source and drain contact diffusions can be extended to interconnect devices, giving in effect a second level of interconnections in addition to the metallization above the silicon dioxide. Second, the devices are self-isolating. Third, field effect transistors are ideal switches, that is, they have no offset at zero current.

Space charge regions in the junction field effect transistor modulate an existing channel. An analogous device can be made using a metal-semiconductor barrier to produce the space charge region. These have been manufactured mostly in gallium arsenide and have produced the highest performance three-terminal semiconductor devices yet fabricated.

TABLE 2. TRANSISTOR MATERIAL PROPERTIES.

MATERIAL	Ge	Si	GaAs	UNITS
BANDGAP	0.8	1.12	1.43	eV
μ_n	3900	1500	8500	cm^2/Vs
μ_p	1900	600	400	cm^2/Vs
v_{LIM}	6×10^6	10^7	$2 \times 10^7/10^7$	cm/sec

Although discrete transistors have had a very large effect on the electronics industry, the integrated circuit has made possible levels of complexity totally unobtainable by other means. Hundreds of thousands of transistors are now incorporated into a single chip. This is done making use of transistors and diffused conductors within the bulk silicon and a multiplicity of conducting patterns separated by intervening dielectric layers above the silicon surface. Both linear and digital integrated circuits have found innumerable applications. Linear integrated circuits require a higher diversity of active devices and have led to the development of lateral as well as vertical diffused transistors and the utilization of parasitic transistors within the structure, such as substrate *pnp* devices.

The properties of semiconductors can be explained using a model in which conduction can take place by either the motion of negatively charged particles (electrons) or the absence of electrons modeled as positively charged particles (holes). Column-three impurities, such as boron, gallium, or indium, added to a column-four semiconductor such as germanium or silicon, accept electrons and provide free holes. Added column-five elements such as phosphorous, arsenic, or antimony donate electrons and provide free electrons for conduction. A semiconductor is called *n*-type if the donated electrons predominate and *p*-type if the holes predominate. An equilibrium tends to exist in which the product of the concentration of holes and electrons is a constant. A perturbation which changes this product from the constant value tends to recover to this constant value. An excess returns to equilibrium through a recombination process where holes and electrons recombine. A deviation below equilibrium is counteracted by generation processes. The time for an excess to decay to $1/e$ of its initial value is called the *minority carrier lifetime* τ, and the distance these charges can diffuse in this time is called the *diffusion length* $(D\tau)^{1/2}$.

If *p*- and *n*-type materials are adjacent, a *pn junction* is formed. At zero bias, carriers tend to diffuse across this junction but set up a built-in field which stops further diffusion by providing equal but opposite drift and diffusion currents. However, if a positive potential is applied to the *p* side relative to the *n* side, forward current flows and minority carriers are injected mostly into the more lightly doped of the two sides of the junction. If a negative potential is applied to the *p* side relative to the *n* side, little current flows. However, any minority carriers in the vicinity of the junction are swept over the potential barrier and cause reverse leakage current. Thus *pn* junctions make excellent rectifiers. If two junctions are in close proximity, a bipolar transistor is formed. The emitter is a forward biased *pn* junction. On the more lightly doped side of the junction, the base side, a nonequilibrium concentration of minority carriers is maintained, the concentration being exponentially proportional to the applied voltage. The other junction, the collector junction, is reverse biased. This maintains the carrier concentration at close to zero. Thus, within the base of the transistor there is a gradient of minority carriers, resulting in minority carrier current. If the base width is small relative to the diffusion length, little recombination occurs in the base and the minority carrier concentration profile is close to linear. Therefore, the transistor can be modeled either as a device which provides an essentially constant current with an increase in impedance or as a transconductance in which a voltage across the emitter-base junction results in a current across the collector-base junction. It is generally more convenient to have current gain as well as power gain and not have to transform impedance between stages. This can be accomplished by using the emitter rather than the base as the common element. If the common base current gain is defined as α, then the common emitter current gain is $\alpha/(1 - \alpha)$. However, this is achieved at the cost of bandwidth, the current gain bandwidth product being essentially constant. Base current provides the majority carriers which combine with the minority carriers. The components of base current are shown in Fig. 2(a). In early transistors, where the base width was of the order of fifty microns, recombination in the base was the principal cause of base current. In modern diffused silicon transistors, this term is fairly low. Recombination in emitter-base space charge regions, minority carriers injected into the emitter, and injection in the parasitic lateral base are dominant. Typical values for a modern diffused transistor[2] are given in Fig. 2(b).

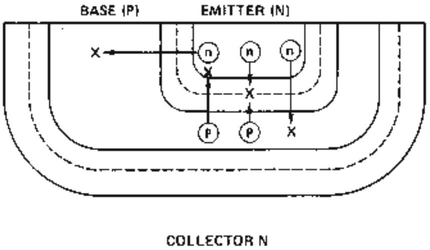

FIG. 2(a). Components of base current.

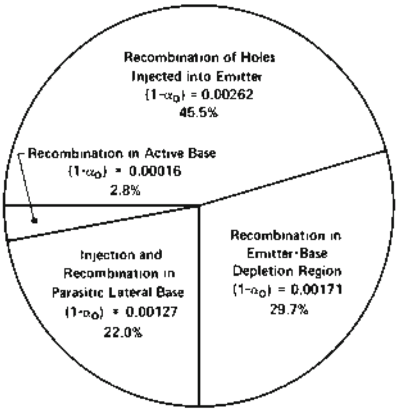

FIG. 2(b). Relative values of the components of base current for a modern diffused transistor. (See Ref. 2 for assumptions.)

In MOS transistors in saturation, the drain current is proportional to the charge induced in the channel divided by the transit time across the channel. For devices in which the gate length is relatively long, so that the fields do not approach the fields necessary to accelerate carriers to scattering limited velocity, the drain current is directly proportional to the mobility, the breadth of the channel and the square of the gate voltage above threshold divided by the oxide thickness. If the gate length is reduced to a value such that the average field over most of the gate is sufficient to accelerate the carriers to scattering limited velocity, then drain current is proportional to the breadth of the channel, the value of scattering limited velocity, and the value of the gate voltage above threshold divided by the oxide thickness. Equations for the transfer characteristics are compared in Table 3. Thus an MOS transistor with $V_D > V_{D\,\mathrm{saturation}}$ can have a transfer characteristic in which the drain current is either linearly proportional to voltage or proportional to the square of the voltage, whereas the bipolar transistor has a transfer characteristic in which the collector current is exponentially proportional to base-emitter voltage. Examples of these three characteristics are given in Fig. 3. It should be noted that although the mobility dominated case has the current proportional to the square of the voltage, because of differences in the proportionality constant the current is still less than in the saturation velocity dominated case where it is linearly proportional to voltage.

The high frequency limit of transistors is due to four factors: the charging time constant of the emitter, the transit time across the base, the drift time across the collector, and the time constant of the collector circuit. Again, modern technology has reduced the base transit time to a small fraction of the total. Figure 4(a) compares common emitter and common base frequency response. For the common emitter case, gain bandwidth product is essentially constant and the phase shift is approximately 90° over most of the frequency range. Figure 4(b) shows the reciprocal of current gain plotted as a function of the reciprocal of emitter current.

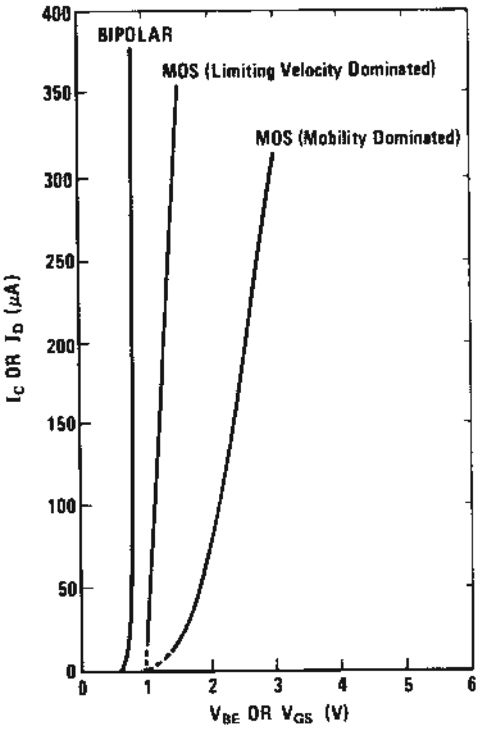

FIG. 3. Comparison of the transfer characteristics of a bipolar transistor, a MOS transistor in which carriers do not reach scattering limited velocity, and an MOS transistor in which carriers do reach scattering limited velocity.

The only one of the aforementioned time constants that is strongly current dependent is the emitter time constant, which is inversely proportional to emitter current. Therefore, over most of this range, as shown in Fig. 4(b), there is a linear relationship between the high frequency current gain and the reciprocal of the emitter current. However, at some high current value the current gain shows a maximum, and this is the practical upper current level of the transistor, typically at a current density of several thousand amperes per square centimeter. In most designs, this is due to the charge in transit modifying the collector depletion region by neutralizing the fixed charge of donors. This results in a shift of this depletion region toward the collector, increasing the base width. This can be minimized by doping the collector heavily. However, this reduces the maximum voltage which can be applied to the collector. Thus the product of gain, bandwidth, and voltage swing tends to be a constant.

The initial application of transistors was in small signal amplifiers. Commonly used equivalent circuits for bipolar transistors are given in Figs. 5(a)–5(c). It should be noted that the input and output impedances are moderate and predominantly real. This makes it easy to design wideband circuits. As shown in Fig. 5(d), the input impedance of the field effect transistor is primarily a small capacitance, where the output is predominantly resistive. This is very similar to a vacuum tube and lends itself to easy application in narrow band tuned circuits.

Both bipolar and field effect transistors make

excellent switches, the bipolar transistor having an offset voltage, the field effect transistor being more ideal. Bipolar transistor switching circuits have their lowest on-voltage drop when driven into saturation, that is, when there is sufficient charge stored in the base that both the emitter-base junction and the collector-base junctions are forward biased. This also stores minority carrier charge in the collector and tends to result in excessive turn-off times. This can be controlled by geometry control, through the use of epitaxial collectors, by adding impurities such as gold to reduce the minority carrier storage time, by clamping the collector out of saturation using metal-semiconductor diodes, or by circuit designs which avoid saturation. MOS transistors, being majority carrier devices, do not have this problem. However, simple *n*-channel or *p*-channel switching circuits have unequal turn-on and turn-off times. Complementary MOS circuits (CMOS) obviate this problem by having equal pull-up and pull-down ability. Switching transistors have found very extensive use in digital logic circuits because the power is small and the speed high. Typical switching times are a few nanoseconds. The transistor has totally revolutionized the production of memory for computers. Sixty-four thousand bits on a chip is common. Both static and dynamic circuits are used.

As previously discussed, bipolar transistors attain their best high frequency performance at collector current as high as possible so as to decrease the emitter time constant, limited, however, by charge in transit effects. Thus in order to obtain high frequency performance, bipolar transistors tend to require considerable power. A figure of merit which is frequently used is the speed power product, typical values are 1 pj. Gallium arsenide devices have the best yet obtained high frequency performance. This is due in part to the high mobility of GaAs and also due to an anomalously low feedthrough capacitance caused by second-order effects involving the formation of a stationary Gunn domain. Gallium arsenide field effect transistors have become the preferred three-terminal active device for very high frequency use. As geometries have tended to become finer and scattering-limited velocity effects dominant, the performance of silicon bipolar, silicon MOS, and gallium arsenide FETs have tended to converge.

An area in which transistors, particularly bipolar transistors, have become dominant is in power control. It is quite difficult to make vacuum tubes with plate current over ½ ampere. It is very easy to make bipolar transistors with collector currents over 10 amperes, and many designs operate in the hundreds of amperes. This is due to the fact that transistor emitters can operate at thousands of amp/cm^2. It had long been thought that field effect transistors had little place in high current applications. However, as integrated circuit technology progressed, it was found that very large gate areas could be made with reasonable yields. Thus, it became possible to use this gate area to form very great gate breadth field effect transistors. At present, MOS field effect transistors are competitive with bipolar transistors at high voltages and at currents up to tens of amperes.

Although polycrystalline material is used in certain steps in transistor fabrication, particularly as a gate electrode, the heart of all transistors is single-crystal material. Single crystals, at the start of the transistor era, were laboratory curiosities. At present, 100- and 125-mm-diameter single crystals of silicon are in common use in semiconductor fabrication. As grown, the silicon crystals have extremely low defect densities. However, much work is currently underway to prevent the introduction of defects during device fabrication. The single crystals are sliced into wafers and additional layers grown by epitaxy.

Modern diffused silicon technology incorporates a series of oxidation, patterning, and diffusion steps. Silicon dioxide is grown at high temperatures in oxygen or steam. It is patterned using photo- or electron-beam-generated masks to transfer the image to an organic photosensitive resist. This is developed and the pattern is etched into silicon dioxide. This is then used as a mask for solid state diffusions. Diffusions with gaseous sources are performed at high temperatures, the depth and concentration being controlled by time and temperature. Recently, ion implantation, in which the desired species of atom is accelerated in an electrostatic accelerator, purified by mass separation and then implanted into the bulk crystal, has tended to displace diffusion. This provides better control than diffusion and produces profiles unattainable by diffusion. Contacts and interconnects are formed by evaporated or sputtered metal.

When integrated circuits were first proposed, people looked at the yields of discrete devices and predicted that integrated circuits of significant size could not be fabricated economically. This was based on two fallacies. First, the devices at that time were much larger than necessary. By refinement of lithographic technique, it proved possible to bring device sizes down by about an order of magnitude, thus reducing the probability of a defect occurring in a device. The reduction in size was possible because the interconnect capacitances being charged were on chip and thus much lower than would be encountered running wiring to other discrete devices. The second fallacy was that the defects were random. It turned out that most wafers had good areas and bad areas. Thus, while calculated random defect yield might be low, there would be areas in the wafer in which the yield would be high. Murphy's law[3] (Fig. 6) for predicting yield has been widely used for extrapolations, but is known to be inaccurate due to the assumption of random defects.

Packaging has possibly been the Achilles' heel of semiconductor technology. The purpose of the package is to protect the device from its environment, to admit power and signal leads, and to conduct heat out. As integrated circuits have gotten larger and more complex, packaging technologies have proved woefully inadequate to meet the needs of modern circuits, which require as many as 72 leads. An ingenious

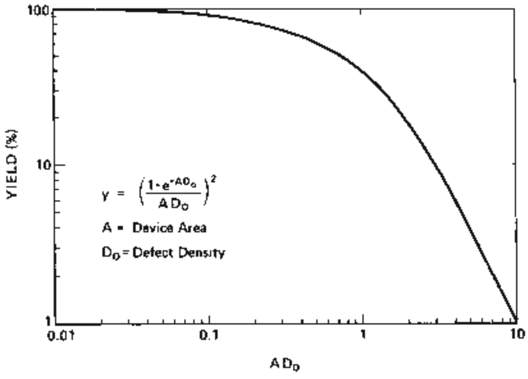

FIG. 6. Yield as predicted by Murphy's law[3] as a function of the product of the susceptible area and the defect density.

FAILURE MODE	CURE
SURFACE INVERSION DUE TO SODIUM DRIFT IN SiO_2	1. CLEAN PROCESSING 2. PHOSPHOROUS DOPED SiO_2 BARRIER
ELECTROMIGRATION FAILURE OF METALLIZATION	1. FOR Al METALLIZATION KEEP $J_{max} < 5 \cdot 10^5$ amp/cm^2 2. ADD Si AND/OR Cu TO Al 3. USE HIGH ATOMIC NUMBER METAL SUCH AS Au, W
PENETRATION OF METAL THROUGH CONTACTS	1. USE BARRIER LAYER SUCH AS Ti, TiSi, PtSi 2. ADD Si TO Al
CORROSION FAILURE OF Al METALLIZATION AND Al BOND WIRES	1. USE Au INSTEAD OF Al 2. CONTROL COMPOSITION OF PHOSPHOROUS DOPED SiO_2 3. CONTROL PURITY OF EPOXY
FAILURE OF Au BOND WIRES DUE TO BRITTLE ALLOY FORMATION	CONTROL RATIO Au TO AVAILABLE Si
CRACKED DIE, WEAK BONDS, etc.	BETTER INSPECTION
THERMAL FATIGUE FAILURE OF DIE ATTACH	USE HARD ALLOY DIE ATTACH i.e. Si – Au
MELTING, OTHER THERMAL FAILURES	BETTER CONTROL OF DIE ATTACH, ELIMINATION OF VOIDS
BLOWN GATES IN MOS AND GaAs FETs	AVOID STATIC DISCHARGE IN DEVICE

method for discrete devices was developed at Bell Laboratories, i.e., the self-encapsulated beam lead transistor. This has attained extremely high reliability, but unfortunately, is applicable only to a limited number of leads and does not meet the needs of modern integrated circuits. Other batch interconnect processes are receiving increased usage.

The ultimate complexity possible in semiconductor systems is limited by the reliability of the components. Great strides have been made in this area, particularly through the efforts of the scientists at Bell Telephone Laboratories and through the impetus of the military in such systems as Minuteman. Under severe operating conditions, failure rates less than 0.01% per 1000 hours are commonly achieved. Fortunately, these numbers tend to refer to packages rather than individual transistors in an integrated circuit. A rule of thumb is that the failure rate increases linearly with the number of leads to the chip, not with the number of devices in the chip. Thus complex integrated circuits have shown good reliability. Common causes of failure are given in Table 4.

The semiconductor industry has become a major one, producing billions of parts per year, and is a major contributor to the economy, particularly in California and in the Northeastern United States. Present shipments in the United States amount to six billion dollars per year, with a similar volume produced for intracompany use by captive suppliers. At present, a battle is being waged between the United States and Japan for supremacy in semiconductors.

TRANSPORT THEORY (RADIATIVE TRANSFER)*

When light passes through an atmosphere, it may be scattered and absorbed. When neutrons move through a medium, collisions with the nuclei of the material may result in absorption of the neutrons; changes in their direction and energy; and sometimes, by the fission mechanism, production of more neutrons.

These two phenomena are examples of transport processes. The problem of specifying the radiation field in an atmosphere stems back to Rayleigh's investigations on the illumination of a sunlit sky. The astrophysicists refer to this general subject as *radiative transfer* and have studied it for well over half a century. Interest in neutron transport has perforce been of more recent origin.

If light is thought of as consisting of photons, then there is seen to be a very strong similarity between neutron transport and radiative trans-

fer. The former process is both complicated and made more interesting by the possibility of fission in various materials. Other physical phenomena, such as the passage of γ-rays through a medium, possess many characteristics of the two processes that have been mentioned.

Fortunately, it is possible to develop a mathematical structure which encompasses all these phenomena. The situation is similar to that in classical diffusion theory, where the same mathematical equations may be interpreted, for example, to yield information concerning the distribution of heat in a metal or the flow of one material into another. The equations describing particle transport are, however, of a much more complicated nature than many of those of classical physics and are only now beginning to yield to the techniques of the mathematicians and theoretical physicists.

All the transport processes described above have the property that the moving particles involved may be thought of as interacting or colliding with fixed centers or nuclei of the material through which they are passing. The moving particles do not collide with each other. The interactions, in the situations which we will consider, are strictly independent and local events—a particle is affected only by a scattering center in its immediate neighborhood. Most important is the fact that a probability of such an interaction may be assigned:

$$\text{Probability of interaction in moving a distance } \Delta = \Sigma\Delta + (\text{terms of higher order in } \Delta). \tag{1}$$

The quantity Σ, called the *macroscopic cross section*, is dependent upon the kind and density of the medium, the type of moving particle (photon, neutron, etc.), the particle energy, etc. Determination of Σ is a complicated problem of experimental and theoretical physics.

An interaction or collision may result in a change in the direction of the moving particle (scattering), disappearance of the particle (absorption), or production of new particles of the same kind (fission). Scattering may produce no energy loss (elastic) or it may involve energy loss (inelastic). Such interactions may affect the transport medium, though for most purposes this change may be neglected. Again, the actual physical determination of the result of a collision is frequently a difficult task. Such information, together with the quantity Σ, must be considered for our purposes as already known.[14]

The central problem of transport theory, as we view the subject, may now be formulated. Given a physical medium with all parameters specified, such as the macroscopic cross section and the results of interactions, let a population of particles of given kind, direction, energy, etc., be present in the material at initial time $t = 0$. Let any internal or external sources of such particles be given. Describe as a function of position, direction, energy, etc., the expected particle population at any time $t > 0$.

The transport process clearly is probabilistic in nature. The resulting stochastic considerations can be very important for situations in which the total particle population is relatively small.[17] However, in most situations of interest these populations are sufficiently large so that stochastic variations are quite negligible. Thus it is customary to study expected value theory. Often the term "expected" is dropped in discussion, so that "expected flux" becomes simply "flux," etc. It is important to remember that this is done only as a matter of convenience in writing.

From Eq. (1) further information concerning the probability of collision may be obtained. Write

$$p(x) = \text{Probability that a particle moves a distance } x \text{ without collision.} \tag{2}$$

Then,

$$p(x + \Delta) = (1 - \Sigma\Delta)p(x) + (\text{terms of higher order in } \Delta). \tag{3}$$

Equation (3) gives

$$\frac{dp}{dx} = -\Sigma p(x)$$

and, if Σ is constant,

$$p(x) = e^{-\Sigma x}. \tag{4}$$

This is the well-known exponential law.

To find the average distance a particle moves without collision observe that

$$F(x) = \text{probability that the } \textit{first} \text{ collision occurs at some } X \leqslant x = 1 - e^{-\Sigma x}. \tag{5}$$

Then the average or expected value of X is

$$E(X) = \int_0^\infty x\, dF(x) = \int_0^\infty \Sigma x e^{-\Sigma x}\, dx = 1/\Sigma. \tag{6}$$

This average distance between collisions is referred to as the *mean free path*, usually denoted λ.

Suppose the half-space $x > 0$ is filled with a medium characterized by constant macroscopic cross section Σ. If a flux of N_0 particles impinges perpendicularly on $x = 0$, then the expected flux at $x = d$ of particles *that have made no collision* is, from Eq. (4),

$$N(d) = N_0 e^{-\Sigma d}. \tag{7}$$

When the collision process involves only absorption, $N(d)$ is the *total* expected flux at $x = d$, but if scattering and fission processes occur, $N(d)$ may be quite different from the total flux. These physical events greatly complicate transport theory.

Some idea of the complexities introduced by the fission process may be obtained by study of a very simple mathematical model in which particles are allowed to move only to the right or left in a rod (i.e., a line segment) of length a. Suppose that in an interaction the colliding particle disappears and two new ones emerge, one moving left and one moving right (binary fission). All particles have the same speed c, and Σ is constant. Finally, assume that the process is such that the average particle density is the same at one time as it is at any other, so that time dependence may be neglected. Denote by $cu(x)$ and $cv(x)$ the right and left fluxes at x.

Then[18]

$$u(x+\Delta) = (1 - \Sigma\Delta)u(x) + \Sigma\Delta u(x) + \Sigma\Delta v(x) + (\text{higher order terms in } \Delta), \qquad (8)$$

which leads to

$$du/dx = \Sigma v. \qquad (9)$$

Similarly,

$$-dv/dx = \Sigma u. \qquad (10)$$

If one left-moving particle per second is introduced at $x = a$, with no source at $x = 0$, then

$$u(0) = 0, \qquad cv(a) = 1, \qquad (11)$$

and the system of Eqs. (9)–(11) yields

$$cu(x) = \frac{\sin \Sigma x}{\cos \Sigma a}, \quad cv(x) = \frac{\cos \Sigma x}{\cos \Sigma a}, \quad 0 \leqslant x \leqslant a. \qquad (12)$$

These results are obviously quite different from any that would be given by a simple attenuation law, such as Eq. (7). Indeed, because of the fission assumed, a collision results in an increase, rather than a decrease, in the particle population. The case $a = \pi/2\Sigma$ is of especial interest. For a rod of that length neither $u(x)$ nor $v(x)$ is defined. Physically, the system is just *critical*. A time-independent population cannot prevail with the source specified. Equations (9) and (10) no longer hold when $a \geqslant \pi/2\Sigma$.

This observation does not imply that supercritical systems cannot be analyzed. To so do requires explicit introduction of the time variable.[18] Equations (9) and (10) are replaced by

$$\frac{1}{c}\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x} = \Sigma v(x,t) \qquad (13)$$

and

$$\frac{1}{c}\frac{\partial v}{\partial t} - \frac{\partial v}{\partial x} = \Sigma u(x,t) \qquad (14)$$

with suitable boundary and initial conditions. For large times it may be shown that the solutions to these equations can be written *approximately* as

$$u(x,t) \doteq u_0(x)e^{\alpha t}, \qquad v(x,t) \doteq v_0(x)e^{\alpha t} \qquad (15)$$

for some α. When $a > \pi/2\Sigma$, α is positive so that the particle fluxes build up exponentially in time. This exponential increase is observed in actual experiments involving fissionable materials. When the particle population in a system is just sustained without introduction of additional particles (sources), the system is just critical (see CRITICAL MASS).

It is possible to consider other relatively simple mathematical models of transport phenomena and from them to determine much valuable information. Any attempt to solve a "realistic" physical problem, however, usually results in great difficulties. The general *transport equation* is of the form

$$\frac{DN}{Dt}(\mathbf{r}, E, \mathbf{\Omega}, t) = -\Sigma(\mathbf{r}, E, \mathbf{\Omega}, t)N(\mathbf{r}, E, \mathbf{\Omega}, t) + \int_{E',\mathbf{\Omega}'} K(\mathbf{r}; E', \mathbf{\Omega}' \rightarrow E, \mathbf{\Omega}; t)\Sigma(\mathbf{r}, E', \mathbf{\Omega}', t) N(\mathbf{r}, E', \mathbf{\Omega}', t)\, dE'\, d\mathbf{\Omega}' + S(\mathbf{r}, E, \mathbf{\Omega}, t) \qquad (16)$$

subject to boundary and initial conditions dependent upon the geometry. In Eq. (16), D/Dt is the total time derivative, E is the energy of a particle, $\mathbf{\Omega}$ is a vector of unit length along the direction of motion of a particle, and K is a function that gives the density of particles emerging at energy E and in the direction $\mathbf{\Omega}$ from a collision at location r and time t involving a particle having energy E' and moving in the direction $\mathbf{\Omega}'$. Sources are represented by S.

It is clear that Eq. (16), while linear, has a much different structure from the classical equations of mathematical physics. This structural difference results in the necessity to use relatively unusual mathematical techniques in the analysis of Eq. (16). For example, it is clear that physically meaningful solutions of the transport equation must be nonnegative. This *positivity property* plays a key role in the analysis of the transport equation.[2] On the other hand, the transport operator does *not* have the properties of being symmetric or positive definite, both of which are widely used in analyzing the classical equations of mathematical physics.

The complexity of the general transport equation, coupled in some cases with the urgencies of designing nuclear weapons, fission and fusion reactors, etc., has resulted in a plethora of approximate methods for its treatment.[1,5,7,8,14] One class of such methods, which was developed relatively early and has been extensively applied, is based upon modifying the exponential attenuation formula Eq. (7) by multiplicative factors intended to account for contributions from collided particles. These modifying factors may be determined either computationally or experimentally. This approach has perhaps achieved its highest form in the "Standard Method" for calculation of the shielding effect of structures against fallout gamma rays.[13]

For situations in which scattering interactions occur much more often than absorptions, the transport equation can be approximated by the neutron diffusion equation.[7] The latter is identical in structure to the heat equation, allowing classical methods of solution to be used in many cases. Neutron diffusion theory often gives surprisingly good results, particularly for systems that are sufficiently large so that boundary effects are quite negligible. Variants of simple neutron difffusion theory are numerous. They include age theory and the continuous slowing-down approximation.

The advent of modern high-speed electronic computers has made it a widespread practice to generate approximations to the solution of Eq. (16) based upon replacing the continuous independent variables by discrete counterparts. Different such discretizations can be used for the four independent variables t, E, $\mathbf{\Omega}$, and $\mathbf{r}$, and these may be combined in many ways. The time variation is almost always approximated by a finite-difference method.

The multigroup method, in which all particles in several contiguous energy ranges are combined, is the most commonly used technique for discretely representing particle energies. This approach has been widely and successfully applied in practice over the past two decades, although the underlying mathematical theory has only very recently begun to be developed.[9] The multigroup method also has been successfully combined with diffusion theory. Other techniques have been developed for discretizing energy, such as the overlapping group method and the multiband approximation. The search for alternatives is largely motivated by situations involving wide variations in cross sections over small energy ranges (e.g., cross-section resonances) because direct application of the multigroup method can be prohibitively time consuming in such circumstances.

The directional variable $\mathbf{\Omega}$ in Eq. (16) can be discretely approximated in various ways. The discrete-ordinates method arises from replacing the directional integral in Eq. (16) by a numerical quadrature. In the closely related S_N method, the directional dependence of the flux is assumed to be piecewise linear. Yet another approach is based upon using a truncated expansion in spherical harmonics to represent the directional dependence of the flux. The latter is theoretically equivalent to an appropriately defined discrete-ordinates approximation.[1] If the expansion in spherical harmonics is truncated at lowest order, then the neutron diffusion equation results.

Finite difference methods are widely used to provide a discrete representation of the spatial variable r. In the past decade it has become increasingly popular to use finite-element methods for this purpose. The recently developed coarse-mesh nodal methods[6] seem particularly promising in terms of computational efficiency.

Discretization of the spatial variable also can be accomplished by techniques such as invariant imbedding[18] or the related method of response matrices.[16] In these approaches attention is focused on determination of particles emergent from a system as a function of the incident particles. Such a viewpoint is quite natural in astrophysics and shielding, which accounts for the rather extensive use of invariant imbedding in these fields.[4,10]

Another popular attack on transport problems is through the Monte Carlo method.[12] There, the particle motion is actually simulated by machine computation. Particles suffer collisions, change direction, lose energy, etc., according to specified probabilities. In principle the particle energy and direction can be retained as continuous variables, but in practice these often are discretized. In the simplest verions of the method, the computer traces the history of a single particle from its appearance in the system until it leaves or is absorbed. This is inefficient for problems in which the primary interest is upon behavior of a relatively small fraction of the total particle population, such as transmission through a thick shield. Accordingly, various biasing techniques have been developed with the objective of reducing computational effort spent upon particles likely to be of little ultimate interest. Events in a particle's history are allowed to happen randomly, the computer deciding on the event according to a preassigned (and presumably physically correct) probability distribution. This method is hence stochastic in nature, although expected values are usually taken after a sufficiently large particle population has been examined. The Monte Carlo technique is often used when the geometry of the problem is complicated.

Another widely used approach to the transport equation is the method of singular eigenfunctions.[3] This method originally was used to obtain semianalytic solutions, but in this framework it seems applicable only in relatively simplified circumstances. In recent years this method and related techniques, such as the F_N method, have been increasingly applied numerically.[11] Singular eigenfunctions originally arose in plasma physics. In the past decade there has been increasing applications of this and other transport-theoretic methods to the transport of charged particles.

It should be pointed out that no theoretical or computational scheme can possibly give satisfactory results without good knowledge, either experimental or theoretical, of the underlying physical parameters Σ and K. Satisfactory determination of these quantities often involves considerable effort and expense. In response to this, substantial recent effort has been directed toward determination of the sensitivity of the solution of the transport equation to errors in these parameters.[15] The underlying idea is to focus efforts in computing or measuring these quantities upon the most crucial materials and energies.

Transport theory is approaching maturity as a subject. Much has been accomplished within the past two decades, but many very challenging and important problems remain, both from the viewpoint of the physicist and from that of the mathematician.

TRANSURANIUM ELEMENTS

The transuranium elements are those elements heavier than uranium, element 92. They are all radioactive and, in general, have half-lives too short to have existed in nature since their original creation. They were all discovered and produced by nuclear synthesis. The presently known (1982) transuranium elements have the following names and symbols: 93, neptunium (Np); 94, plutonium (Pu); 95, americium (Am); 96, curium (Cm); 97, berkelium (Bk); 98, californium (Cf); 99, einsteinium (Es); 100, fermium (Fm); 101, mendelevium (Md); 102, nobelium (No); 103, lawrencium (Lr); 104, rutherfordium (Rf); 105, hahnium (Ha); 106, not named; 107, not named.

The heaviest elements of the periodic system with atomic numbers 89 (actinium) through 103 (lawrencium) are members of the actinide series, analogous to the lanthanide series or rare earths (atomic numbers 57 through 71). An inner electron shell, consisting of fourteen $5f$ electrons, is filled in progressing across the series. The electronic configurations of the actinide transuranium elements are given in Table 1.

Since the actinide series is completed with lawrencium, element 103, the succeeding "transactinide" elements with atomic numbers 104 through 108 should be chemical homologs to the known elements with atomic numbers 72 (hafnium) to 76 (osmium). This analogy should continue in the still heavier transuranium ele-

[a] Configurations in parentheses have not been determined experimentally.

ments, and element 118 should be a noble gas. Some typical predicted electronic configurations for transactinide elements are given in Table 2.

Chemically the transuranium elements which are members of the actinide series are very similar, although the observed differences are those expected and anticipated from their unique position in the periodic system as part of a second rare-earth series. All have trivalent ions, which form inorganic complex ions and organic chelates. Also in common are acid-insoluble trifluorides and oxalates, soluble sulfates, nitrates, chlorides, and perchlorates. Neptunium, plutonium, and americium have several higher oxidation states in aqueous solution (similar to uranium), but the stability of these states relative to the common trivalent ion becomes progressively less as one proceeds to the higher atomic numbers. This is a direct consequence, indeed an identifying feature, of the actinide role as a second rare-earth type transition series.

One of the most important methods for study and elucidation of chemical behavior of the actinide elements has been ion-exchange chromatography. Adsorption on and elution from ion-exchange columns have made possible the identification and separation of trace quantities of all of the actinides. The behavior of each actinide transuranium element in this respect is very similar to its analogous rare-earth element. This has made it possible to detect as little as one or two atoms when this small a number has been made in some of the transmutation experiments.

Each of the transuranium elements (except for the last two) has a number of isotopes, some of which can be obtained in isotopically pure form. They are produced by neutron- or charged-particle-induced transmutation. The first eight have an average of about 15 isotopes (including isomers) apiece. The total number of known nuclides for the 15 elements is about 200, when the approximately 30 short-lived, so-called "fission isomers" are included. The isotopes available in weighable quantity, and hence suitable for investigation, are listed in Table 3.

The concept of atomic weight in the sense applied to naturally occurring elements is not applicable to the transuranium elements, since the isotopic composition of any given sample depends on its source. In most cases, the use of the mass number of the longest-lived isotope in combination with an evaluation of its availability has been adequate. Good choices at present are neptunium, 237; plutonium, 242; americium, 243; curium, 248; berkelium, 249; californium, 249; einsteinium, 254; and fermium, 257.

Brief descriptions of the transuranium elements follow:

Neptunium (Np, atomic number 93, after the planet Neptune.) Neptunium was the first of the synthetic transuranium elements to be

TABLE 3. LONG-LIVED TRANSURANIUM ISOTOPES AVAILABLE FOR INVESTIGATION.

Nuclide	$t_{1/2}$	Isotopic Composition (%)	Amounts Available
^{237}Np	2.14×10^6 y	100	kg
^{238}Pu	87.74 y		10–100 g
^{239}Pu	2.41×10^4 y	99.7	kg
^{240}Pu	6.57×10^3 y	98.3	10–50 g
^{241}Pu	14.4 y	93.4	1–10 g
^{242}Pu	3.76×10^5 y	99.9	100 g
^{244}Pu	8.1×10^7 y	88.6	10–100 mg
^{241}Am	433 y	100	kg
^{243}Am	7.37×10^3 y		10–100 g
^{242}Cm	162.8 d	100	100 g
^{243}Cm	28.5 y		10–100 mg
^{244}Cm	18.11 y	>95%	10–100 g
^{248}Cm	3.5×10^5 y	97	10–100 mg
^{249}Bk	0.88 y	100	10–50 mg
^{249}Cf	351 y	100	1–10 mg
^{250}Cf	13.1 y		10 mg
^{252}Cf	2.64 y		10–1000 mg
^{254}Cf	60.5 d		μg
^{253}Es	20.47 d		1–10 mg
^{254}Es	276 d	100	5–10 μg
^{257}Fm	100.5 d		1 pg

discovered; the isotope ^{239}Np was produced by McMillan and Abelson in 1940 at Berkeley, California, as the result of the bombardment of uranium with cyclotron-produced neutrons. The isotope ^{237}Np (half-life 2.14×10^6 years) is currently obtained in kilogram quantities as a by-product of nuclear power reactions. Trace quantities of the element are actually found in nature owing to transmutation reactions in uranium ores produced by the neutrons which are present.

Neptunium metal has a silvery appearance, is chemically reactive, melts at 637°C, and exists in at least three structural modifications: α-neptunium, orthorhombic, density = 20.45 g/cm^3; β-neptunium (above 280°C), tetragonal, density (313°C) = 19.36 g/cm^3; γ-neptunium (above 577°C), cubic, density (600°C) = 18.0 g/cm^3.

Neptunium gives rise to five ionic oxidation states in solution: Np^{3+} (pale purple), analogous to the rare earth ion Pm^{3+}, Np^{4+} (yellow-green), NpO_2^+ (green-blue), NpO_2^{2+} (pale pink), and NpO_5^{3-} (green). These oxygenated species are in contrast to the rare earths which exhibit only simple ions of the (II), (III), and (IV) oxidation states in aqueous solution. The element forms tri- and tetrahalides such as NpF_3, NpF_4, $NpCl_3$, $NpCl_4$, $NpBr_3$, NpI_3, and oxides of various compositions such as are found in the uranium-oxygen system, including Np_3O_8 and NpO_2.

Plutonium (Pu, atomic number 94, after the planet Pluto.) Plutonium was the second transuranium element to be discovered; the isotope ^{238}Pu was produced in 1940 by Seaborg, McMillan, Kennedy, and Wahl at Berkeley, California, by deuteron bombardment of uranium in the 150-cm cyclotron. By far of greatest importance is the isotope ^{239}Pu (half-life 24 400 years), which is fissionable with thermal neutrons and produced in extensive quantities in nuclear reactors from the abundant nonfissionable uranium isotope ^{238}U:

$$^{238}U(n,\gamma)\,^{239}U \xrightarrow{\beta^-} {}^{239}Np \xrightarrow{\beta^-} {}^{239}Pu$$

Plutonium (in the form of ^{239}Pu) has assumed the position of dominant importance among the transuranium elements because of its successful use as an explosive ingredient in nuclear weapons and the place which it holds as a key material in the development of industrial utilization of nuclear energy, one pound being equivalent to about 10 000 000 kWh of heat-energy equivalent. In certain nuclear reactors called breeder reactors, it is possible to create more new plutonium from ^{238}U than plutonium consumed in sustaining the fission chain reaction. Because of this, plutonium is the key to unlocking the enormous energy reserves in the nonfissionable isotope ^{238}U.

Plutonium (in the form of ^{239}Pu) also exists in trace quantities in naturally occurring uranium ores. It is formed in much the same manner as neptunium, by irradiation of natural uranium with the neutrons which are present. Much smaller quantities of the longer-lived isotope, ^{244}Pu, (half-life 83 000 000 years), have been found in nature; in this case it may represent the small fraction remaining from a primordial source or it may be due to cosmic rays.

Much of the early work on the determination of the chemical and physical properties of plutonium has been done employing the isotope ^{239}Pu. However, the relatively high specific alpha particle radioactivity of this isotope leads to difficulties caused by radiation damage and self-heating of the material under investigation. Hence, the longer-lived isotope ^{242}Pu (half-life 390 000 years) is better suited for such investigations; this isotope is rather readily available in high isotopic purity as the result of successive neutron capture reactions when plutonium is irradiated over sufficiently long periods of time in very high neutron flux reactors:

$$^{239}\mathrm{Pu}\ (n,\gamma)\ ^{240}\mathrm{Pu}\ (n,\gamma)\ ^{241}\mathrm{Pu}\ (n,\gamma)\ ^{242}\mathrm{Pu}$$

The still longer-lived ^{244}Pu is even better suited for such investigations, but the difficulty of producing it limits its availability; in this case the neutron capture reactions must continue for two additional steps:

$$^{242}\mathrm{Pu}\ (n,\gamma)\ ^{243}\mathrm{Pu}\ (n,\gamma)\ ^{244}\mathrm{Pu}$$

and the yield is drastically reduced owing to the short half-life of ^{243}Pu (4.96 hours).

Plutonium metal can be prepared, in common with neptunium and uranium, by reduction of the trifluoride with alkaline-earth metals. The metal has a silvery appearance, is chemically reactive, and melts at 640°C. It exhibits six crystalline modifications: α-plutonium, primitive monoclinic, below 115°C; β-plutonium, monoclinic, 115 to 185°C; γ-plutonium, face-centered orthorhombic, 185 to 310°C; δ-plutonium, face-centered cubic, 310 to 452°C; δ'-plutonium, tetragonal, 452 to 480°C; and ϵ-plutonium, body-centered cubic, 480°C up to the melting point.

Plutonium also exhibits five ionic valence states in aqueous solutions: Pu^{3+} (blue-lavender), Pu^{4+} (yellow-brown), PuO_2^+ (pink), PuO_2^{2+} (pink-orange), and PuO_5^{3-} (blue-green). The ion PuO_2^+ is unstable in aqueous solutions, disproportionating into Pu^{4+} and PuO_2^{2+}; the Pu^{4+} thus formed, however, oxidizes the PuO_2^+ into PuO_2^{2+}, itself being reduced to Pu^{3+}, giving finally Pu^{3+} and PuO_2^{2+}.

Plutonium forms binary compounds with oxygen: PuO, PuO_2, and intermediate oxides of variable composition; with the halides: PuF_3, PuF_4, $PuCl_3$, $PuBr_3$, PuI_3; with carbon, nitrogen, and silicon: PuC, PuN, $PuSi_2$; in addition oxyhalides are well known: PuOCl, PuOBr, PuOI.

Because of the high rate of emission of alpha particles, and the physiological fact that the element is specifically absorbed by bone marrow, plutonium, like all of the transuranium elements, is a radiological poison and must be handled with special equipment and precautions.

Americium (Am, atomic number 95, after the Americas.) Americium was the fourth transuranium element to be discovered; the isotope ^{241}Am was identified by Seaborg, James, Morgan, and Ghiorso late in 1944 at the wartime Metallurgical Laboratory (now the Argonne National Laboratory) of the University of Chicago as the result of successive neutron capture reactions by plutonium isotopes in a nuclear reactor:

$$^{239}\mathrm{Pu}\ (n,\gamma)\ ^{240}\mathrm{Pu}\ (n,\gamma)\ ^{241}\mathrm{Pu} \xrightarrow{\beta^-} {}^{241}\mathrm{Am}$$

Americium is produced in kilogram quantities. Since the isotope ^{241}Am can be prepared in relatively pure form by extraction as a decay product over a period of years from plutonium containing ^{241}Pu, this isotope has been used for much of the chemical investigation of this element. Better suited is the isotope ^{243}Am owing to its longer half-life (7.4×10^3 years as compared to 433 years for ^{241}Am). A mixture of the isotopes ^{241}Am, ^{242}Am, and ^{243}Am can be prepared by intense neutron irradiation of ^{241}Am according to the reactions $^{241}\mathrm{Am}\ (n,\gamma)\ ^{242}\mathrm{Am}\ (n,\gamma)\ ^{243}\mathrm{Am}$. Nearly isotopically pure ^{243}Am can be prepared by the reactions $^{242}\mathrm{Pu}\ (n,\gamma)\ ^{243}\mathrm{Pu} \xrightarrow{\beta^-} {}^{243}\mathrm{Am}$, and the ^{243}Am can be chemically separated.

Americium can be obtained as a silvery white reactive metal by reduction of americium trifluoride with barium vapor at 1300°C. It appears to be more malleable than uranium or neptunium and tarnishes slowly in dry air at room temperature. The density is 13.67 g/cm^3 with a melting point at 1176°C. It has a double hexagonal-close-packed crystalline structure at temperatures up to 1079°C (α-americium) and a face-centered cubic structure above 1079°C (β-americium).

The element exists in four oxidation states in aqueous solution: Am^{3+} (light salmon), AmO_2^+ (light tan), AmO_2^{2+} (light tan), and a fluoride complex of the 4+ state (pink). The trivalent state is highly stable and difficult to oxidize. AmO_2^+, like plutonium, is unstable with respect to disproportionation into Am^{3+} and AmO_2^{2+}. The ion Am^{4+} may be stabilized in solution only in the presence of very high concentrations of fluoride ion, and tetravalent solid compounds are well known. Divalent americium has been prepared in solid compounds; this is consistent with the presence of seven $5f$ electrons in americium (enhanced stability of half-filled

$5f$ electron shell) and is similar to the analogous lanthanide, europium, which can be reduced to the divalent state.

Americium dioxide, AmO_2, is the important oxide; Am_2O_3 and, as with previous actinide elements, oxides of variable composition between $AmO_{1.5}$ and AmO_2 are known. The halides AmF_2 (in CaF_2), AmF_3, AmF_4, $AmCl_2$, $AmCl_3$, $AmBr_3$, AmI_2, and AmI_3 have also been prepared.

Curium (Cm, atomic number 96, after Pierre and Marie Curie.) Although curium comes after americium in the periodic system, it was actually known before americium and was the third transuranium element to be discovered. It was identified by Seaborg, James, and Ghiorso in the summer of 1944 at the wartime Metallurgical Laboratory in Chicago as a result of helium-ion bombardment of ^{239}Pu in the Berkeley, California, 150-cm cyclotron. It is of special interest because it is in this element that the first half of the transition series of actinide elements is completed.

The isotope ^{242}Cm (half-life 163 days) produced from ^{241}Am by the reactions $^{241}Am\ (n, \gamma)\ ^{242}Am \xrightarrow{\beta^-} {}^{242}Cm$ was used for much of the early work with macroscopic quantities, although this was difficult due to the extremely high specific alpha activity. A better, but still far from ideal, isotope for the investigation of curium is ^{244}Cm. Its somewhat longer half-life of 18 years still presents a problem of relatively high specific alpha activity, but it has been used extensively because of its availability as the result of production by the reactions $^{243}Am\ (n, \gamma)\ ^{244}Am \xrightarrow{\beta^-} {}^{244}Cm$. Much better suited for such investigations are the longer-lived isotopes ^{247}Cm (half-life 16 000 000 years) and ^{248}Cm (half-life 350 000 years) which are becoming available in increasing quantities as the result of their production in high neutron-flux reactors through the successive capture of neutrons in the reactions $^{244}Cm\ (n, \gamma)\ ^{245}Cm\ (n, \gamma)\ ^{246}Cm\ (n, \gamma)\ ^{247}Cm\ (n, \gamma)\ ^{248}Cm$; the difficulties of this long production chain are compounded by the necessity of separating the ^{247}Cm and ^{248}Cm from the remaining lower mass-number isotopes by mass spectrometric methods in order to obtain final products of the desired low specific alpha activity. ^{248}Cm is also produced in relatively high isotopic purity as the alpha-decay daughter of ^{252}Cf.

Curium metal resembles americium metal in crystal structure (α and β modifications) but melts at the considerably higher temperature of 1340°C. It can be prepared by heating curium trifluoride with barium vapor at 1350°C. The density is 13.51 at room temperature.

Curium exists solely as Cm^{3+} (colorless to yellow) in the uncomplexed state in aqueous solution. This behavior is related to its position as the element in the actinide series in which the $5f$ electron shell is half filled, i.e., it has the especially stable electronic configuration, $5f^7$, analogous to its lanthanide homolog, gadolinium. Similarly to americium (IV) a curium (IV) fluoride complex ion exists in aqueous solution. Solid compounds include Cm_2O_3, CmO_2 (and oxides of intermediate composition), CmF_3, CmF_4, $CmCl_3$, $CmBr_3$, and CmI_3.

Berkelium (Bk, atomic number 97, after Berkeley, California.) Berkelium, the eighth member of the actinide transition series, was discovered in December 1949, by Thompson, Ghiorso, and Seaborg and was the fifth transuranium element synthesized. It was produced by cyclotron bombardment of ^{241}Am with helium ions at Berkeley, California.

The only isotope available in weighable quantities for the study of the chemical and physical properties of berkelium is ^{249}Bk (half-life 314 days) produced in limited quantity by the neutron irradiation of somewhat rare ^{248}Cm by the reactions $^{248}Cm\ (n, \gamma)\ ^{249}Cm \xrightarrow{\beta^-} {}^{249}Bk$. This isotope is difficult to work with because of its relatively high specific beta particle radioactivity and because of continuous self-contamination with its daughter ^{249}Cf radioactivity.

Berkelium metal can be prepared by the reduction of BkF_3 with lithium at 1025°C. It exists in a double hexagonal-close-packed α phase (presumably the low temperature phase) and a face-centered cubic β phase and melts at 986 ± 25°C. It has a density of 14.78 at room temperature.

Berkelium exhibits two ionic oxidation states in aqueous solution, Bk^{3+} (yellow-green) and somewhat unstable Bk^{4+} (yellow) as might be expected by analogy with its rare-earth homolog terbium. Solid compounds include Bk_2O_3, BkO_2 (and presumably oxides of intermediate composition), BkF_3, BkF_4, $BkCl_3$, $BkBr_3$, and BkI_3.

Californium (Cf, atomic number 98, after the state and University of California.) Californium, the sixth transuranium element to be discovered, was produced by Thompson, Street, Ghiorso, and Seaborg in January 1950, by helium-ion bombardment of microgram quantities of ^{242}Cm in the Berkeley 150-cm cyclotron.

The best isotope for the investigation of the chemical and physical properties of californium is ^{249}Cf (half-life 352 years), produced in pure form as the beta-particle decay product of ^{249}Bk, which is available in only limited quantity because its production from lighter isotopes requires multiple neutron capture over long periods of time in high neutron-flux reactors. Mixtures of californium isotopes produced by reactions such as $^{249}Bk\ (n, \gamma)\ ^{250}Bk \xrightarrow{\beta^-} {}^{250}Cf\ (n, \gamma)\ ^{251}Cf\ (n, \gamma)\ ^{252}Cf$ are also used but these have the disadvantage of high specific radioactivity, especially the spontaneous fission decay of ^{252}Cf.

Californium metal can be prepared by the reduction of CfF_3 with lithium. It is quite volatile and can be distilled at temperatures of the order of 1100 to 1200°C. It appears to exist in three crystalline modifications, hexagonal (α), face-centered cubic (β) and face-centered cubic (γ). It has a melting point of 900 ± 30°C. The density is 15.1 at room temperature.

Californium exists mainly as Cf^{3+} in aqueous solution (emerald green), but it is the first of the actinide elements in the second half of the series to exhibit the (II) state, which becomes progressively more stable on proceeding through the heavier members of the series. It also exhibits the (IV) oxidation state in CfF_4 and CfO_2 which can be prepared under somewhat intensive oxidizing conditions. Solid compounds also include Cf_2O_3 (and higher intermediate oxides), CfF_3, $CfCl_3$, $CfBr_2$, $CfBr_3$, CfI_2, and CfI_3.

Einsteinium (Es, atomic number 99, after Albert Einstein.) Einsteinium, the seventh transuranium element to be discovered, was identified by Ghiorso et al. in December 1952, in the debris from a thermonuclear explosion in work involving the University of California Radiation Laboratory, the Argonne National Laboratory, and the Los Alamos Scientific Laboratory. The isotope produced was the 20-day ^{253}Es, originating from beta decay of ^{253}U and daughters.

Einsteinium can be investigated with macroscopic quantities using the isotopes ^{253}Es (half-life 20.5 days), ^{254}Es (half-life 276 days), and ^{255}Es (half-life 38.3 days), whose production by the irradiation of lighter elements is severely limited because of the required long sequence of neutron capture reactions over long periods of time in high-neutron-flux reactors. Most of the investigations have used the short-lived ^{253}Es because of its greater availability, but the use of ^{254}Es will increase as it becomes more available. In any case the investigation of this element is very difficult due to the high specific radioactivity and small available quantities of the isotopes.

Einsteinium metal, which is quite volatile, can be prepared by the reduction of EsF_3 with lithium and has a face-centered cubic crystal structure. It melts at 860 ± 30°C.

Einsteinium exists in normal aqueous solution essentially as Es^{3+} (green) although Es^{2+} can be produced under strong reducing conditions. Solid compounds such as Es_2O_3, $EsCl_3$, $EsOCl$, $EsBr_3$, and EsI_3 have been made.

Fermium (Fm, atomic number 100, after Enrico Fermi.) Fermium, the eighth transuranium element to be discovered, was identified by Ghiorso et al. early in 1953 in the debris from a thermonuclear explosion in work involving the University of California Radiation Laboratory, the Argonne National Laboratory, and the Los Alamos Scientific Laboratory. The isotope produced was the 20.1-hour ^{255}Fm, originating from the beta decay of ^{255}U and daughters.

No isotope of fermium has yet been isolated in weighable amounts and thus all the investigations of this element have been done with tracer quantities. The longest-lived isotope is ^{257}Fm (half-life about 100 days) whose production in high-neutron-flux reactors is extremely limited because of the very long sequence of neutron-capture reactions that is required.

Despite its very limited availability, fermium, in the form of the 3.24-hour ^{254}Fm isotope, has been identified in the "metallic" zero-valent state in an atomic-beam magnetic resonance experiment. This established the electron structure of elemental fermium in the ground state as $5f^{12}7s^2$ (beyond the radon structure).

Fermium exists in normal aqueous solution almost exclusively as Fm^{3+} but strong reducing conditions can produce Fm^{2+} which has greater stability than Es^{2+} and less stability than Md^{2+}.

Mendelevium (Md, atomic number 101, after Dmitri Mendeleev.) Mendelevium, the ninth transuranium element to be discovered, was first identified by Ghiorso, Harvey, Choppin, Thompson, and Seaborg in early 1955 as a result of the bombardment of the isotope ^{253}Es with helium ions in the Berkeley 150-cm cyclotron. The isotope produced was ^{256}Md which decays by electron capture to ^{256}Fm, which in turn decays predominantly by spontaneous fission with a half-life of 2.6 hours. This first identification was notable in that only of the order of one to three atoms per experiment were produced. The extreme sensitivity for detection depended on the fact that its chemical properties could be accurately predicted as eka-thulium and there was a high sensitivity for detection because of the spontaneous fission decay.

All of the isotopes of mendelevium, which include the relatively long-lived ^{258}Md (half-life 56 days), are produced by the bombardment of lighter elements with charged particles provided by accelerators. The chemical properties have, of necessity, been determined solely by the use of the tracer method. Mendelevium has the ions Md^{3+} and Md^{2+} in aqueous solution with the former somewhat more stable than the latter.

Nobelium (No, atomic number 102, after Alfred Nobel.) The discovery of nobelium, the tenth transuranium element to be discovered, corresponds to a complicated history. For the first time scientists from countries other than the United States embarked on serious efforts to compete with the United States in this field. The reported discovery of element 102 in 1957 by an international group of scientists working at the Nobel Institute for Physics in Stockholm, who suggested the name nobelium, has never been confirmed and must be considered to be erroneous. Working at the Kurchatov Institute of Atomic Energy in Moscow, G. N. Flerov and co-workers in 1958 reported a radioactivity which they thought might be attributed to element 102 but a wide range of half-lives was suggested and no chemistry was performed. As the result of more definitive work performed in 1958, Ghiorso, Sikkeland, Walton, and Seaborg reported an isotope of the element produced by bombarding a mixture of curium isotopes with ^{12}C ions in the then-new Heavy Ion Linear Accelerator (HILAC) at Berkeley. They described a novel "double recoil" technique which permitted identification by chemical means of any daughter isotope of element 102 that might have been formed. The isotope ^{250}Fm was identified conclusively by this means, indicating that its parent should be the isotope of element 102 with mass number 254 produced by the reaction of ^{12}C ions with ^{246}Cm. However, another isotope of element 102, with half-life 3 seconds, also observed indirectly in 1958, and whose alpha particles were shown to have an energy of 8.3 MeV by Ghiorso and co-workers in 1959, was shown later by G. N. Flerov and co-workers (working at the Dubna Laboratory near Moscow) to be due to an isotope of element 102 with mass number 252 rather than 254; in other words two isotopes of element 102 were discovered by the Berkeley group in 1958 but the correct mass number assignments were not made until later. On the basis that they identified the atomic number correctly, the Berkeley scientists probably have the best claim to the discovery of element 102; they suggest the retention of nobelium as the name for this element.

All isotopes of nobelium are short-lived and are produced by the bombardment of lighter elements with charged particles; thus all of the chemical investigations have been done on the tracer scale. These have demonstrated the existence of No^{3+} and No^{2+} in aqueous solution with the latter much more stable than the former. The stability of No^{2+} is consistent with the expected presence of the completed shell of 14 5*f* electrons in this ion.

Lawrencium (Lr) atomic number 103, after Ernest O. Lawrence.) Lawrencium was discovered in 1961 by Ghiorso, Sikkeland, Larsh, and Latimer using the Heavy Ion Linear Accelerator (HILAC) at the University of California at Berkeley. A few micrograms of a mixture of ^{249}Cf, ^{250}Cf, ^{251}Cf, and ^{252}Cf were bombarded with ^{10}B and ^{11}B ions to produce an isotope of element 103 with a half-life measured as eight seconds and decaying by the emission of alpha particles of 8.6 MeV energy. Ghiorso suggested at that time that this radioactivity might be assigned the mass number 257. G. N. Flerov and co-workers have disputed this discovery on the basis that their later work suggests a greatly different half-life for the isotope with the mass number 257. Subsequent work by Ghiorso and co-workers proves that the correct assignment of mass number to the isotope discovered in 1961 is 258, and this later work gives four seconds as a better value for the half-life.

All isotopes of lawrencium are short-lived, are produced by bombardment of lighter elements with charged particles, and all chemical investigations have been performed in the tracer scale. These have demonstrated that the normal oxidation state in aqueous solution is the (III) state, corresponding to the ion Lr^{3+}, as would be expected for the last member of the actinide series.

Rutherfordium (Rf, atomic number 104, after Lord Ernest Rutherford.) Rutherfordium, the first transactinide element to be discovered, was probably first identified in a definitive manner by Ghiorso, Nurmia, Harris, K. Eskola, and P. Eskola in 1969 at Berkeley. Flerov and co-workers have suggested the name kurchatovium (after Igor Kurchatov with symbol Ku) on the basis of an earlier claim to the discovery of this element; they bombarded, in 1964, ^{242}Pu with ^{22}Ne ions in their cyclotron in Moscow and reported the production of an isotope, suggested to be ^{260}Ku, which was held to decay by spontaneous fission with a half-life of 0.3 second. After finding it impossible to confirm this observation, Ghiorso and co-workers reported definitive proof of the production of alpha particle emitting ^{257}Rf and ^{259}Rf, demonstrated by the identification of the previously known ^{255}No and ^{253}No as decay products, by means of the bombardment of ^{249}Cf with ^{12}C and ^{13}C ions in the Berkeley HILAC.

All isotopes of rutherfordium are short-lived and are produced by bombardment of lighter elements with charged, heavy-ion particles. The isotope ^{261}Ru (half-life 65 seconds) has made it possible, by means of rapid chemical experiments, to demonstrate that the normal oxidation state of rutherfordium in aqueous solution is the (IV) state corresponding to the ion Rf^{4+}. This is consistent with expectations for the first transactinide element which should be a homolog of hafnium, an element that is exclusively tetrapositive in aqueous solution.

Hahnium (Ha, atomic number 105, after Otto Hahn.) Hahnium, the second transactinide element to be discovered, was probably first identified in a definitive manner in 1970 by Ghiorso, Nurmia, K. Eskola, Harris, and P. Eskola at Berkeley. They reported the production of alpha particle emitting ^{260}Ha, demonstrated through the identification of the previously known ^{256}Lr as the decay product, by bombardment of ^{249}Cf with ^{15}N ions in the Berkeley HILAC. Again the Berkeley claim to discovery is disputed by Flerov and co-workers who in 1970 reported the discovery of an isotope held to be element 105, decaying by the less definitive process of spontaneous fission, produced by the bombardment of ^{243}Am with ^{22}Ne ions in the Dubna cyclotron; later work by Flerov has confirmed the alpha particle emitting isotope of element 105 reported by Ghiorso and workers. Flerov has suggested Nielsbohrium (after Niels, Bohr, symbol Ns) as the name for element 105.

All the isotopes of element 105 are short-

lived and are produced by bombardment of lighter elements with charged, heavy-ion particles. The isotope ^{262}Ha (half-life 40 seconds) makes it possible, with rapid chemical techniques, to study the chemical properties of hahnium. It should exhibit the (V) oxidation state like its homolog tantalum.

Element 106 Experiments leading to competing claims for the discovery of element 106 were performed essentially simultaneously at Berkeley and Dubna in 1974. Ghiorso et al. produced the new isotope ^{263}106 through the bombardment of ^{249}Cf with ^{18}O ions in the Berkeley SuperHILAC. Decaying with a half-life of 0.9 second, this isotope was identified through the observation of previously known ^{259}Rf and ^{255}No as its daughter and granddaughter. Oganessian et al. of the Dubna Laboratory reported the observation of spontaneous fission activity with a half-life of 4–10 milliseconds, which was produced by bombarding ^{207,208}Pb with ^{54}Cr in their cyclotron and which they attributed to ^{259}106. Neither group has suggested a name for element 106. Its chemical properties should be like those of its homolog tungsten.

Element 107 In 1976, Oganessian et al. reported the observation of a 2 ms spontaneous fission activity produced in the bombardment of ^{209}Bi with ^{54}Cr ions, which they assigned to ^{261}107. In 1981, Münzenberg et al., using the linear accelerator (UNILAC) in the GSI laboratory in Germany, found an alpha-particle activity, produced in the bombardment of ^{209}Bi with ^{54}Cr ions, which could be assigned to ^{262}107 on the basis of the identification of its daughter ^{258}105 (which also undergoes alpha-particle decay). On the basis of the clear identification through the genetic relationship, as opposed to the indefinite identification through spontaneous fission, the discovery of element 107 must be credited to Münzenberg et al. Element 107 should have chemical properties like those of its homolog rhenium.

The transactinide elements with atomic numbers 104 to 118 clearly should be placed in an expanded periodic table under the row of elements beginning with hafnium, number 72, and ending with radon, number 86 (Table 4). This arrangement allows prediction of the chemical properties of these transactinide elements and it is suggested that they will have an element-by-element chemical analogy with the elements immediately above them in the periodic table. In other words, rutherfordium should chemically be like hafnium, hahnium like tantalum, element 106 like tungsten, 107 like rhenium, and so on across the periodic table to element 118, which should be a noble gas like radon. Beyond element 118, the elements 119, 120, and 121 should fit into the periodic table under the elements francium, radium, and actinium (atomic numbers 87, 88, and 89). At about this point there should start another, but a special kind of inner transition series perhaps similar in some respects to the actinide series. However, this series, which may be termed the "superactinide" series, will be different in that it will contain 32 elements, corresponding to the filling of the 18 member inner $5g$ and 14 member inner $6f$ shells. After the filling of these shells the still higher elements should again be placed in the main body of the periodic table.

It is not considered to be possible to synthesize and identify transuranium elements with atomic numbers as large as those in the superactinide series (approximately 121 to 153) or beyond. Even the earliest transactinide elements have short half-lives and are produced in small yields, and these half-lives and yields rapidly become shorter and smaller with increasing atomic number. Thus a simple extrapolation would indicate we might reach the end of the road at only a few elements beyond the heaviest now known. However, theoretical considerations suggest that elements in the region of atomic number (proton number) 114 and neutron number 184 should be stabilized against fission (the main mode of decay for the heaviest elements). This stabilization would be due to the filling of major proton and neutron shells in this region and is analogous to the stabilization of chemical elements, such as the noble gases, by the filling of their electronic shells. The elements constituting such an "island of stability" have come to be known as "superheavy elements." Many attempts have been made to synthesize and identify such elements, through bombardments with heavy ions, but success has not yet been achieved. The efforts are continuing.

The IUPAC Commission on Nomenclature of Inorganic Chemistry has recommended that temporary names be assigned to new transuranium elements until their names have been assigned in the traditional manner by their discoverers. They advocate using the "ium" ending preceded by the following roots: nil = 0, un = 1, bi = 2, tri = 3, quad = 4, pent = 5, hex = 6, sept = 7, oct = 8, and enn = 9. The corresponding chemical symbols would have three letters. Some examples from this system are: 108, Unniloctium (Uno); 112, Ununbium (Unb); 118, Ununoctium (Uuo); 140, Unquadnilium (Uqn); 200, Binilnilium (Bnn); 500, Pentnilnilium (Pnn). An alternative system, which is much easier to use, is to designate the new elements simply by their atomic numbers.

TUNNELING

Tunneling is a quantum mechanical process without a classical analog. An electron (or other quantum mechanical particle) incident upon a potential barrier whose height is larger than the kinetic energy of the electron will penetrate (tunnel) a certain distance into the barrier. This is most easily visualized by considering the one-dimensional Schrödinger equation for the wave function $\psi(x)$ of such an electron:

$$-\frac{\hbar^2}{2m}\frac{\partial^2\psi}{\partial x^2} + V(x)\psi = E\psi \qquad (1)$$

If V varies relatively slowly with distance, the solution of Eq. (1) can be approximated by

$$\psi \approx \psi_0 \exp\left[\pm i \frac{\sqrt{2m}}{\hbar}\sqrt{E - V(x)}\, x\right] \qquad (2)$$

The nonclassical case is the one where the electron energy E is smaller than the potential $V(x)$. Then ψ is no longer an oscillating wave, but it is real and decays exponentially with distance into the barrier. The penetration probability through a given barrier is equal to the ratio of the probability density $|\psi(x)|^2$ at the exit from the barrier to its value at the entrance. Equation (2) shows that this probability is exponentially dependent on barrier height and thickness. The tunneling takes place at constant electron energy as there is no scattering involved.

A more accurate solution of Eq. (1), which adequately describes many real situations, may be calculated by the Wentzel, Kremers, Brillouin

(WKB) approximation. The tunneling probability through a barrier then becomes

$$P \approx \exp\left[-2\int_{x_1}^{x_2} \frac{\sqrt{2m}}{\hbar}\sqrt{V(x) - E}\, dx\right] \tag{3}$$

An idea of the magnitude of the tunneling probability may be obtained by calculating the value of Eq. (3) for a rectangular barrier 1 eV higher than the particle energy and 25 Å wide. The result for an electron is $P \approx 10^{-11}$; for a proton, $P \approx 10^{-400}$.

Tunneling can occur in many physical situations. The simplest case is that of FIELD EMISSION. This is the emission of electrons from a solid by the application of very high fields. The energy-band diagram for such a system is shown in Fig. 1.

The electrons in a metal surrounded by vacuum may be regarded as an ensemble of quasi-free electrons held in a potential well by the positive charges of the metal ions. The depth of the well is called the electron affinity χ. The potential well is filled with electrons up to the Fermi level (E_F) and consequently electrons at this level "see" a barrier $\phi_M = \chi - E_F$ (work function) surrounding them. They can tunnel a short distance into the walls of the potential well, but of course cannot escape from it.

If a high positive field ξ is applied to the metal (e.g., by applying a potential difference between the metal under consideration and an adjacent piece of metal), the potential energy distribution is that shown in Figure 1. There now exists a barrier through which, under appropriate conditions, the electrons may tunnel. The maximum height of the barrier is ϕ_M, and its width is approximately ϕ_M/ξ so that the current becomes

$$I \propto P \approx \exp\left[-2\,\frac{2}{3}\,\frac{\sqrt{2m}}{\hbar}\sqrt{\phi_M}\,\frac{\phi_M}{\xi}\right]$$
$$\approx \exp\left[-10^8\,\frac{{\phi_M}^{3/2}}{\xi}\right] \tag{4}$$

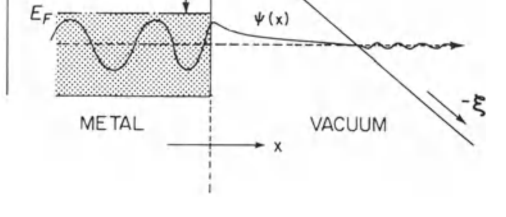

FIG. 1. Simplified energy-band diagram for field emission from a metal. $\psi(x)$ represents the wave function of an electron with energy E.

if ϕ_M is given in units of electron volts and ξ in units of volts per centimeter. Since ϕ_M generally has a value between 2 and 5 eV, an electric field of the order of 10^7 volts/cm is required before appreciable numbers of electrons will be emitted into vacuum.

Figure 1 is a somewhat simplified picture of an actual metal-vacuum interface. An electron outside the metal experiences a polarization force towards the metal, the so-called image force. While this is not a true potential, it may nevertheless be included in the potential energy diagram as a rounding-off of the well edge. When the field is applied, the barrier is lowered and so the tunneling probability increases. Particularly at high fields this causes a departure from the simple current relationship described above. If these effects are included in the calculation, good agreement can be obtained with experimental results.

Current flow at a metal-insulator interface may be treated in the same way as that at a metal-vacuum boundary. The potential barrier height is now given by the distance from the metal Fermi level to the bottom of the insulator conduction band, which is usually smaller than the work function. Also the dielectric constant of the insulator must be taken into account (e.g., in the image force). These modifications do not change the basic current-voltage relationship [Eq. (4)]. This simple picture has been extended by including electron coherency effects and detailed agreement has been obtained in semiconductor-insulator structures.

There may be localized electronic states in the barrier region, either due to impurities in the insulator layer or due to adsorbed molecules at the metal-insulator or metal-vacuum interfaces. An electron in the metal at the energy of the impurity state will then have a higher probability of tunneling to the impurity state and from there to the other side of the barrier than the probability of tunneling directly through the barrier. This means that when the applied voltage raises the Fermi level in the metal to the energy of impurity states in the barrier, there will be a sudden increase in current. The current-voltage relationship can thus be used to study the distribution of impurity states.

In case of a very thin insulator layer (<60Å) bounded on both sides by metallic regions, tunneling occurs even in the absence of fields. The band structure may be approximated by the square potential barrier discussed initially. The top of the barrier is again formed by the conduction band of the insulator, modified appropriately by image force considerations. In equilibrium, there will be equal numbers of electrons tunneling in both directions through the insulator; no net current flows.

When a potential difference is applied, one tunneling direction is favored and net current flows. For small potential differences (much less than the barrier heights) the tunneling probability does not vary with applied field and the current flowing will be proportional to the difference in number of electrons available on the two sides of the barrier at the same energies. These numbers are in turn closely related to the density of electronic states in the metals at these energies. The tunneling current may therefore be used to investigate the density of states in certain materials, where this quantity changes rapidly with energy.

This technique for determining the density of states has been put to particularly good use in the case of superconductors. The fact that the superconductor has an energy gap in the density-of-states function at the Fermi level leads to nonlinearities and negative resistance regions in the current-voltage characteristics. This has become the most accurate method of measuring the energy gap of superconductors as a function of temperature, magnetic field and other variables. More complicated phenomena, such as simultaneous tunneling of two electrons as a pair, have also been observed. This forms the basis for the Josephson effects.

Other nonlinearities are observed at small voltages in junctions made of normal as well as superconducting metals. These are due to inelastic tunneling where the electron changes energy during tunneling by interaction with lattice excitations; e.g., it may emit or adsorb a phonon. Emission can only take place if the applied voltage is larger than the phonon energy so that a step in the current (or in its derivative) is expected at that voltage. This is observed experimentally at low temperatures. It has become one of the best tools for quantitative study of the properties of electrons and phonons in metals. In some cases, anomalies are also observed at zero voltage and they may be due to magnetic interactions.

Tunneling out of a three-dimensional well is treated similarly to tunneling through the one-dimensional barrier. The exact exponential dependence will be different from Eq. (2) and depend on the form of the barrier. One type of three-dimensional well is formed by an impurity in a semiconductor or insulator which may form a bound state in the region of the forbidden gap. An electron can only tunnel out of such a state when a high field is applied, as in field emission from metals.

A different type of three-dimensional potential well is found in the atomic nucleus. A combination of short-range nuclear attraction and Coulomb repulsion forms a potential barrier of the type shown in Fig. 2. Many heavy radioactive nuclei contain α-particles with high enough kinetic energy to tunnel through the barrier (α-decay). Because of the much heavier mass and high barrier energy, the barrier must be considerably thinner than for an electron ($\sim 10^{-12}$ cm). Again calculations for a Coulomb barrier agree well with experimental observations of the energy dependence of the decay time (Geiger-Nuttall relation).

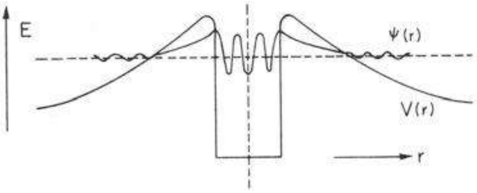

FIG. 2. Model of the nucleus, with $\psi(r)$ the wave function of an α-particle.

Tunneling of entire atoms can take place in solids, particularly when there are two possible equilibrium states (potential minima) at equal energy for the atoms which are separated by a small distance and low potential barrier. Examples of this are ferroelectric crystals of the hydrogen-bonded type (e.g., KH_2PO_4). The hydrogen atom has two possible positions in the hydrogen bond, near one or the other of the adjacent atoms. In the ferroelectric phase, all hydrogen atoms occupy the same potential well and a reversal of polarization direction is accomplished by a switch from one well to the other.

Tunneling of one or more atoms has also been used to explain the low-temperature properties of some solids. Alkali halide crystals doped with certain impurities exhibit reduced thermal conductivity at low temperatures with resonance peaks. These impurities have more than one equilibrium position in the lattice and can tunnel between these positions (either by rotation or by displacement). These low-frequency excitations produce the observed phonon scattering.

A related situation applies in amorphous solids. The thermal and acoustic properties of glasses differ significantly from those of crystalline solids at low temperatures. It has been proposed that some atoms in the disordered solid can exist in more than one potential minimum. In contrast to the crystalline case, these minima vary in energy depending on the local environment. The excitation energies related to tunneling between two such minima are randomly distributed, so that no resonances are observed in thermal spectra.

Electron tunneling is also observed in semi-

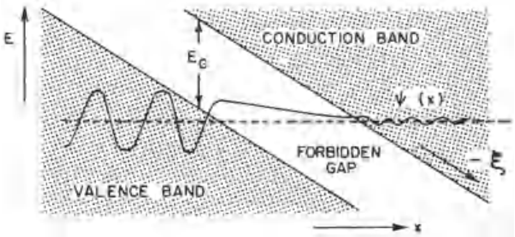

FIG. 3. Band structure of a semiconductor or insulator under an applied field.

conductors (Zener tunneling), but in this case the situation cannot be represented by the kind of barrier discussed previously. The band structure of a semiconductor under a large applied field is shown in Fig. 3. There exists no set of real energy states connecting the two regions, and an electron must always make a discontinuous step in passing from the valence band to the conduction band. Still the tunneling probability may be calculated with an approximation equivalent to that used for the simple barrier, and except for a numerical factor, the result is the same as Eq. (4) with ϕ_M replaced by E_G.

Conduction of this type is observed in very narrow *p-n* junctions under reverse bias (Zener breakdown) or in insulators where there are no free carriers available. In the former case, there is a large built-in field even at zero external voltage which is produced by the difference in the electrochemical potentials of the *n*- and *p*-regions. A small additional voltage (1 to 2 volts) raises the field to the value required for tunneling.

In still narrower *p-n* junctions ("tunnel diodes") tunneling readily takes place even where no applied voltage exists. As in the case of the very thin insulator, the electrons tunneling in opposite directions then just cancel one another out. The current-voltage curve of such a junction is drawn in Fig. 4. The band structure configurations at two values of forward bias are also shown. Net tunneling current will flow in either direction of applied voltage, as long as there are electrons on one side opposite empty states of the same energy on the other side. Under large forward current this condition is no longer fulfilled, as the bottom of the conduction band on the *n*-type side comes opposite the forbidden energy gap on the *p*-type side. This means that the current passes through a maximum value and then decreases towards zero with increasing forward bias. At still larger bias, the conventional forward diode current becomes dominating.

In actual diodes, the current never decreases completely to zero. There always exist impurity states in the forbidden gap to which an electron of appropriate energy may tunnel and from which it may drop into an empty state in the valence band giving up energy to localized lattice vibration. Alternatively, the electron need not actually occupy the impurity state but can tunnel "inelastically" directly to the valence band while simultaneously giving up the difference energy to the impurity atom and its vibration.

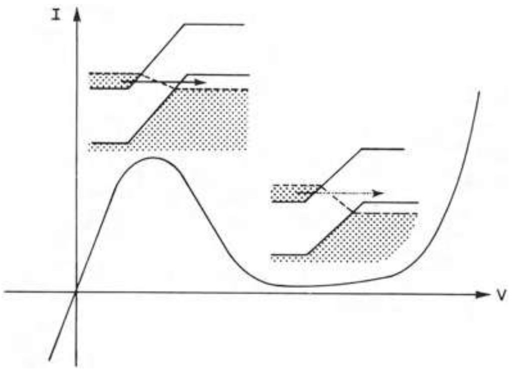

FIG. 4. Current-voltage characteristic of a tunnel diode. The two inserts depict the band structure at the maximum tunnel current and at the valley where tunneling is no longer possible.

ULTRASONICS

Ultrasonic Waves Ultrasonic waves are sound waves above the frequency normally detectable by the human ear, i.e., above about 20 kHz. The particles of matter transmitting a *longitudinal* wave move back and forward about mean positions in a direction parallel to the path of the wave. Alternate compressions and rarefactions in the transmitting material exist along the wave propagation direction. Such waves are possible in solids, liquids or gases. In solids, *shear* waves can also propagate. For these, the particles move perpendicularly to the direction of wave propagation. When material boundaries are present in the vicinity of a wave more complicated particle motions take place. Common examples are *Rayleigh* waves (at the boundary between a solid and air) and *Lamb* waves (in thin plates whose thickness is of the order of the wavelength of sound). The predominant particle displacement in these latter cases is perpendicular to the surface of the solid (see WAVE MOTION). Examples of the propagation velocities for these mode types are given in Table 1.

If an ultrasonic wave is normally incident on a boundary between two media of different densities ρ and velocities V, the fractions of the wave amplitude which are reflected (R) and transmitted (T) are:

$$R = \frac{\rho_2 \ V_2 - \rho_1 \ V_1}{\rho_2 \ V_2 + \rho_1 \ V_1}$$

$$T = \frac{2\rho_2 \ V_2}{\rho_2 \ V_2 + \rho_1 \ V_1}.$$

For oblique incidence the reflection and transmission at a boundary are more complicated since the incident wave is transformed into reflected and refracted shear and longitudinal waves. *Snell's Law* governs the angles of *reflection* and *refraction* for both types of waves. It states that

TABLE 1. APPROXIMATE SOUND VELOCITIES

	In Water (m/sec)	In Steel (m/sec)
Longitudinal	1.5×10^3	6×10^3
Transverse	Cannot be supported	3×10^3
Rayleigh	Cannot be supported	3×10^3

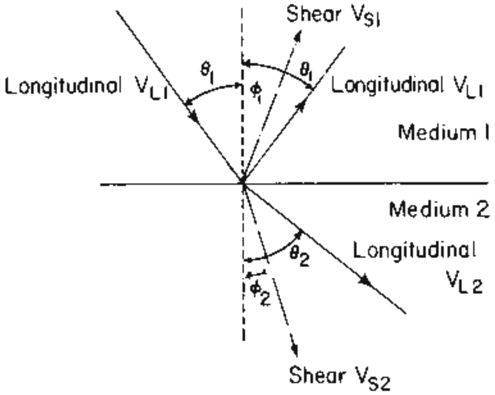

FIG. 1

$$\frac{\text{Sin } \theta}{V} = \text{Constant}$$

where θ is the angle the beam makes with a normal to the intervening surface and V is the sound velocity. Therefore, in Fig. 1,

$$\text{Constant} = \frac{\sin \theta_1}{V_{L1}} = \frac{\sin \theta_2}{V_{L2}} = \frac{\sin \phi_2}{V_{S2}} = \frac{\sin \phi_1}{V_{S1}}$$

Transducers In general an electromechanical transducer is a device to convert electrical energy into mechanical vibrations which are then directed into the specimen. The transducer also commonly reconverts received mechanical oscillations back into electrical signals for amplification and recognition. Transducers can be *piezoelectric*, *ferroelectric*, *magnetostrictive*, or *optical* in nature.

Until recently, the only peizoelectric transducer in general use was *quartz*, but now several synthetic ceramic materials are employed. The application of a voltage across a piezoelectric crystal causes it to deform with an amplitude of deformation which is generally a simple function of the voltage. Reversal of the voltage causes reversal of the mechanical strain.

Transducer crystals are normally cut to vibrate at a resonant frequency, the thickness being one-half the acoustic wavelength. A bond between the crystal transducer and the specimen matches the acoustic impedance and carries the acoustic power into the specimen. Such a device can produce a wave motion in the material at the resonant and harmonic frequencies of the transducer. Backing layers may be affixed to the rear surface of the transducer and can be designed to perform a number of functions: transformation of the resonant transducer into a broadband transducer with center freuqency near the original resonance, reflection of power forward into the crystal and specimen, or simplification of the form of the signals measured in material testing applications.

A new transducer, of particular importance in research applications, is the *laser*. A high power pulsed laser can be used for the generation of ultrasonic pulses and a *laser interferometer* for the direct measurement of displacement amplitudes of ultrasonic waves. An obvious advantage of the laser is that it requires no mechanical contact with the specimen.

Ultrasonic Testing Most ultrasonic test equipment employs pulses of high-frequency sound (>1 MHz), the pulse width being adjustable between 0.1 and 1.0 msec and the repetition rate between 60 and 1000 pulses per second. Figure 2 shows a typical block diagram of ultrasonic testing equipment.

The synchronizer triggers a pulse in the generation circuit which is converted into an acoustic pulse by the transducer crystal. The synchronizer also starts the sweep circuit of the cathode ray tube (CRT) and the marker circuit, the latter making marker pips along the time base. Separate transducer crystals may be used for transmission and reflection, or one crystal may be made to carry out both functions. The echo from the back face of the specimen block arrives at twice the transmission time after the initial pulse. The marker pips can then be calibrated in terms of depth. A fault will show up as an extra echo whose depth into the specimen can be read from the marker pip which coincides with its position on the screen of the CRT.

The transducer is coupled into the specimen under test by an oil or adhesive. In high-speed testing or in cases where rough surfaces are encountered, the specimen may be immersed in a liquid or a stream of liquid passed between the transducer and the specimen in order to give sonic coupling.

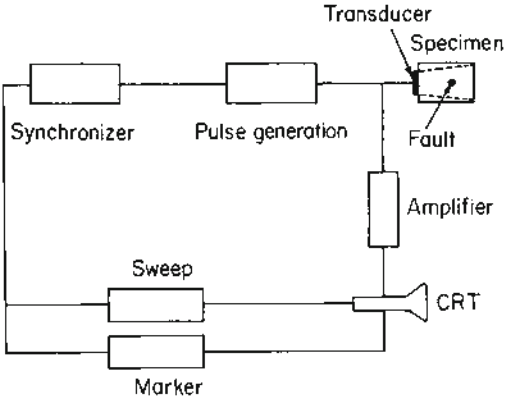

FIG. 2

Examples of Ultrasonic Testing. Solid objects of thickness about 1 cm or greater may be tested for inhomogeneities. Special techniques also exist for sheet testing. Heavy forgings, crank shafts, rails, concrete structures and a host of other manufactured objects are now regularly scanned for porosity or internal faults. The frequencies employed are normally about 1–15 MHz for metal objects, about 0.5 MHz for many plastics, and 0.1 MHz for concrete.

Ultrasonic Scanning can be used to record the spatial variation of the reflection or transmission properties of an object. In earlier usage, echoes were recorded on the CRT which was circularly scanned (like the P.P.I. radar system). Nowadays automatic scanning and *data processing* are commonly used to obtain recognizable ultrasonic images of internal structure. Typical applications are the imaging of a fetus, tumor, or gallstone in medical applications; the imaging of the microstructure of solids using the acoustic microscope; the characterization of internal flaws in *nondestructive evaluation* applications. Typical measurements of these types are carried out at relatively high ultrasonic frequencies to achieve maximum resolution. In particular the *acoustic microscope* involves measurement of the attenuation of 100 MHz ultrasonic waves with a resulting resolution ~10 μm. In *sonar* underwater detection, on the other hand, frequencies must be low because of the high attenuation in water (60 dB/km at 100 kHz), with consequent reduction in resolution by many orders of magnitude compared to the acoustic microscope. Sea noises, fish, and underwater refraction by layers at different temperatures introduce difficulties of interpretation into the echo patterns. Depth recording is now accomplished by the use of many sending and receiving transducers coupled to a computing system which interprets differences of arrival times in terms of variation of path length and ultimately of depth. Continuous records of the ocean bed or the depth of surface ice can be made.

Examples of the Use of Ultrasonic Power. Longitudinal ultrasonic waves can be produced with sufficient intensity to cause pronounced physical changes in materials of industrial importance. In many cases, standing waves are set up in a containing vessel with resulting periodic variation of vibration amplitude. In almost all cases ceramic transducers are used. Emulsifying, mixing, dispersing, degassing, and cleaning applications generally employ unfocused acoustic radiation. In welding, soldering, drilling, machining, and the neurosurgical controlled damage of brain tissue, on the other hand, a focused acoustic beam is always used.

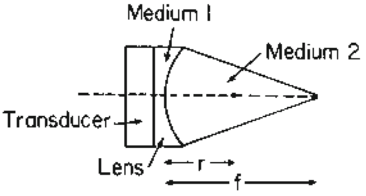

FIG. 3

Focusing may be done by the use of either an acoustic horn or by an acoustic lens. Figure 3 shows the principle of a simple plano-concave lens whose radius of curvature, r is given by

$$r = f\left(\frac{n - 1}{n}\right)$$

where n, the index of refraction, is the ratio of velocities in the lens and adjacent medium:

$$n = \frac{V_1}{V_2}$$

Fundamental Research in Physics by Ultrasonics *Acoustic Velocity*. The acoustic velocity in a material is fundamentally related to the binding forces between the atoms or molecules. Measurement of the velocity is made by a pulse technique or by vibrating a specimen of known dimensions in one of its fundamental modes of oscillation and recording the frequency.

Acoustic Attenuation. Attenuation measurements are made by recording the decay in oscillation amplitude with time of a solid material set to ring in one of its natural modes or from the decrease in amplitude of successive echoes passing through the material. The attenuation of material is a measure of energy losses and may be used to study a variety of fundamental loss mechanisms.

Under the influence of *thermal activation*, impurity elements or defects may switch positions in a crystal lattice. This they do in a definite *relaxation time*, which is related exponentially to the temperature and to the difference in energy of the defect in its two positions. Now if the switching of position of the defect also causes a difference in dimension of the specimen, a maximum in attenuation is found when the period of an applied acoustic stress just matches the thermal relaxation time. A whole spectrum of relaxation attenuation maxima has been found in solids. Each is related to a definite internal process, each with its characteristic energy difference. Perhaps the best known of these is the relaxation maximum given by the diffusion of carbon atoms in iron from which the activation energy for carbon diffusion can be calculated (Snoek peaks).

Dislocations are line defects in crystalline material the movement of which is involved in all cases of plastic deformation. Acoustic waves vibrate the dislocations and, in general, the more freely the dislocation moves, the more the acoustic beam is attenuated. Attenuation measurements thus give information on how well the dislocation is locked in position in the solid, i.e., on the strength of the material. Pinning down of the dislocations may be effected by alloying or by radiation with high-energy particles which cause internal damage. Measurement of acoustic attenuation is therefore encountered in such studies.

Electrons in metals also attenuate acoustic waves if the frequencies are sufficiently high (>5 MHz) and the temperature sufficiently low (<10 K) so that the acoustic wavelength is comparable with the mean free path of the electrons. Attenuation measurements give information on relaxation times of electrons, and hence their energies. Such measurements can be used to determine the dimensions and shape of the *fermi surface* in metals and are intimately related to the phenomena of electrical and thermal conductivity. The onset of *superconductivity* in some metals and alloys at low temperatures is characterized by a fall to zero electrical resistance and also by a sharp fall in high-frequency acoustic attentuation.

In nonmetallic crystalline materials, thermal vibrations or *phonons* interact with one another and limit heat conductivity. Ultrasonic waves are phonons of known frequency and polarization, both being mechanical vibrational modes of the material. Hence, measurement of the attenuation of ultrasonic waves can be used to study phonon-phonon interaction and consequently the mechanisms of thermal conductivity. Such a study is usually carried out in materials below 100 K using ultrasonic waves at extremely high frequencies (>1000 MHz). Such information may lead to the elucidation of the spectrum of thermal vibrations in all materials above the absolute zero of temperature.

Acoustic Emission. Acoustic emission is a new technique which is evolving from ultrasonics. In acoustic emission only a detecting transducer is used, the information being generated by gross internal changes in the specimen material. Acoustic emission is the transient elastic wave generated by the rapid release of energy within a material under stress. Detection of the acoustic emission is usually accomplished using an ultrasonic transducer. During the last 25 years, several investigators have identified and studied the many sources of acoustic emission which include slip, dislocation breakaway and pinning, mechanical phase transitions, stress corrosion, and fatigue crack growth.

The stress waves emitted by the release of energy from defects can span a very wide frequency range, and indeed can include all frequencies up to thermoelastic waves. In the cases of the "cracking" of timber prior to failure, and the "cry" of tin undergoing bending, elastic energy is emitted in the audio range, and is audible to the human ear, while acoustic emission from crack advance is detectable up to several megahertz. Acoustic emission activity is often observed to be irreversible, in the sense that during the reloading of a material, acoustic emissions are not generated until the stress level exceeds its previous maximum value. This phenomenon is known as the *Kaiser effect.*

While acoustic emission is expected at much higher frequencies, the range over which most measurements are currently made is 0.1–1.0 MHz. This frequency range is chosen since it is high enough to avoid most environmental noise, and low enough to avoid excessive acoustic attenuation in most materials.

Two types of acoustic emissions are observed in ductile materials. *Continuous emissions* are attributed to the low-level, relatively steady noise which results from slow, undirectional loading of an unflawed specimen. Dislocation motion has been cited as a probable cause of this type of noise. *Burst emissions* are transients which appear only occasionally, are usually of much higher amplitude than the continuous type of emissions, and have been attributed to sudden gross structural changes such as microcracking. During fatigue failure, both continuous and burst emissions occur. The continuous emissions increase in amplitude prior to the occurrence of the high amplitude burst emissions.

ULTRAVIOLET RADIATION

Ultraviolet radiation comprises the region of the electromagnetic spectrum extending from the violet end of the visible, wavelength 4000Å, to the beginning of X-RAYS, arbitrarily taken as 100Å, a span of more than five octaves. The unit of wavelength generally used for the ultraviolet is Å = 10^{-8} cm; it is named after A. J. Ångström, Swedish pioneer in SPECTROSCOPY, who made in 1868 the first accurate measurements of the wavelengths of spectral lines. Although still occasionally heard, the term ultraviolet rays has become obsolete. Ultraviolet light, however, is an expression which is usually acceptable even though ultraviolet cannot ordinarily be seen by the eye.

The ultraviolet is subdivided into several parts: The near ultraviolet, 4000 to 3000Å, present in sunlight, producing important biological effects, but not detectable by the eye; the middle ultraviolet, 3000 to 2000Å, called by biologists the far ultraviolet, not present in sunlight as it reaches the earth's surface, but well transmitted through air; the long range 2000 to 100Å known as the extreme ultraviolet, abbreviated XUV, since it connects the ultraviolet and x-rays. The XUV is known also as the vacuum ultraviolet, VUV, because it is not transmitted through air, and is sometimes called the far ultraviolet. The portion of the XUV from 2000 to 1350Å is known as the Schumann region, after its discoverer.

The boundary, 100Å, between XUV and x-rays is arbitrary; it is often preferred to make the distinction on the basis of the method of production and analysis. Radiation is called x-rays if produced by the classical x-ray tube in which bombardment by electrons removes inner-shell electrons from atoms of the target material, with radiation emitted when outer electrons fall back; x-rays are also generated by the BREMSSTRAHLUNG process when fast electrons are suddenly decelerated. In sparks, arcs, and electrical discharges through gases, the classical sources of ultraviolet, it is the outer electrons of either neutral atoms or ions that are excited; the radiation occurs when the outer electrons are recaptured and fall back to their ground states (see ELECTRICAL DISCHARGES IN GASES).

Ultraviolet radiation was discovered by Ritter in 1801; he found that silver chloride was blackened, as it is by visible light, if placed beyond the violet end of the sun's spectrum, where nothing can be seen. Stokes, in 1862, using a prism of quartz rather than glass, observed to a short-wavelength limit of 1830Å radiation produced by a spark discharge between aluminum electrodes by using a fluorescent plate detector. The break-through further into the ultraviolet was made between 1885 and 1903 by Victor Schumann, an instrument maker and machine shop owner of Leipzig. Schumann realized that there are three reasons why ultraviolet of shorter wavelengths had not been detected: (1) air is opaque, (2) quartz prisms and lenses do not transmit, (3) ordinary photographic emulsions are not sensitive, because of absorption by gelatin. He overcame these difficulties by constructing the first vacuum spectrograph by using optics of crystal fluorite instead of quartz, and by making photographic plates with almost no gelatin, now known as Schumann plates. Theodore Lyman of Harvard University, soon passed 1300Å, the limit reached by Schumann, by constructing a vacuum spectrograph with a reflection-type concave diffraction grating instead of the fluorite prism and lenses. He discovered the Lyman series of hydrogen, the most fundamental spectral series of the simplest and most abundant element, with first line, Lyman-alpha, at 1215.67Å and series limit at 911.7Å. Further progress reaching 140Å was made by R. A. Millikan and his students at the California Institute of Technology with the aid of a "hot" spark in vacuum. Finally Osgood, in 1927, closed the gap to x-rays by combining the hot spark and a grating used at grazing incidence; in the same year, Dauvillier reached 121Å in the XUV from the x-ray side, using an x-ray tube with a spectrometer utilizing a crystal of large lattice constant, made from a fatty acid.

Ultraviolet radiation is emitted by almost all light sources, to some extent. In general, the higher the temperature or the more energetic the excitation, the shorter are the wavelengths. Tungsten lamps in quartz envelopes radiate in the ultraviolet in accordance with Planck's law, slightly modified by the emissivity function of tungsten. Because of its high temperature, 3800K, the crater of an open carbon arc is an excellent source of ultraviolet extending to the air cutoff. Electrical discharges through gases produce intense ultraviolet emission, mainly in lines and bands. The most widely used is the quartz mercury arc; when the Hg pressure is allowed to rise to several atmospheres, the intensity becomes great, and the spectrum is a quasi continuum. For the shortest wavelengths, still higher temperatures are required, as produced by discharging a large capacitor at some 50 kV between metal electrodes in vacuum. This violent discharge vaporizes atoms from the electrodes, then strips off as many as 10 or 15 outer electrons. The emission line radiation emitted when these highly ionized atoms recapture electrons extends to very short wavelengths. A similar short-XUV "spark" can also be produced by focusing a high-power laser beam on a metal surface. Another source producing highly ionized atoms and emission lines in the XUV is the magnetically compressed plasma such as produced by the devices known as zeta and theta pinch, which reaches a temperature of half a million degrees. A relatively new source of XUV and x-rays is the synchrotron, in which electrons are accelerated to energies of the order of one billion electron volts while constrained to a circular orbit by a magnetic field. The electromagnetic radiation produced by the great centripetal acceleration is intense and is plane-polarized. Most important, its spectrum is a smooth, broad continuum which is far more useful for many purposes than any other XUV continuum. The position of the broad intensity peak depends on the electron energy and the magnetic field and can be placed at any wavelength between approximately 1000 Å and 1 Å by selecting the proper value of electron energy within the range several hundred MeV and a few GeV. The type of synchrotron known as the storage ring is particularly useful because of the high degree of control of the XUV beam that emerges. These sources offer powerful new technologies for the study of the fine structure of materials, particularly when samples are available only in minute quantities. Techniques are now available for producing the radiation in the form of very short pulses of extremely high intensity, which are especially useful in the study of transient reactions in matter. Another new source of radiation is the laser, with which extremely high values of intensity can be produced. The laser's spectrum is strictly monochromatic, exactly the opposite of the perfect continuum of the synchrotron. Progress is being made toward the development of lasers for the UV, and to a lesser degree for the XUV and x-rays. Applications, as yet, are few. For great XUV intensity, however, no man-made source has equaled the atomic bomb.

Solids, liquids, and gases usually transmit well in the near ultraviolet but always become opaque somewhere in the middle or extreme ultraviolet. Among solids, both crystal and fused quartz transmit to a short wavelength limit between 2000 and 1500Å, depending on purity; CaF_2 (fluorite), to 1230Å; MgF_2 to 1140Å; and LiF, the most transparent known solid, to 1050Å. These materials are invaluable for constructing lenses and prisms for ultraviolet instruments.

Solids in the form of very thin films transmit to some extent throughout the XUV, but the thickness must be less than a few thousand Ångstroms. Certain thin films are useful as optical filters; Al, for example transmits from 837Å corresponding to its plasmon frequency, to its x-ray L-edge at 170Å, and to a small extent as far as 150Å. Films of plastics, such as collodion of 300Å thickness, transmit fairly well below 500Å; they are useful as windows for low-pressure gas retention.

Gases vary greatly in their absorption characteristics. Molecular oxygen causes air to become opaque below about 1850Å, because of absorption in the Schumann-Runge band system, followed by continuous absorption from 1750 to 1290Å, and strong irregular absorption to shorter wavelengths. Molecular nitrogen, however, is relatively transparent all the way to 1000Å. Hydrogen absorbs in the Lyman series lines, and in an ionization continuum beyond the series limit, 911.7Å. Of all the gases, helium is the most transparent; absorption first takes place in the resonance lines, the longest lying at 584Å, and in a continuum beyond the series limit, 504Å. More complicated molecular gases, such as CO_2, NO, and N_2O are rather opaque throughout most of the XUV. Water vapor is much like O_2 with absorption commencing below 1850Å.

Reflection occurs for ultraviolet, just as for visible radiation. In general, the reflectance becomes less, as the wavelength decreases. Aluminum is the best reflector over much of the long-wavelength region; when properly prepared, by rapid evaporation of the pure material in an excellent vacuum, the reflectance is greater than 90 per cent to 2000Å, and can be maintained to 80 per cent at 1200Å by overcoating with a thin layer of MgF_2 to prevent growth of Al_2O_3. Below 1000Å, platinum is best with a reflectance of about 20 per cent at 600Å, but only about 4 per cent at 300Å.

Ultraviolet can be detected in a variety of ways, making use of effects produced when it is absorbed by matter, e.g., fluorescence with reradiation of longer wavelengths; chemical reactions in solids; dissociation of gas molecules, with ensuing reactions; ionization of gases; emission of photoelectrons from surfaces of solids. In general, the shorter the wavelength, the more energetic is the reaction. This is in accordance with Einstein's law, $E = h\nu$, giving the energy of a photon in terms of Planck's constant, h, and its frequency ν (velocity of light ÷ wavelength). Thus, ultraviolet photons range up to about 10 000 times more energetic than visible photons, and effects produced by them are much easier to observe.

The simplest way to detect and measure ultraviolet radiation is by making use of the fluorescence process, converting the ultraviolet into visible radiation which can be seen, or into near ultraviolet which is easily photographed or measured with conventional photomultipliers. Calcium tungstate, for example, is an excellent converter for the middle ultraviolet. Materials much used for the extreme ultraviolet are oil and sodium salicylate. The latter is especially valuable because its quantum efficiency of fluorescence is high and is nearly independent of wavelength. An ordinary photomultiplier, with its glass window coated with a layer of sodium salicylate becomes a sensitive radiometer for use throughout the entire ultraviolet.

Ordinary photographic emulsions containing gelatin as a binder are useful only to about 2500Å; they can be sensitized easily by overcoating with oil or sodium salicylate. Eastman Kodak spectroscopic-type plates and films are available with ultraviolet sensitization, produced by overcoating with a fluorescent lacquer. Nearly gelatin-free Schumann-type emulsions combine greater sensitivity and higher resolving power than fluorescence-sensitized emulsions; they are available as Eastman Kodak 104 (formerly called SWR), the higher-speed 101, and Kodak Pathé SC5 and 7. All types must be handled so that the delicate emulsion surface is never touched.

Ultraviolet radiation is easily detected and measured directly by means of photomultipliers if they are equipped with ultraviolet transmitting windows or are used without an envelope in a vacuum. Almost all materials emit photoelectrons to some extent when ultraviolet-irradiated, but in applications, the problem is usually to devise a photocathode surface that has extremely high efficiency in a certain spectral region and is insensitive in others. When constructed with ultraviolet-transmitting envelopes, the various visible-sensitive photocathodes respond well throughout the ultraviolet. For applications in the presence of sunlight, however, it is often necessary to use a "solar blind" surface, having negligible sensitivity longward of 2900Å; one of the best surfaces is RbTe, with quantum efficiency of $< 10^{-3}$ at $\lambda > 3000$Å and ≈ 0.1 at $\lambda < 2600$Å.

For use at wavelengths shorter than 1300Å the best photocathodes are simple metal surfaces, such as tungsten, used directly in vacuum. Most metals exhibit a strong internal photoelectric effect at $\lambda < 1500$Å, which reaches a high value of about 15 per cent at 1000Å. This high work function results in low sensitivity to long-wavelength stray light, and low noise. By coating the metal cathode with LiF, MgF_2, or other compounds, the spectral response curve can be greatly modified and the long wavelength cut-off displaced, to adapt the detector for special applications. Metal photocathodes are available in electrostatically focused photomultipliers with photocathode and dynodes of Be-Cu or stainless steel, and magnetically focused strip-photomultipliers with tungsten photocathodes. The sensitivity is little changed by repeated exposure to air.

Ionization chambers and Geiger counters form another useful class of detectors of XUV radiation. Knowledge of the ionization efficiency of the gas makes it possible to use them for measurement of absolute energy. One of the most useful is filled with NO, responding from the ionization limit, 1350Å, to the transmission limit of the LiF window, 1050Å. To shorter wavelengths, it is possible to use Geiger counters without a window, by maintaining a slight positive gas pressure inside the tube. When filled with a rare gas, they count all incident photons of wavelengths shorter than the ionization limit of the gas, since the gas ionization efficiency is 100 per cent.

Ultraviolet radiation can, of course, be detected with a thermocouple, by direct conversion of its energy into heat. Because of low sensitivity, this fundamental absolute method of energy measurement is resorted to only when no other method is available, for example, in order to establish that the ionization efficiency of the rare gases is 100 per cent for radiation below their series limits.

Mankind's principal source of energy, the sun, emits strongly throughout the ultraviolet, but only the near ultraviolet reaches the surface of the earth. Wavelengths shorter than 2900Å are absorbed by a layer of ozone (O_3) with center at an altitude of about fifteen miles.

The principal action of solar ultraviolet is to produce sunburn, or erythema, but it is only the shortest wavelengths penetrating the ozone layer which have this action. Since the effective band is centered at 2967Å and extends to about 3100Å, sunlight becomes rapidly more effective in burning the skin when the subject goes to a high altitude and when the sun lies high in the sky. Excessive exposure is known to be a cause of skin cancer.

The normal eye does not sense the sun's ultraviolet, although it does have a small sensitivity below 4000Å. Young eyes transmit more than old, and do, indeed, detect ultraviolet from 4000Å to about 3130Å as a faint, bluish sensation, but sharp images are not formed without special corrective lenses, on account of the chromatic aberration of the eye's optical system. To shorter wavelengths, ultraviolet is absorbed by the cornea and causes fluorescence, which is seen as a general haze. Excessive exposure to wavelengths short of 3000Å, however, causes conjunctivitis, a painful burn of the cornea. For this reason, it is extremely important to wear glass goggles, when in the presence of intense sources of middle ultraviolet radiation. Similarly, on snowfields and glaciers, goggles must be worn to prevent the form of conjunctivitis known as snow blindness.

A new and unfortunate action of solar ultraviolet is the production of Los Angeles-type smog, containing molecules which irritate the eye and causes damage to plants. The photochemical processes are complicated and are not as yet completely understood. It is well established, however, that the principal atmospheric contaminants involved are nitrogen oxide, nitrogen dioxide, and various organic molecules present in gasoline engine exhausts. The initial process appears to be the absorption of solar ultraviolet by NO_2, which produces O and NO. The principal reactions, however, are the photolysis of mixtures of nitrogen oxides and hydrocarbons in air, caused by absorption of solar ultraviolet. The products of the reactions are ozone, aldehydes, acrolein, acetone, and peroxyacyl nitrates and nitrites (PAN); among these, formaldehyde, acrolein, and PAN are specific eye irritants. One principal phytotoxicant is ozone, which produces a mottling or bleaching of the upper surfaces of leaves; various others cause a bronzing or glazing of the underneath surfaces of leaves. Obviously, solar ultraviolet cannot be eliminated; photochemical smog relief must come from the chemist.

The principal present-day application of ultraviolet radiation is in increasing the efficiency of conversion of electrical energy into light. The fluorescent lamp utilizes a coating of a crystalline substance, such as manganese-activated zinc silicate, on the inside wall of a mercury arc lamp, to convert the middle- and near-ultraviolet radiation from the mercury vapor column into visible light and thus add to the visible-line spectrum emission of the mercury. The efficiency of fluorescent lamps may reach values 2.5 times greater than those of commonly used incandescent tungsten lamps.

Another widespread use of ultraviolet is in "black lighting," largely for the theater. By introducing an ultraviolet-transmitting, visible-opaque filter over a carbon arc projector, an intense ultraviolet beam can be projected onto the stage. There it causes different materials to glow brilliantly, with color determined by the particular dye molecule.

As a technical industrial tool, ultraviolet spectroscopic analysis has become of extreme importance. In the production of steel, for example, a sample can be analyzed in minutes, by introducing it into a source electrode, and analyzing the radiation with a multichannel spectrometer. Different exit slits select the strongest and most sensitive emission lines of the various elements present; with photomultipliers, their intensities are measured and converted at once to give the composition of the steel.

Among various biological and medical applications of middle-ultraviolet radiation, perhaps the most important are its uses to kill bacteria and fungi in hospitals and especially in operating rooms to eliminate the hepatitis virus from blood plasma, to keep foods sterile, and to treat skin diseases. Rickets and certain other diseases, can be cured by exposure of the body to ultraviolet, which produces vitamin D. Similarly, vitamin D is produced in milk by ultraviolet irradiation.

The middle- and extreme-ultraviolet radiation from the sun, although not able to reach the earth's surface, nevertheless affects man and his activities through its powerful influence on the upper atmosphere. First knowledge of the sun's ultraviolet spectrum was obtained in 1946, when a spectrograph was flown in a V-2 rocket by the U.S. Naval Research Laboratory and the solar spectrum was recorded from 3000 to 2200Å. In the thirty-six years since this event, great progress has been made in studying, from rockets and orbiting vehicles, the true solar spectrum, the reactions produced in the atmospheric gases when the sun's short wavelengths are absorbed, and the physical processes in the solar atmosphere giving rise to these radiations. Grouped together broadly as a space science, they comprise several fields, such as aeronomy, solar physics, solar-terrestrial relationships, and ionospheric research. In the years to come, it is certain that orbiting observatories will monitor the ultraviolet and x-ray emissions from the sun. An important advance in this direction was the solar experimentation carried out by instruments in the Apollo Telescope Mount (ATM) of NASA's Skylab. Operated on a daily basis by the astronauts, these spectrographs and solar imaging devices produced from May 1973 to

February 1974 a wealth of information on the XUV and x-ray emissions from the sun that is not likely to be surpassed for many years. Eventually, orbiting observatories will monitor routinely these solar emissions, complementing the work of the great ground-based observatories that study in visible light and in the near UV, the phenomena taking place in the solar atmosphere. The next major step is now being made from NASA's Space Shuttle, by experiments designed to record with high accuracy the spectrum of the sun's radiation in the UV and XUV. This work is planned to cover at least one entire solar cycle in order to learn more about the variability of the sun's short wavelength radiations and the connections with changes produced in the earth's atmosphere.

As affecting our present-day way of life, perhaps the most important action of solar short-ultraviolet and soft x-rays is in producing the several ionospheric layers; acting as mirrors, they reflect radio waves and so make possible radio communication over great distances. Far more important for mankind, however, is the solar radiation in the Schumann region, 2000 to 1300Å. It is upon this radiation that the human race relies for survival; absorption of these wavelengths by molecular oxygen in the high atmosphere gives rise to atomic oxygen, which then reacts with molecular oxygen to form ozone. It is this permanent layer of ozone which protects all forms of terrestrial life from the lethal effects of the sun's middle-ultraviolet radiation.

V

VACUUM TECHNIQUES

The term "vacuum," which strictly implies the unrealizable ideal of a space entirely devoid of matter, is used in vacuum technique to denote gas pressure below the normal atmospheric pressure of 760 torr = 1 bar (1 torr = 1 mm of mercury = 133 pascal; 1 bar = 1000 mbar, where 1 mbar = 1 millibar). The degree of quality of the vacuum attained is indicated by the total pressure of the residual gases in the vessel which is pumped. Table 1 shows the accepted terminology in denoting degrees of vacuum together with the pressure range concerned, the calculated molecular density (from the equation $p = nkT$ where p is the pressure, n is the molecular density, i.e., number of molecules per cubic centimeter, k is Boltzmann's constant, and T is the absolute temperature taken to be 293 K or 20°C) and the mean free path λ from the approximate equation for air: $\lambda = 5/p$ cm, where p is the pressure in millitorr.

Vacuum Pumps There are several types of vacuum pumps. The two most widely used are the mechanical rotary oil-sealed pump and the vapor pump. The former provides a medium vacuum and works relative to the atmosphere; the vapor pump, on the other hand, provides a high or very high vacuum and operates relative to a medium vacuum provided by a rotary pump, referred to as a backing pump in this connection. Thus, the most widely used high-vacuum system able to establish an ultimate pressure of about 10^{-6} torr or below consists of a vapor pump backed by a rotary pump.

Four or five patterns of rotary oil-sealed pump exist, but they have in common the fact that the volume between a rotor (or rotating plunger) and a stator is divided into two-crescent-shaped sections which are isolated from one another as regards the passage of gas. Further, they are furnished with an intake port and a discharge outlet valve to the atmosphere. On revolution of the rotor (speeds of 450 to models with direct motor drive of speeds of 1500 rpm are used) gas is swept from the intake port, compressed, and discharged to the atmosphere via the one-way outlet valve. The mechanism is immersed in a low-vapor-pressure oil for sealing and lubrication in a small pump; larger units have a separate oil reservoir and feed device. A spring-loaded vane type of rotary oil-sealed pump is shown in Fig. 1(a). A single-stage pump of this kind provides an ultimate pressure of about 10^{-2} torr; a two-stage one with two units in cascade will give an ultimate of about 10^{-4} torr. Rotary pumps with speeds from 20 to 20 000 liters/min are commercially available, the smallest being driven by an $\frac{1}{8}$-hp motor, the largest requiring a 40-hp motor.

These pumps handle permanent gases efficiently. Condensable vapors, e.g., water vapor, are not satisfactorily pumped because they may liquefy during the compression part of the rotation. To prevent this, gas ballast is a common provision whereby air from the atmosphere is admitted to the pump through a simple, adjustable screw valve to the region between the rotor and stator just before the discharge outlet valve. The amount of extra air admitted is readily adjusted to provide a compressed gas-vapor mixture which opens the discharge valve before vapor condensation occurs. Gas ballasting will clearly increase significantly the ultimate

TABLE 1. DEGREES OF VACUUM AND PRESSURE RANGES

Degree or Quality of Vacuum	Pressure Range (torr*)	Molecular Density, n (molecules/cm^3)	Mean Free Path, λ (cm)
Coarse or rough vacuum	760–1	2.69×10^{19}–3.5×10^{16}	6.6×10^{-6}–5×10^{-3}
Medium vacuum	1–10^{-3}	3.5×10^{16}–3.5×10^{13}	5×10^{-3}–5
High vacuum	10^{-3}–10^{-7}	3.5×10^{13}–3.5×10^{9}	5–5×10^{4}
Very high vacuum	10^{-7}–10^{-9}	3.5×10^{9} –3.5×10^{7}	5×10^{4}–5×10^{6}
Ultrahigh vacuum	$<10^{-9}$	$<3.5 \times 10^{7}$	$>5 \times 10^{6}$

*1 torr = 133 pascal = 1.32 mbar.

pressure provided by the pump, but this is not important since the gas-ballast valve can be closed after initial pumping has removed most of the water vapor.

Vapor pumps are of two main types: vapor diffusion pumps and vapor ejector pumps. Both employ vapor (of either mercury or a low-vapor-pressure oil) issuing from a nozzle as a means of driving gas in the direction from the intake port to the discharge outlet which is maintained at a medium vacuum by a backing rotary pump. In the diffusion pump [a two-stage design utilizing oil as the pump fluid is shown in Fig. 1(b)] the vapor issuing from the top, first-stage nozzle is directed downward towards the backing region. Gas molecules from the intake port diffuse into the streaming vapor. The directed oil molecules collide with the gas molecules to give them velocity components toward the backing region. A large pressure gradient is thereby established in the pump so that the intake pressure may be over 100 000 times less than the backing pressure. The intake pressure may therefore be 10^{-6} torr or lower with a backing pressure of 10^{-1} torr.

In the diffusion pump, the vapor stream is not essentially influenced by the gas pumped. In the vapor ejector pump, however, the vapor stream is enabled by a higher boiler pressure to be denser and of greater speed with a higher intake pressure, so that the gas is entrained by the high-speed vapor. Viscous drag and turbulent mixing now carry the gas at initially supersonic speeds down a pump housing of diminishing cross section. The ejector pump is designed to operate with a maximum pumping speed at an intake pressure of 10^{-1} to 10^{-3} torr and with a backing pressure of 0.5 to 1 torr or more. The diffusion pump, on the other hand, is designed to have a fairly constant speed from 10^{-3} torr down to an ultimate 10^{-6} torr or much lower in a modern, bakeable stainless steel system.

An important mechanical pump which operates in the same pressure region as the oil ejector is the Roots pump, capable of very great speeds and requiring backing by a rotary oil-sealed pump.

A vacuum system consisting of a diffusion pump and a backing pump, together with baffles, cold traps and isolation valves, is shown in Fig. 1(c). The cold trap is essential if a mercury vapor diffusion pump is used and is best filled with liquid nitrogen (−196°C); otherwise, the system will be exposed to the mercury vapor pressure, which is 10^{-3} torr at 18°C.

Ultrahigh-vacuum systems with stainless steel traps and metal sealing gaskets, and bakeable (except for the pumps) for several hours to 300°C, may be constructed on the lines of that shown in Fig. 1(c) to provide an ultimate pressure of 10^{-10} to 10^{-11} torr.

Other vacuum pumps include the sorption type based on the high gas take-up of charcoal or molecular sieve material at liquid nitrogen temperatures. Sorption pumps may be used in place of rotary pumps, with a desirable freedom from rotary pump oil vapor, especially in systems where the amount of gas to be handled is limited.

The chief rivals to the vapor diffusion pump at present are the getter-ion pump of the Penning discharge type with electrodes of titanium, sometimes called the sputter-ion pump, and the turbomolecular pump. The principle of operation of the former is illustrated by Fig. 2, where an egg-box type anode is situated between plane cathodes. The anode-cathode operating potential difference is of the order of 2–10 kV, and the magnetic flux density is about 3,000 gauss (0.3 tesla). The chief pumping action with active gases such as nitrogen and oxygen is to the anode, which receives deposited titanium (which has very high gas affinity) sputtered from the cathodes under the action of the positive ion bombardment. Some gas, especially inert gas like argon and the hydrogen gas present (which is certainly not inert) is pumped to the cathodes.

A typical multicell pump of moderate size of this type has a pumping speed of about 250 liters/sec. Much larger pumps with speeds of up to 5000 liters/sec are commercially available, as are small single-cell units with speeds of some 2 liters/sec.

The sputter-ion pumps provide a vapor-free system giving a so-called dry vacuum, and they are often incorporated in plant with molecular sieve sorption as the auxiliary pump. For medium-size laboratory plant able to provide ultrahigh vacuum they are most attractive. Probably their chief disadvantage is that the life of the pump is only about 40 hours at 10^{-3} torr, but this increases inversely with the pressure, so that it is 40 000 hours at 10^{-6} torr. They are therefore strong rivals to the diffusion pump for plant where moderate amounts of gas are handled in the lower pressure ranges. The turbomolecular pump (usually abbreviated TMP) has probably now become more important than the titanium sputter-ion pump as a rival to the diffusion pump, but it is more costly than either.

Introduced in 1958 by Becker as an important advance on the older molecular drag pumps originated by Gaede in 1913, Holweck's version in 1923, and that of Siegbahn in 1944, the TMP operates relative to a backing pressure of about 10^{-1} torr and provides an inlet pressure of 10^{-8} torr and down to 5×10^{-10} torr and below, provided that suitable bake-out is practiced.

In the turbomolecular pump (Fig. 3) the rotor consists of a special arrangement of separated, slotted disks mounted on a shaft. These disks are interleaved between similar stationary slotted vanes attached to the cylindrical housing. The rotor is driven at speeds of 16,000 rpm or greater to achieve movement of the gas from the inlet to the discharge outlet by virtue of a

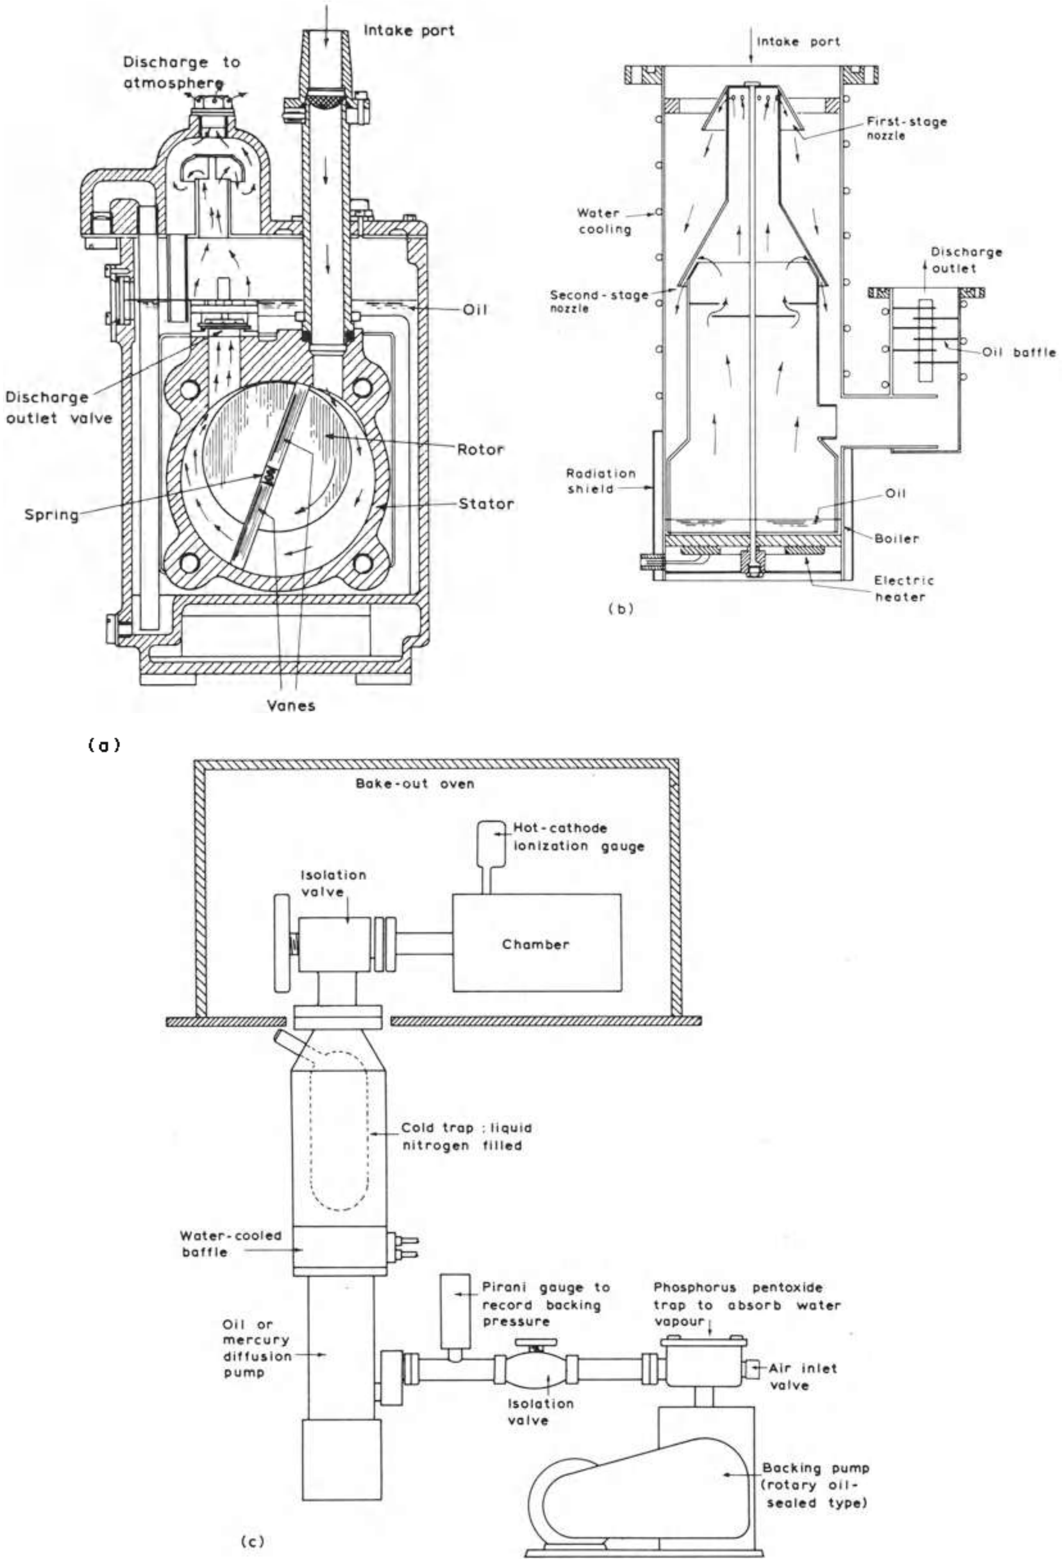

FIG. 1. (a) A spring-loaded vane type of rotary oil-sealed pump. (b) A two-stage or diffusion pump. (c) A diffusion pump-rotary backing pump vacuum system.

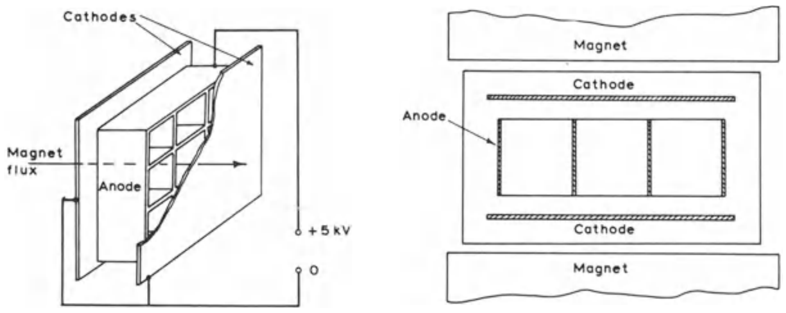

FIG. 2. A sputter-ion pump.

complex entrainment and drag of the gas within the wedge-shaped channels between the angled slots in the adjacent rotor and stator disks. As back-streaming is virtually absent (there is no back-streaming as in a vapor pump, only that of a modest amount of lubrication on the shielded axle bearings), turbomolecular pumps are increasingly being used in systems demanding the production of fluid-free high and ultrahigh vacuum.

In addition, models with vertically mounted housings have been introduced instead of the horizontal ones such as that of the original Becker-type pumps. This possibility of vertical mounting enables the TMP to be used more readily in a vacuum system in place of the usually vertically mounted oil diffusion pump. Examples of the use of TMPs in general are in particle accelerators, where very low pressures are needed and they are used in conjunction with sputter-ion pumps after the initial pumping by conventional mechanical rotary gas-ballast pumps; and in modern electron microscopes and other specialized instruments used in surface science studies, especially in cases where high-speed pumping with freedom from oil contamination at pressures well below 10^{-6} torr is demanded.

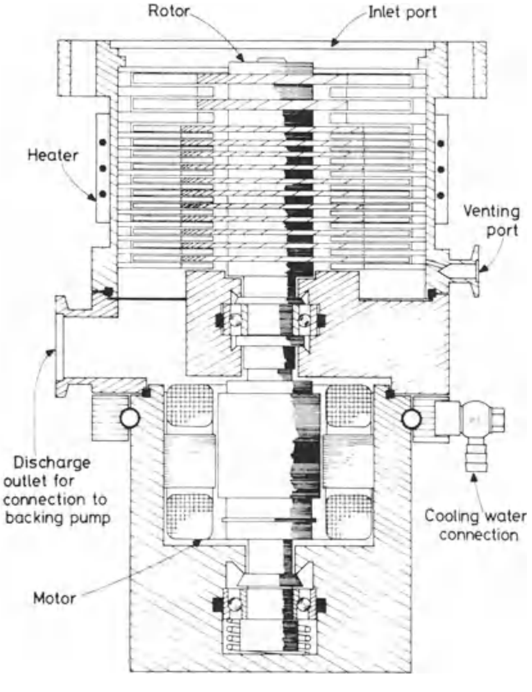

FIG. 3. A modern turbomolecular pump. (A Balzers vertical design, the PFEIFER-TURBO TPH 110)

Titanium sublimation pumps (getter pumps) in a range of sizes are frequently used. Typically, the titanium is sublimed from an electrically heated tungsten or tantalum alloy filament loaded with titanium wire to become deposited on the interior wall of the surrounding casing, which may be air-cooled, water-cooled, or refrigerated with liquid nitrogen. The sorption of the active gases by the titanium provides high-speed pumping. Apart from their use as auxiliary pumping devices (particularly in the ultrahigh-vacuum region) frequently adopted practice is to use such pumps in conjunction with a sorption pump and a sputter-ion pump or with a turbomolecular pump backed by a mechanical rotary pump. Indeed, the latter system is able to provide readily ultrahigh vacuum at pressures of 10^{-11} torr or even lower.

Cryogenic pumping is presently receiving much attention. Here, basically, the provision is, within an initially evacuated system (at a total pressure of, say, 10^{-3} torr) a surface which is at such a low temperature that gas impinging on it is condensed. Apart from the fact that this enables an ideal vacuum pump to be produced in locations (such as within the vacuum chamber itself) where pumping is really needed, the use of cryogenic pumping has recently received a considerable boost because of the introduction of mechanical refrigerators (such as the Philips cryogenerator K20) able to produce temperatures as low as 20 K.

If the surface is maintained at the even lower temperature of liquid helium (4 K)—20 K is actually the same as the boiling point of liquid hydrogen—all other gases then have insignificantly low vapor pressures and molecules of these gases (except for helium itself and neon) impinging on the surface would remain there. A pumping speed for nitrogen of nearly 12 liters sec^{-1} cm^{-2} of cooled surface is hence theoretically possible. Liquid helium, together with molecular sieve and other sorbent surfaces as well as mechanical cryogenerators, are all being actively investigated with the possibility of providing very high pumping speeds (10^6 liters/sec is not out of question) in space simulators and possible other plant. Some experienced vacuum technologists consider that the future of vacuum pumping methods is going to depend on the developments in cryogenic techniques. As so often happens, however, the question of economy may well be decisive here.

Vacuum Gauges A considerable problem in vacuum technique is that there is only one straightforward gauge able to measure low gas pressures absolutely in the sense that its calibration is independent of the nature of the gas and can be directly referred to millimeters of mercury: the McLeod gauge (Fig. 4). This gauge is clumsy, contains mercury, and is easily broken. It is subject to important errors. It is best not used on a vacuum system, unless the system is intended for absolute low-pressure calibration purposes, and is used by a technologist who knows what he is doing.

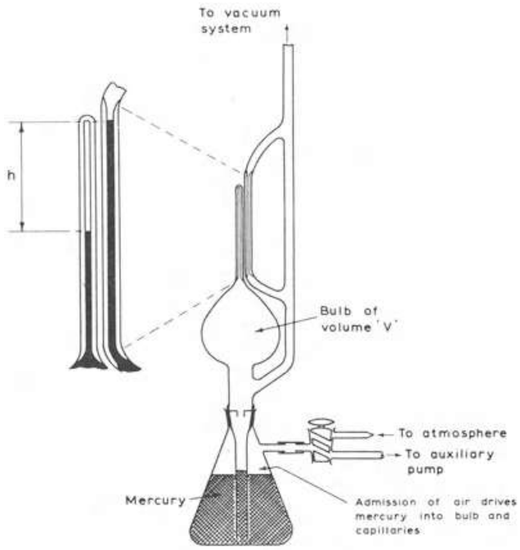

FIG. 4. The McLeod gauge.

More recently there has grown up considerable interest in the capacitance manometer (Fig. 5) (the original model is due to Alpert, Matland, and McCoubrey, as long ago as 1951). This provides a gauge the calibration of which is independent of the nature of the gas; it must, however, be calibrated for absolute pressure measurement against a U-tube manometer or a McLeod gauge. The chief manufacturers of modern capacitance manometers (variously called the Baratron or the Barocel, depending on the manufacturer) have been MKS Instrument Inc. in the USA, who provide an instrument with a digital display of the pressure.

Capacitance manometers also lend themselves very well to the design of pressure-

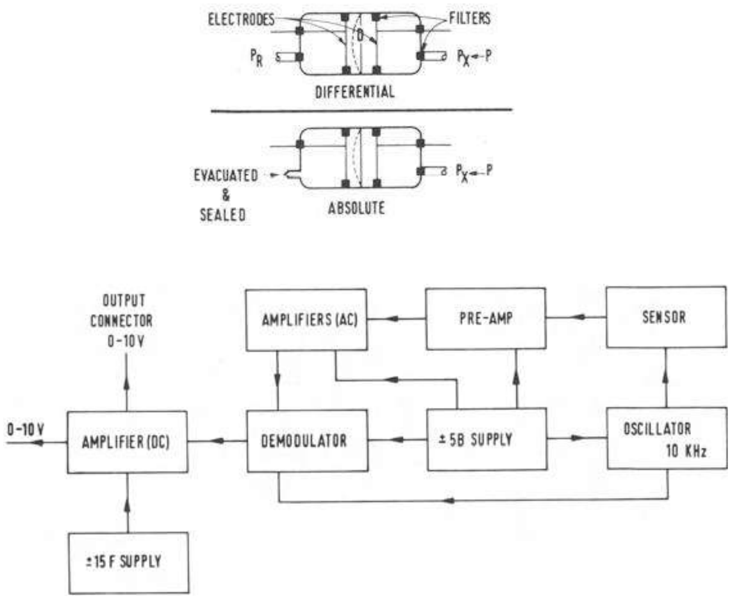

FIG. 5. The capacitance manometer.

controlled switches, in which the output is switched when the gas pressure exceeds a certain amount. This is because they depend essentially on the deflection of a diaphragm by gas pressure. They have also proved to be useful in the design of control systems based on gas flow ratios.

There are several alternative gauges for low-pressure gas measurement, but none of them is an absolute gauge and their calibrations all depend on the nature of the gas. Of the many possibilities, the thermal conductivity guages of the Pirani and thermocouple types are useful within the pressure range from 10^{-4} to 10 torr; these operate by virtue of the dependence of the thermal conductivity of a gas on the pressure at low pressures. Two types of ionization gauge have been used at pressures below 10^{-3} torr. The first of these is the Penning cold-cathode gauge, with a range from 5×10^{-3} to 10^{-7} torr which has been extended in the inverted magnetron type (Redhead gauge) to 10^{-11} torr or below. The second is the widely used hot-cathode ionization gauge (of which the most popular pattern is the Bayard-Alpert gauge, Fig. 6). The Bayard-Alpert gauge has become almost indispensable as a measuring instrument on high and ultrahigh vacuum systems; it has a range from 10^{-3} to 5×10^{-11} torr.

A Bayard-Alpert gauge will typically have a sensitivity for nitrogen of about 12 torr^{-1}; the positive ion current will be 12 μA with an electron current of 1 mA at a nitrogen pressure of 10^{-3} torr, and will decrease in direct proportion to the pressure until at about 10^{-10} torr (or less) the arrival of electrons at the positive grid causes the production of x-rays. These x-rays are able to release further electrons from the ion collector, and the release of these negatively charged—electrons is indistinguishable from the arrival of pressure-dependent positive ions at the ion collector; i.e., the so-called "x-ray effect" sets the low pressure limit of the hot-cathode ionization gauge. This limit is at about 10^{-8} torr for conventional hot-cathode ionization gauges and about 10^{-10} torr for the Bayard-Alpert type.

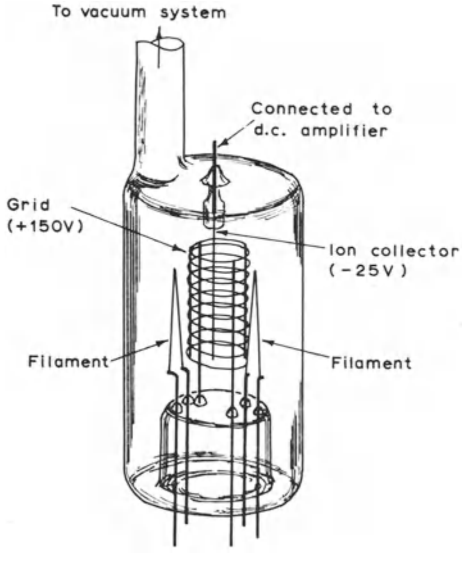

FIG. 6. The Bayard-Alpert hot-cathode ionization gauge.

In the measurement of gas pressure the determination of the partial pressures of the constituent gases is often as important as a knowledge of the total pressure. Gas analyzers for this purpose are based on the mass spectrometer of the magnetic deflection type, on the radio-frequency mass spectrometer, and on the quadrupole mass spectrometer. These gas analyzers also play an important part in leak detection techniques.

Recent developments concerned with gauges capable of giving an electrical output in the determination of low gas pressures in vacuum sysgems have been devoted to providing a digital readout in place of the usual analog one, to the link-up of the gauge output to a digital computer so as to provide a continuous record of the total and partial pressures prevailing in the vacuum system (a method which is particularly useful for partial pressure cases, as in the use of the quadrupole mass spectrometer), and to the control and automation of vacuum systems. The last possibility—providing an automatically operated vacuum plant—becomes more difficult as the total pressure in the plant is made lower because of the problems associated with the satisfactory operation of gas-metering and isolation vacuum values, especially when they are only very slightly open.

The applications of vacuum techniques are numerous. They include the coating of a substrate in a vacuum with metallic and insulating films in the production of optical mirrors, electrical resistors, and capacitors; microelectronics (in the manufacture of integrated circuits); and the production of semiconductor active devices by the methods of ion implantation. There should also be mentioned such specialties as antireflection and enhanced reflection coatings on glass, interference filters, and sorption and chemically active layers. The application of vacuum technology to the electron tube industry has been on the wane because with the advent of semiconductor electronics the only electron tube still in wide use is the cathode-ray tube—especially in domestic television. There, the manufacture and re-conditioning especially of color television receiver tubes has involved vacuum technology, but even cathode ray tubes may become obsolete with advances in opto-electronic devices.

Further important fields of activity which involve vacuum technology are electron beam welding (developments are likely to play a major part in the automobile manufacturing industry), vacuum drying and freeze-drying, distillation and molecular distillation, vacuum metallurgy (including metal degassing), and space simulation. In some quarters there are also developments in the areas of rough vacuum use, probably due to the great current interest in oil exploration under the seas.

VAPOR PRESSURE AND EVAPORATION

Vapor Pressure Vapor pressure is the term applied to the driving force behind the apparently universal tendency for liquids and solids to disperse into the gaseous phase. All known liquids and solids possess this fundamental property, although in some cases it is too minute to be measurable. A typical liquid will exert a vapor pressure which is constant and reproducible. This pressure is dependent only upon the temperature of the system, and increases with increasing temperatures.

The molecular theory explains the phenomenon of vapor pressure through molecular activity. The molecules of a liquid are in rapid motion, even though they are in contact with each other. This motion or activity increases with temperature. At the vapor-liquid interface, this motion results in diffusion of some molecules from the liquid into the vapor. The attraction between molecules is strong, and some of the molecules dispersed into the vapor return to the liquid. The net number of molecules escaping produces the vapor pressure. For all practical purposes, this vapor pressure can be assumed constant whether the system is at equilibrium or not, due to the extremely high rate of molecular diffusion at the interface of the two phases.

In solids, the attractive forces of the molecules are so dominant that each is more or less frozen in place. Some diffusion does occur, however, as evidenced by the evaporation of ice, the odor of moth balls, and the slow diffusion or alloy formation of some metals kept in intimate contact. This vapor pressure increases with temperature, but is also a function of the molecular arrangement of the solid. As some solids such as sulfur are heated and molecular rearrangements take place, forming another allotrope of the same element, the vapor pressure changes sharply as this rearrangement occurs.

Vapor pressure can only be exhibited when the molecular activity is at a low enough level to permit continuous contact of the molecules and thus formation of a liquid. The maximum temperature at which this is possible is a fundamental property and is called the *critical temperature*. Above this temperature the material cannot be compressed to form a liquid, and only one phase results. This temperature is 374.0°C (705.4°F) for water and -240.0°C (-399.8°F) for hydrogen.

The fundamental relationship between temperature and vapor pressure can be derived from thermodynamic laws. With certain limiting assumptions, the Clausius-Clapeyron equation is most often applied:

$$\frac{dp}{dT}=\frac{qP}{RT^2}$$

$\frac{dp}{dt}$ = slope of vapor pressure vs temperature curve at the point in question in cm mercury per °C
q = heat of vaporization in calories per gram mol
P = pressure in cm of mercury
R = gas constant in calories per ° C per gram mol
T = temperature in Kelvin

Because of these limiting assumptions, the integrated form of this equation is used in practice primarily as a guide to develop methods of correlating and plotting vapor pressure data.

The vapor pressure of a solution containing a nonvolatile substance (e.g., salt in water) is lower than that of the pure liquid. This phenomenon can be explained by interference with the liquid molecular activity by the dissolved substances. The relationship between this vapor pressure depression and the concentration of the dissolved substance is valid for most substances at low concentrations. It was found to be dependent on the relative numbers of molecules of the solute and the solvent, and allowed accurate determinations of molecular weights of unknown solutes. If the Clausius-Clapeyron equation given above is combined with the above concentration relationship, it can be shown that:

$$\Delta T=\frac{RT^2}{q}\cdot C$$

where ΔT is the elevation of the boiling point. and C is the mol ratio of solute to solvent. This defines the effect of any solute on the vapor pressure exhibited by any solvent of latent heat q.

In the same manner, the vapor pressure of one component of a solution of two liquids has a different relationship with temperature than if it were pure. For many liquid mixtures, such as most hydrocarbon mixtures, the vapor pressures of the components vary directly from that exhibited in the pure form as their molar concentration in the solution. This relationship is known as Raoult's law:

$$\text{Partial pressure} = P_0 x$$

where x is the molar concentration of the component in the liquid and P_0 is the vapor pressure of the pure component at the same temperature as the mixture. A mixture following this rule is called an *ideal* solution, and its total volume is the sum of its components' volume.

If the gas phase above the liquid is also "ideal," the partial pressure of a component in this phase is equal to the total system pressure times the mole fraction of the component in the gas phase. This is called Dalton's law:

$$\text{Partial pressure} = P_t y$$

Combining these two formulas, it can be seen that:

$$\frac{y}{x} = \frac{P_0}{P_t} = K$$

for any particular temperature. This relationship can largely define many very complex liquid mixtures if the pressures used in the correlation are corrected by experimental data for deviation from the ideal.

A different relationship results if two liquids are relatively immiscible in each other. Molecular interference is minimal, and the total pressure exerted is equal to the sum of that of the individual pure components.

The fundamental property of vapor pressure is thus dependent on temperature and composition of the material considered. These known and reproducible relationships have great technical application.

Vapor pressure relations can be used to determine heats of solution, heats of sublimation, and heats of fusion. Problems dealing with the solution of gases in liquids and adsorption of gases by solids are best handled by vapor pressure concepts. In dealing with solutions of miscible liquids, the most simple and useful relationship involves plotting the mole fraction y of one component in the vapor against x, the mole fraction of the component in the liquid. The ratio of y/x is called the phase equilibrium constant K and is used for definition of bubble points and dew points of simple and complex hydrocarbon mixtures over temperature and pressure ranges to near the critical.

Some equations of state also define vapor pressure relationships. One of the most recognized is that developed by Benedict, Webb, and Rubin due to its ability to predict *P-V-T* properties in the two-phase region and to describe behavior of the superheated vapor. See *J. Chem. Phys.*, **8**, 334 (1940); ibid., **10**, 747 (1942); and *Chem. Eng. Progr.*, **47** (1951). The utility of this Benedict, Webb, and Rubin (BWR) equation has been expanded greatly since it was first proposed in 1940. It is now an indispensable tool in process design work. References for existing compounds, for utilization of experimental data, for mixtures, and for extending the BWR application where normal procedures cannot be applied are listed below:

E., Natural Gas Processors Association Enthalpy Project Progress Report, Sept. 30, 1968 (Development of the BWRS); Nishiumi, H., and Saito, S., *J. Chem. Eng. Japan*, **8**, 356 (1975).

(3) Improvement in agreement for mixtures by including interaction parameters: Bishnoi, P. R., and Robinson, D. B., *Can. J. Chem. Eng.*, **50**, 506 (1972); Gugnoni, R. J., Eldridge, J. W., Okay, V. C., and Lee, T. J., *A.I.Ch.E. Journal*, **20**, 357 (1974).

(4) Extending the application of the BWR to systems where the experimental data is insufficient for normal procedures: Edmister, W. C., Vairogs, J., and Klekers, A. J., *A.I.Ch.E. Journal*, **14**, 479 (1968); Kaufmann, T. G., *I & E.C. Process Design and Devel.*, **7**, 115 (1968).

Evaporation The above effects of mixtures and of solutes on vapor pressure of a component are the very reasons why continuous generation of vapor (or *evaporation*) is the major tool of most process separations.

These effects permit us to separate salts from solutions, to separate liquid components from mixtures, and to use the energy relationships in process control of all kinds.

When molecules of a liquid do leave the surface and become vapor, they do so by overcoming the rather large attractive forces existing when they were in the liquid state. These forces were large since the molecules were in very close proximity in the liquid. Overcoming these attractive forces requires *energy*, heat energy, this is named the "*latent heat*" or "heat of vaporization" of the fluid. In general, this is in terms of heat units per weight unit of material, such as Btu per pound, or calories per gram. In magnitude, latent heat will decrease as the liquid temperature increases or as the kinetic energy of the molecules increases. At the critical temperature, there is no latent heat—the molecules are in such an excited state that formation of a liquid is not possible.

For continuous evaporation, a continuous supply of energy is required. An available utility such as steam is a typical source.

Depending on the process, the evaporation is done:

(1) In equipment named "evaporators" such as the popular LTV of forced or natural circulation design used in acid concentration, salt production, sugar solution concentration and others.

(2) In distillation towers in a stepwise manner, tray to tray, resulting in a slight change in composition at each tray until required terminal conditions of overhead and bottom composition are reached.

(3) In reactors of various designs where one or more components are driven off, frequently by the heat of reaction.

(4) In "cooling towers" where the desired effect is not the separation or concentration of components but the use of the latent heat of evaporating water to remove unwanted process heat.

(5) In all steam generating boilers.

(6) In any process step where a liquid/vapor phase change occurs.

The concentration and energy relationships discussed before apply.

Evaporation is thus the most widely used tool of nature and of industry. For this reason, an intimate knowledge of the theory of heat transfer, of the large quantity of experimental data available, and of the more sophisticated methods of utilizing equations of state to correlate these data, are all essential to understand and properly develop almost any industrial process.

VECTOR ANALYSIS

Introduction The concept of vectors and vector analysis was formulated in the last part of the 19th Century by Gibbs and others as an alternative to Hamilton's quaternions.[4] These concepts form an invaluable tool in the formulation and analysis of a wide range of physical problems, for two reasons. First, vector notation provides a compact and convenient mathematical description of many complex physical situations. Second, if the mathematical model of a physical situation is expressed in terms of vector equations, this model will be independent of any coordinate system or frame of reference. The generalization and abstraction of elementary vector concepts leads to such diverse mathematical structures as tensor analysis and the theory of linear vector spaces, which are the basic mathematical foundations of much of modern theoretical physics.

Vector Algebra[2,7,8,10,12,14] Although it is usually appropriate to begin a discussion of mathematical entities by defining the quantity under discussion, this is not the case for vectors. There are several reasons why it is not feasible to give an elementary definition of a vector. Chief of these is the fact that the definition is very dependent on the context in which it is used. Second, for the vectors discussed here, any initial definition would have to be greatly modified as the discussion proceeds. The quantities considered here are undefined geometrical entities called *vectors* (denoted by **boldface** letters) which can be represented by directed line segments in the two- or three-dimensional spaces of ordinary experience.

In the development of an algebra for geometrical vectors, it is necessary to introduce an additional set of quantities known as *scalars*. These scalars are elements of what is technically known as a commutative field. It is sufficient here to let the set of scalars be the real numbers. In a two- or three-dimensional space which satisfies the postulates of Euclidean geometry, the representation of geometric vectors by directed line segments endows them with the properties of length and direction. The length or magnitude of a vector is the length of its representative line segment, and its direction is represented by the direction of the line segment.

The preliminary algebraic concepts required are the idea of equality of two vectors, the addition of vectors, and the multiplication of a vector by a scalar. Two vectors **A** and **B** are said to be *equal* if their representative line segments are parallel and of the same length. Additional restrictions may be required on the equality of vectors when they represent physical quantities. This definition of equality implies that a given vector is unaltered, i.e., is invariant, when displaced parallel to itself. *Addition* of two vectors **A** and **B** is defined in terms of geometrical construction with their representative line segments. (See Fig. 1.) Bring the tail of the line segment **B** into coincidence with the head of the line segment **A** by means of a parallel displacement. Construct the directed line segment from the tail of **A** to the head of **B**. This line segment **C** represents the vector sum of the vec-

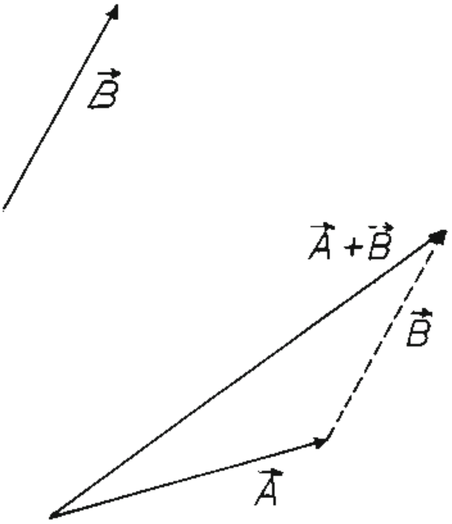

FIG. 1. The addition of vectors.

tors **A** and **B**,

$$\mathbf{C} = \mathbf{A} + \mathbf{B}.$$

The *product of the scalar* α *and the vector* **A**, written $\alpha\mathbf{A}$, is represented by the line segment parallel (anti-parallel if $\alpha < 0$) to that representing **A** of length $|\alpha|\ ||\mathbf{A}||$, where $||\mathbf{A}||$ is the magnitude of **A**.

These definitions of the sum of two vectors and the scalar multiple of a vector have the following properties:

(1) For every pair of vectors **A** and **B**, their sum **A** + **B** is a vector. This property is known as *closure under addition*.

(2) Addition is *commutative*, that is

$$\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}.$$

(3) For every three vectors **A**, **B**, and **C**,

$$\mathbf{A} + (\mathbf{B} + \mathbf{C}) = (\mathbf{A} + \mathbf{B}) + \mathbf{C}.$$

This property is known as *associativity of addition*.

(4) There is a vector **0**, known as the *null vector*, such that

$$\mathbf{A} + \mathbf{0} = \mathbf{A}$$

for all vectors **A**.

(5) Corresponding to each vector **A**, there is a *negative* vector (−**A**) such that

$$\mathbf{A} + (-\mathbf{A}) = \mathbf{0}.$$

The negative vector (−**A**) is represented by a line segment of the same length as that representing **A** and anti-parallel to **A**.

(6) For every vector **A** and every scalar α, there is a unique vector $\mathbf{B} = \alpha\mathbf{A}$, i.e., *the set of all vectors is closed under scalar multiplication*. In particular, there is a scalar 1 such that $1\mathbf{A} = \mathbf{A}$ for all vectors **A**.

(7) *Scalar multiplication is cummutative and associative*, that is, for every vector **A** and every pair of scalars α and β,

$$(\alpha + \beta)\mathbf{A} = \alpha\mathbf{A} + \beta\mathbf{A}$$

$$\alpha(\beta\mathbf{A}) = (\alpha\beta)\mathbf{A} = \beta(\alpha\mathbf{A}).$$

(8) *Scalar multiplication distributes over addition*. Given two vectors **A** and **B** and a scalar α,

$$\alpha(\mathbf{A} + \mathbf{B}) = \alpha\mathbf{A} + \alpha\mathbf{B}.$$

Used in an abstract setting, these properties form part of the definition of an abstract linear vector space.

There are two additional operations, which are essentially algebraic, that can be defined for every pair of vectors **A** and **B**. The first of these is the *inner* or *dot product*, which associates a scalar with each pair of vectors **A** and **B**. This unique scalar is denoted $\mathbf{A} \cdot \mathbf{B}$, and is defined in the following way: Let **A** and **B** have the same initial point, and let θ denote the angle between their representative line segments, measured from **A** to **B** as shown in Fig. 2. Then,

$$\mathbf{A} \cdot \mathbf{B} = ||\mathbf{A}||\ ||\mathbf{B}||\ \cos\theta.$$

It can be shown, although the proof is by no means trivial, that the inner product satisfies the following identities:

(9) $\mathbf{A} \cdot \mathbf{B} = \mathbf{B} \cdot \mathbf{A}$.

(10) $\mathbf{A} \cdot (\mathbf{B} + \mathbf{C}) = \mathbf{A} \cdot \mathbf{B} + \mathbf{A} \cdot \mathbf{C}$.

(11) $\alpha(\mathbf{A} \cdot \mathbf{B}) = (\alpha\mathbf{A}) \cdot \mathbf{B} = \mathbf{A} \cdot (\alpha\mathbf{B})$.

(12) $\mathbf{A} \cdot \mathbf{A} \geqslant 0$, with the equality holding if and only if $\mathbf{A} = \mathbf{0}$.

The second product, known as the *cross product*, associates with each pair of vectors **A**

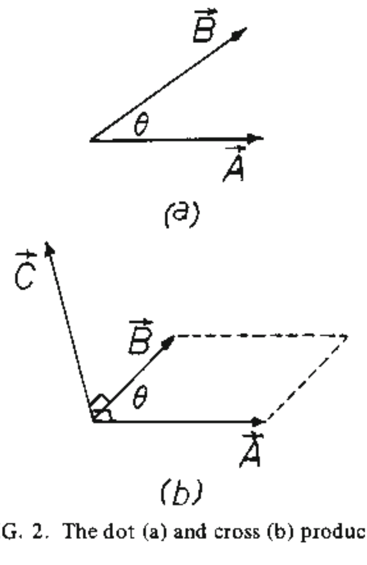

FIG. 2. The dot (a) and cross (b) products.

and **B** a vectorlike object denoted by

$$\mathbf{C} = \mathbf{A} \times \mathbf{B}$$

which is defined as follows: Let **A** and **B** have a common initial point, and let the angle θ between them be measured from **A** to **B**. Then **C** is defined to have a magnitude

$$\|\mathbf{C}\| = \|\mathbf{A} \times \mathbf{B}\| = \|\mathbf{A}\|\,\|\mathbf{B}\| \sin \theta$$

and a direction normal to the plane of **A** and **B** in the direction of advance of a right-hand screw as **A** is rotated into **B**. This construction is also illustrated in Fig. 2. The arbitrary choice of direction for the cross product prevents it from having all of the properties required of vectors. Quantities of this type are called *pseudo-* or *axial vectors*. In most applications the distinction between axial vectors and true vectors is unimportant. For any three vectors **A**, **B**, **C**, and every scalar α, the following identities are satisfied:

$$(13)\quad \mathbf{A} \times \mathbf{B} = -\mathbf{B} \times \mathbf{A}.$$
$$(14)\quad \mathbf{A} \times (\mathbf{B} + \mathbf{C}) = \mathbf{A} \times \mathbf{B} + \mathbf{A} \times \mathbf{C}.$$
$$(15)\quad (\alpha\mathbf{A}) \times \mathbf{B} = \mathbf{A} \times (\alpha\mathbf{B}) = \alpha\mathbf{A} \times \mathbf{B}.$$
$$(16)\quad \mathbf{A} \times (\mathbf{B} \times \mathbf{C}) = (\mathbf{A} \cdot \mathbf{C})\,\mathbf{B} - (\mathbf{A} \cdot \mathbf{B})\,\mathbf{C}.$$

There are a number of important consequences of the identity (16). One of the most important of these is the Jacobi identity:

$$\mathbf{A} \times (\mathbf{B} \times \mathbf{C}) + \mathbf{B} \times (\mathbf{C} \times \mathbf{A}) + \mathbf{C} \times (\mathbf{A} \times \mathbf{B}) = \mathbf{0}.$$

The dot and cross products have a number of elementary applications to the three-dimensional geometry of lines and planes. Some of these are:[17]

(1) Two lines L_1 and L_2 are parallel (antiparallel) if and only if $\mathbf{L}_1 \times \mathbf{L}_2 = 0$, where $\mathbf{L}_1$ and $\mathbf{L}_2$ are vectors whose representative line segments lie on the given lines.

(2) Two lines $\mathbf{L}_1$ and $\mathbf{L}_2$ are perpendicular if and only if $\mathbf{L}_1 \cdot \mathbf{L}_2 = 0$.

(3) Relative to an arbitrary origin O, the vector **R** is described by the directed line segment from O to the point P. Hence, the point P is specified by the vector **R**, and there is a one-to-one correspondence between the points in space and the position vectors **R**. The equation of a line through the point P_0 parallel to a given line L can be written as $(\mathbf{R} - \mathbf{R}_0) \times \mathbf{L} = \mathbf{0}$, where **R** is any other point on the line.

(4) The equation of a plane through the point P_0 perpendicular to a given vector **N** can be written as $(\mathbf{R} - \mathbf{R}_0) \cdot \mathbf{N} = 0$, where **R** is the position vector of any other point in the given plane.

There is an additional product of three vectors which finds frequent application. If **A**, **B**, and **C** are three noncoplanar vectors, the scalar $\mathbf{A} \cdot (\mathbf{B} \times \mathbf{C})$ is equal to the volume of the parallelepiped defined by the three vectors. The mixed *triple product* satisfies the following commutation relations:

$$\mathbf{A} \cdot (\mathbf{B} \times \mathbf{C}) = \mathbf{B} \cdot (\mathbf{C} \times \mathbf{A}) = \mathbf{C} \cdot (\mathbf{A} \times \mathbf{B}).$$

Vector Fields[1,2,7,8,10,11,12,13,14] In order to have a differential and integral calculus for vector quantities, it is necessary to introduce the concept of a *vector field*. A vector field associates with each point in some region of space a unique vector $\mathbf{F}(P)$. Although it is not necessary, it is convenient to describe the points in the given region and the associated vectors in terms of some coordinate system. A particularly simple choice of coordinates is the set of rectangular cartesian coordinates, with arbitrary origin, as shown in Fig. 3.

Before a description of the vector field $\mathbf{F}(P)$ can be obtained, a representation of the algebraic operations on vectors in terms of cartesian coordinates must be given. Introduce the triplet of unit vectors (vectors with unit magnitude) $\{\mathbf{i}, \mathbf{j}, \mathbf{k}\}$ along the X-, Y-, and Z-coordinate axes, respectively, so that

$$\mathbf{i} \times \mathbf{j} = \mathbf{k}, \qquad \mathbf{j} \times \mathbf{k} = \mathbf{i}, \qquad \mathbf{k} \times \mathbf{i} = \mathbf{j}.$$

This construction defines a *right-handed coordinate system*. In terms of the set of unit vectors $\{\mathbf{i}, \mathbf{j}, \mathbf{k}\}$, a given vector **F** has the representation

$$\mathbf{F} = F_1\,\mathbf{i} + F_2\,\mathbf{j} + F_3\,\mathbf{k}$$

where

$$F_1 = \mathbf{F} \cdot \mathbf{i}, \qquad F_2 = \mathbf{F} \cdot \mathbf{j}, \qquad F_3 = \mathbf{F} \cdot \mathbf{k}$$

are known as the *cartesian components of* **F**. In terms of the cartesian components, the various algebraic operations have the following representations:

$$(\mathbf{A} + \mathbf{B}) = (A_1 + B_1)\,\mathbf{i} + (A_2 + B_2)\,\mathbf{j} + (A_3 + B_3)\,\mathbf{k}$$

$$\alpha\mathbf{A} = \alpha A_1\,\mathbf{i} + \alpha A_2\,\mathbf{j} + \alpha A_3\,\mathbf{k}$$

$$\mathbf{A} \cdot \mathbf{B} = A_1 B_1 + A_2 B_2 + A_3 B_3$$

$$\mathbf{A} \times \mathbf{B} = (A_2 B_3 - A_3 B_2)\,\mathbf{i} + (A_3 B_1 - A_1 B_3)\,\mathbf{j} + (A_1 B_2 - A_2 B_1)\,\mathbf{k}.$$

A given point P in space can be represented in terms of its cartesian coordinates, or its position vector $\mathbf{R} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k}$. Then, a vector field is described by specifying the cartesian components of **F** as functions of the cartesian coordinates of P, i.e.,

$$\mathbf{F}(P) = F_1(x, y, z)\,\mathbf{i} + F_2(x, y, z)\,\mathbf{j} + F_3(x, y, z)\,\mathbf{k}.$$

Since a given vector is uniquely described by its cartesian components, the vector field $\mathbf{F}(P)$ is

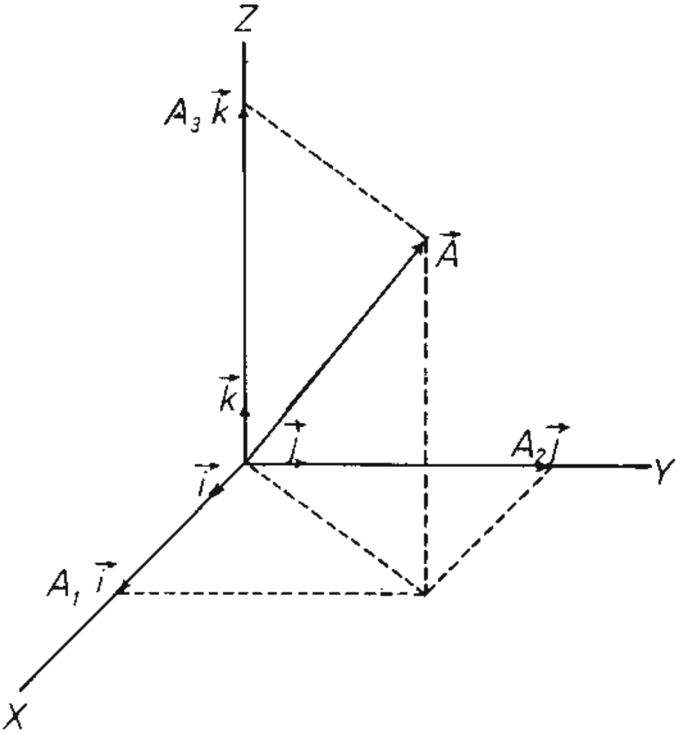

FIG. 3. The cartesian components of a vector.

said to be *differentiable if and only if each of* its cartesian components is a differentiable function of the coordinates.

If $\mathbf{F}(\mathbf{R})$ is a differentiable vector field, and $\phi(x, y, z)$ is a differentiable scalar function of the coordinates, the three basic differential operations involving vectors have the following cartesian representations:

$$\text{grad } \phi = \frac{\partial \phi}{\partial x}\,\mathbf{i} + \frac{\partial \phi}{\partial y}\,\mathbf{j} + \frac{\partial \phi}{\partial z}\,\mathbf{k}$$

$$\text{div } \mathbf{F} = \frac{\partial F_1}{\partial x} + \frac{\partial F_2}{\partial y} + \frac{\partial F_3}{\partial z}$$

$$\text{curl } \mathbf{F} = \left[\frac{\partial F_3}{\partial y} - \frac{\partial F_2}{\partial z}\right]\mathbf{i} + \left[\frac{\partial F_1}{\partial z} - \frac{\partial F_3}{\partial x}\right]\mathbf{j} + \left[\frac{\partial F_2}{\partial x} - \frac{\partial F_1}{\partial y}\right]\mathbf{k}.$$

These vector derivatives are known as the *gradient* of a scalar and the *divergence* and *curl* of a vector, respectively. The forms of these derivatives suggest the symbolic representations grad $\phi = \nabla\phi$, div $\mathbf{F} = \nabla \cdot \mathbf{F}$, curl $\mathbf{F} = \nabla \times \mathbf{F}$, where ∇ (del) is the vector differential operator

$$\nabla = \mathbf{i}\,\frac{\partial}{\partial x} + \mathbf{j}\,\frac{\partial}{\partial y} + \mathbf{k}\,\frac{\partial}{\partial z}.$$

The cartesian representations are inadequate as definitions of the derivative operations, since they are coordinate dependent. They do, however, provide a convenient method of computation.

Two important results can be obtained from the cartesian representations of the divergence and curl: (1) $\nabla \times \mathbf{F} = 0$ if and only if $\mathbf{F} = \nabla\phi$ for some scalar function ϕ; and (2) $\nabla \cdot \mathbf{F} = 0$ if and only if $\mathbf{F} = \nabla \times \mathbf{A}$ for some vector field $\mathbf{A}$. The quantities ϕ and $\mathbf{A}$ are known as the *scalar* and *vector potentials* for the field $\mathbf{F}$, respectively. It can be shown that any vector field $\mathbf{F}$ is determined by its scalar and vector potentials through the relation

$$\mathbf{F} = \nabla\phi + \nabla \times \mathbf{A}.$$

This result which is important in electromagnetic theory, is known as *Helmholtz' theorem.*

Symmetry considerations frequently make it desirable to describe the points of space in terms of coordinate systems which are not cartesian. In these cases, the descriptions of vectors and the derivative operations are somewhat more complicated. The form of the derivative operators with respect to these curvilinear coordinate systems must be derived from coordinate-free definitions of the gradient, divergence, and curl. Suppose that $\phi(P)$ and $\mathbf{F}(P)$ are differentiable scalar and vector fields respectively. Enclose any point P in the domain of definition by a small closed surface ΔS, and let $\mathbf{n}$ denote a unit vector at each point on ΔS which points out of the enclosed volume and is normal to ΔS (unit outward normal). If ΔV represents the volume enclosed by ΔS, the gradient, divergence, and curl are defined by the limiting processes

$$(\nabla\phi)(P) = \lim_{\Delta V \to 0} \frac{\iint_{\Delta S} \phi\, \mathbf{n}\, dA}{\Delta V}$$

$$(\nabla \cdot \mathbf{F})(P) = \lim_{\Delta V \to 0} \frac{\iint_{\Delta S} \mathbf{F} \cdot \mathbf{n}\, dA}{\Delta V}$$

$$(\nabla \times \mathbf{F})(P) = \lim_{\Delta V \to 0} \frac{\iint_{\Delta S} \mathbf{n} \times \mathbf{F}\, dA}{\Delta V}$$

if the limits exist and are independent of the way in which ΔV tends to zero. General discussions of curvilinear coordinates and explicit representations in the more common curvilinear coordinate system are given in Refs. 1, 7, 11, and 13.

In three dimensions, there are essentially three types of integrals involving vector fields. These are: (1) Integrals along some space curve C between two points P and Q; (2) integrals over an open surface S, bounded by some closed curve C; and (3) integrals over a volume enclosed by a closed surface S. The first of these integrals is motivated by the physical concept of the work done by a variable force $\mathbf{F}$ acting along the curve C. If $\mathbf{R}$ denotes the position vector of the points on $\mathbf{C}$, and s is the distance from P to R measured along C, then $d\mathbf{R}/ds$ is the vector tangent to C at $\mathbf{R}$. The scalar $\mathbf{F} \cdot (d\mathbf{R}/ds)$ is the component of the vector field $\mathbf{F}$ tangent to the curve C at each point on C. The integral

$$\int_C \mathbf{F} \cdot (d\mathbf{R}/ds)\, ds = \int_C \mathbf{F} \cdot d\mathbf{R}$$

is called the *line integral* of $\mathbf{F}$ from P to Q along the curve C. In general, the value of the integral depends not only on the end points P and Q, but also on the particular curve C connecting these points. If the integral is independent of the curve, the vector field $\mathbf{F}$ is called *conservative*. It is clear that the line integral of a conservative vector field vanishes whenever the curve C is closed. A necessary and sufficient condition for $\mathbf{F}$ to be conservative is that $\nabla \times \mathbf{F} = \mathbf{0}$.

Integrals involving the curl of a vector field over an open surface can frequently be transformed into line integrals over the bounding curve through the use of *Stokes's theorem*. Let S be an open surface with unit positive normal $\mathbf{n}$ which is bounded by the simple closed curve C. Then,

$$\iint_S (\nabla \times \mathbf{F}) \cdot \mathbf{n}\, dA = \oint_C \mathbf{F} \cdot d\mathbf{R}.$$

This result, which can be proved from the general definition of the curl, has an important role in the theory of differential forms.[5] In an elementary setting, Stokes' theorem is an extension to three dimensions of the two-dimensional Green's theorem.[17]

There is also a relation between the integral of the divergence of a vector field over a closed volume and the surface integral of the component of the vector field normal to the surface enclosing the volume. This relation, which follows immediately from the definition of the divergence, is known as the *divergence theorem*. Symbollically, the theorem can be stated as

$$\iiint_V \nabla \cdot \mathbf{F}\, dv = \iint_S \mathbf{F} \cdot \mathbf{n}\, dA$$

where S is any closed surface with unit outward normal $\mathbf{n}$ which encloses the volume V.

A combination of the divergence and gradient operations, known as the *Laplacian*, occurs in many of the partial differential equations of mathematical physics. The list of such equations included Poisson's equation, the heat equation, the diffusion equation, the wave equation and Schrödinger's equation. If ϕ is a twice differentiable scalar function, the Laplacian of ϕ is defined as $\nabla^2\phi = \nabla \cdot \nabla\phi$. In terms of a cartesian coordinate system (x, y, z), the Laplacian of ϕ has the explicit representation

$$\nabla^2\phi = \frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2}.$$

The definition of the Laplacian of a vector field $\mathbf{F}(\mathbf{R})$ is somewhat more complicated. The cartesian components of the combination

$$\nabla \times (\nabla \times \mathbf{F}) - \nabla(\nabla \cdot \mathbf{F})$$

satisfy the partial differential equation

$$[\nabla \times (\nabla \times \mathbf{F}) - \nabla(\nabla \cdot \mathbf{F})]_i = \frac{\partial^2 F_i}{\partial x^2} + \frac{\partial^2 F_i}{\partial y^2} + \frac{\partial^2 F_i}{\partial z^2} = \nabla^2 F_i.$$

Hence, the Laplacian of the vector field $\mathbf{F}$ is generally defined by

$$\nabla^2 \mathbf{F} = \nabla \times (\nabla \times \mathbf{F}) - \nabla(\nabla \cdot \mathbf{F}).$$

Vector Mechanics[3,6,7,16] The elementary use of vectors in mechanics arises from the fact that many mechanical quantities such as displacement, velocity, acceleration, and force require both a magnitude and direction for their complete specification. It was known before the introduction of vector concepts that these mechanical quantities combine according to a parallelogram law.

Consider a particle of mass m whose position is space at any given time t is specified by the cartesian coordinates $[x(t), y(t), z(t)]$ which are twice differentiable functions of t. The instantaneous position of the particle is alternatively described by the position vector

$$\mathbf{R}(t) = x(t)\mathbf{i} + y(t)\mathbf{j} + z(t)\mathbf{k}.$$

Velocity and acceleration vectors are defined as the first and second time derivatives of the position vector:

$$\mathbf{v}(t) = \frac{d\mathbf{R}}{dt} = \frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} + \frac{dz}{dt}\mathbf{k}$$

$$\mathbf{a}(t) = \frac{d^2\mathbf{R}}{dt^2} = \frac{d^2x}{dt^2}\mathbf{i} + \frac{d^2y}{dt^2}\mathbf{j} + \frac{d^2z}{dt^2}\mathbf{k}.$$

The specification of the acceleration vector and specific values of the velocity and position vectors at $t = 0$ gives a complete kinematical description of the motion of the particle.

The dynamical description of the particle involves the relation between the particle's motion and its interaction with its environment. The interaction of the particle and its environment is described by a force vector **F**, which is usually a function of the position of the particle, i.e. the environment gives rise to a force field which interacts with the particle. The vector sum $\mathbf{F} = \sum \mathbf{F}_i$ of all of the forces acting on a given particle is related to the motion of the particle through Newton's second law, which has the vector form

$$\mathbf{F} = d\mathbf{p}/dt$$

where the linear momentum **p** is the product of the (scalar) particle mass with its linear velocity **v**. This relation gives a dynamical description of the motion of a simple mass particle.

In mechanics, it is not always possible to consider "free" vectors (vectors which are translationally invariant). As an example of this, consider a particle of mass m which moves under the action of a force **F**, but which is constrained to remain a fixed distance from a given axis. This may be accomplished by fixing the particle at one end of a massless rod which is free to rotate about an axis through the other end. In this case, the rod exerts an unknown force on the particle which maintains the fixed distance. The only possible motion of the particle is a rotation about the axis, and we wish to find a description of this motion. It is convenient to define an *angular velocity vector* $\boldsymbol{\omega}$ which is along the axis of rotation such that if **R** is the instantaneous position vector of the particle relative to the axis, the linear velocity of the particle is given by

$$\mathbf{v} = \boldsymbol{\omega} \times \mathbf{R}.$$

The time derivative of the angular velocity is defined to be the *angular acceleration* $\boldsymbol{\alpha}$. Differentiation with respect to time of the relation between the linear and angular velocities results in

$$\mathbf{a} = \boldsymbol{\alpha} \times \mathbf{R} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{R}).$$

The second term in the equation for the linear acceleration is called the *centripetal acceleration*, and results from the force on the particle exerted by the rod. An analog of Newton's second law for the rotational motion can be obtained by first defining an angular momentum for the particle. If the particle has linear momentum **p**, the angular momentum is defined to be $\boldsymbol{\ell} = \mathbf{R} \times \mathbf{p}$. Similarly, the torque acting on the particle is defined as $\boldsymbol{\tau} = \mathbf{R} \times \mathbf{F}$. It is clear in this case, that the vectors **p** and **F** are not free, but must be attached to the particle (the concepts of free and fixed vectors are discussed in detail in Ref. 8). The analog of Newton's second law is

$$\boldsymbol{\tau} = d\boldsymbol{\ell}/dt.$$

Detailed discussions of rotational motion and the motion of rigid bodies in vector terms is given in Ref. 16.

Many other mechanical concepts are most easily expressed in vector terms. Some of these are concepts such as the work done by a variable force moving along a given curve C. This work is given by the line integral

$$W = \int_C \mathbf{F} \cdot d\mathbf{r}.$$

If the work integral is independent of the path, the force **F** is conservative, and hence can be derived as the gradient of a scalar potential function. In particular, **F** is defined as

$$\mathbf{F} = -\nabla\phi.$$

Then, the scalar ϕ defines the potential energy of a particle in the given force field. Similarly, on the basis of Newton's second law and the work integral, the kinetic energy of a particle is defined as

$$T = \frac{\|\mathbf{p}\|^2}{2m}.$$

Electromagnetic Theory[7,9,15] The study of the electromagnetic field employs the full power of vector notation and the analysis of vector quantities. The fundamental laws governing the electromagnetic field are expressed by the set of four Maxwell equations, a set of constituitive relations, and an equation of continuity which expresses the conservation of electric charge. The set of Maxwell equations is:

$$\nabla \times \mathbf{E} = \frac{\partial \mathbf{B}}{\partial t}$$

$$\nabla \cdot \mathbf{D} = \rho$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t}$$

$$\nabla \cdot \mathbf{B} = 0.$$

In these equations, **E** is known as the *electric field intensity*, **D** the *electric displacement*, **H** the magnetic field intensity, **B** the *magnetic induction*, **J** the *electric current density*, and ρ the *electric charge density*. The electric field intensity and the electric displacement are related by the constituitive equation

$$\mathbf{D} = \epsilon \mathbf{E}$$

where ϵ is the *electric permittivity* and characterizes the electrical properties of the medium where the field exists. Similarly, the magnetic intensity and the magnetic induction are related by $\mathbf{B} = \mu \mathbf{H}$, where the magnetic permeability μ characterizes the magnetic properties of the medium. The final equation defining the electromagnetic field is the *equation of continuity:*

$$\nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t} = 0.$$

Maxwell's equations can be derived from the experimental laws of Coulomb, Ampère, Biot-Savart, and Faraday.[7,9]

At a surface separating two different media which are characterized by $\{\epsilon_1, \mu_1\}$ and $\{\epsilon_2, \mu_2\}$ respectively, the four vector fields satisfy the boundary conditions

$$(\mathbf{B}_2 - \mathbf{B}_1) \cdot \mathbf{n} = 0$$

$$(\mathbf{D}_2 - \mathbf{D}_1) \cdot \mathbf{n} = \omega$$

$$\mathbf{n} \times (\mathbf{E}_2 - \mathbf{E}_1) = \mathbf{0}$$

$$\mathbf{n} \times (\mathbf{H}_2 - \mathbf{H}_1) = \mathbf{K}$$

where ω and **K** are a surface charge density and a surface current density, respectively. The unit normal **n** points from region 1 into region 2.

Much of modern electromagnetic theory consists of finding solutions of the set of Maxwell equations for given current and charge densities and specified boundaries between media. Details of such a program are given in Refs. 9 and 15.

VELOCITY OF LIGHT

Every elementary electric charge occupies a small volume. The charge is surrounded by a radially directed electric field, the strength of which decreases by the square of distance. By any motion with a velocity $v > 0$ of the charge relative to some fixed point, the distance and/or direction is changed and, thereby, the (vector) value of the field strength at the point. Here the field change occurs a while after the moment of charge motion. Otherwise expressed, the field change propagates with a finite velocity, usually labeled c. Moreover, during the short time for the action from a *certain part* of the charge volume to pass the rest of it, the volume moves a small distance proportional to v/c. This very small displacement creates the magnetic field always associated with an electric field change. In fact, magnetism is due to a (usually very small) part of the electric field.

Any change in the electromagnetic field propagates with the very high velocity of $c = 3 \times 10^{10}$ cm/sec, called the velocity of light. For, if the charge motion happens to be an oscillation of frequency ν between 4×10^{14} and 8×10^{14} cps, we note the corresponding field variations as visible light. According to definition it is

$$c = \nu \cdot \lambda \tag{1}$$

where λ is the wavelength in vacuum. The movements of the elementary charges are mostly oscillatory. By means of the field, after the delay due to c, they act on surrounding charges, and in that way all events in the atomistic world depend on the value of c. Therefore, the knowledge of c has turned out to be of extreme importance to our modern civilization.

The wave velocity according to Eq. (1) has a constant value, independent of all movements and, strictly speaking, independent of the medium where the propagation takes place. In a transparent body, in the intermediate space the action among the elementary charges of the atoms disperses with the velocity c. By inertia, the oscillating of the charges due to the active field is somewhat delayed as compared to the field. Now, the oscillating charge itself is a radiating source and its own delayed field interferes with the original one, creating a sum-wave, the velocity v of which is $v < c$. Exceptionally, in cases of resonance and absorption $v > c$. Our observation of light propagation in a substantial body relates to that slower interference wave. For the body, e.g., the medium of atmospheric air, we obtain corresponding to Eq. (1):

$$v = \nu \cdot \lambda_a \tag{2}$$

From plain optical geometry we know that the refractive index of a medium is

$$n = \frac{c}{v} = \frac{\lambda}{\lambda_a} \tag{3}$$

The technique for determining the wavelengths of light has progressed very far, and one can easily obtain an accurate value of n. For visible light, n depends on the wavelength used according to

$$n = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} \tag{4}$$

where A, B and C are positive constants. Close to resonance, the formula is not valid.

Direct determinations of the velocity of light, usually performed in air, are all based on the measurement of the time for a light pulse to cover a known distance. Such a pulse means an increase, followed by a decrease, of the amplitude of the light vibrations. What we observe is energy exchange associated with the amplitude changes, and as a result, we obtain the propagation velocity of the light energy. A change of amplitude is, however, equivalent to an interference among a series of adjacent wavelengths, since that change is created by just such an interference. The light pulse, therefore, consists of a whole group of adjacent wavelengths, interfering with each other. Interference is a sum-product. If the participating waves have different velocities, one will find by simple addition of two sine oscillations, that the group formed has a velocity different from those of the waves creating the grcup. On the surface of a calm sea, we observe a group of waves moving forward. The waves are created at the back of the group, travel through it, and disappear at the front. The difference between wave and group velocity is directly proportional to the wavelength and to the dependence of the wave velocity on the wavelength. Thus, calling the group velocity u, we obtain the difference:

$$v - u = \lambda_a \cdot \frac{dv}{d\lambda_a} \tag{5}$$

Analogously to Eq. (3), we introduce a "group index"

$$n_g = \frac{c}{u} \tag{6}$$

If, as in the case of air, $dv/d\lambda_a$ is a small quantity, we get, after some recalculation,

$$n_g = n - \lambda \cdot \frac{dn}{d\lambda} \tag{7}$$

From Eq. (4) it is evident that $dn/d\lambda$ is a negative quantity, i.e., $n_g > n$. In vacuum, all velocities are equal: $u = v = c$.

The group velocity refers to the energy transport. Thus, in a medium there are the original waves of vacuum velocity c. By interference with waves from local charge oscillators, they create a wave system characteristic of the medium being considered and with the velocity $v < c$. By external energy action, that system is divided into an increasing number of adjacent waves, again interfering, of "second order," thereby forming groups of velocity $u < v$ (if normally $dn/d\lambda < 0$). Application of Eq. (7) to Eq. (4) yields:

$$n_g = A + \frac{3B}{\lambda^2} + \frac{5C}{\lambda^4} \qquad (8)$$

In the case of visible light or $\lambda = 0.4 - 0.8\mu$ ($\mu = 0.001$ mm) and in dry air of 0°C, 760 mm Hg, $A = 1.000287619$, $B = 16.204 \times 10^{-7}$, $C = 0.1391 \times 10^{-7}$ (based on values derived by Edlén). Inserting n_{0g} corresponding to the λ used, we get

$$n_g = 1 + \frac{n_{0g} - 1}{1 + \alpha t} \cdot \frac{p}{760} - 0.55 \times 10^{-7} \cdot \frac{e}{1 + \alpha t} \qquad (9)$$

where t is expressed in degrees Celsius, p in millimeters Hg, e in millimeters Hg of humidity, and $\alpha = 1/273$. For visible light, the error of Eq. (9) is less than 5×10^{-8}.

There is an experimental check of Eq. (8) for glass and calcite. Their refraction is 1000 times that of air. In calcite the group velocity ellipsoid was situated inside the ordinary one (Bergstrand, 1954). A more accurate control is proposed by Danielmeyer and Weber (Danielmeyer, 1971).

For micro- and radar waves with $\lambda > 700\mu$ the influence of λ in Eq. (8) is insignificant. Increasing influence of humidity, however, makes

$$n = 1 + \left[\frac{103.64}{T}(p - e) + \frac{86.26}{T}\left(1 + \frac{5748}{T}\right)e\right] \times 10^{-6} \qquad (10)$$

where $T = t + 273.16$. By using 103.64 in place of 103.49, as recommended by the International Association of Geodesy, the influence of a CO_2-term is partly compensated for. The uncertainty of Eq. (10) is about 5×10^{-7}.

There are a variety of methods for the determination of c. Among the direct ones, is the measurement of the travel time for a light pulse to cover a known distance. Usually there is a continuous series of pulses; i.e., the intensity is varied with a definite and known frequency. At every moment, there is a definite state of phase of the variation period. After reflection, the light returns, and one makes a phase comparison between emitted and received intensity. Thus, the intensity variation is used as a clock for the measurement of the running time. If the phase comparison is based on having the maximum of emitted light intensity coincide with the maximum of received intensity, the running time evidently is an even multiple of the period (=time) of a complete intensity variation cycle. Usually only one definite multiple number yields reasonable values, and there is no need for a special determination of the multiple.

The indirect methods are of much more varied character.

Determination of c Galileo was the first to try to show a finite light velocity. In his direct method, he used lanterns which could be screened off rapidly. The time elapsed on a distance of a few kilometers was, of course, too small to be observed visually.

In August 1676 at Paris, the Danish astronomer Ole Römer determined the revolution period of a satellite of Jupiter by its eclipse times into the planet's shadow. He used the result, 42 hours, to calculate the point of time for an eclipse occurring in November. It really occurred 10 minutes later. Römer explained this by the longer time for the light to reach the earth, now at a considerably greater distance from Jupiter. From the dimensions of the earth's orbit Römer defined c to be

$$c = 214\ 300 \text{ km/sec}$$

A modern value according to the same method is 299 840 ± 60 km/sec.

In 1725 the Englishman Bradley discovered astronomic aberration. Due to the velocity v of the earth in her orbit, the apparent direction to the stars normal to v is changed by v/c. Bradley could detect and measure the angle v/c because of its alternate sign for opposite parts of the earth orbit. Knowing v Bradley computed

$$c = 295\ 000 \text{ km/sec}$$

A modern value is 299 857 ± 120 km/sec.

In 1849 the Frenchman Fizeau took the next step. By projection of the image of a point source on the edge of a rapidly revolving cogged wheel, he got the required light pulse series. A blink or pulse passing through a cog interspace traveled the distance of 8633 meters to a reflector and back again along the optically identical path. Once more, now in the opposite direction, the pulse reached the cogged edge. For a suitable rotational speed the next cog interspace had now moved into position to let through the pulse; a case of "coincident maxs" (maxima). The time was computed from the revolution speed and the number of cogs. Fizeau's value was:

$$c = 315\ 300 \pm 500 \text{ km/sec}$$

In 1850, after an idea of Arago, using a point light source, Fizeau's compatriot Foucault directed a beam of constant intensity to a rapidly revolving plane mirror. During the time for the light to cover the distance to a second fixed mirror and back the revolving mirror had turned through a small angle, and the image of the light source was slightly displaced from its position when the mirror was stationary. Foucault's value was:

$$c = 298\ 000 \pm 500 \text{ km/sec}$$

In 1856 the German scientists Kohlrausch and Weber achieved a very important indirect determination. The magnetic field strength depends on v/c, the charge velocity v creating the magnetic field. Therefore, based on the same unit of force, the ratio between the unit of charge in electric and in magnetic measuring systems becomes c. Kohlrausch and Weber measured a charge (1) by its attraction to a second equal charge and (2) by the current produced at the passage of the charge through a galvanometer which showed a deflection due to the magnetic force. From (1)/(2) = c, they got:

$$c = 310\ 800 \text{ km/sec}$$

Rosa and Dorsey in 1906 measuring a capacity obtained 299 784 ± 30 km/sec.

In 1891 the Frenchman Blondlot transmitted Hertz waves along two straight and parallel wires, a Lecher guide system. After reflection, the waves created a standing wave system. Observing the nodal points Blondlot determined the wavelength. The frequency was known, and using Eq. (1) he obtained:

$$295\ 000 < c < 305\ 000 \text{ km/sec}$$

At this time, however, one was very uncertain as to the ratio between the velocities in vacuum and along the wires. Gutton solved this problem in 1911 by aid of the Kerr cell, making possible light variations of a frequency equal to that applied to the Lecher system. In a Kerr cell, the light passes between two condenser plates, lowered into nitrobenzene. Due to the directive action of the electric field between the plates on the oblong dipole molecules, the fluid acquires optical double-refracting properties. As soon as the field ceases, the molecules recover their random directions through the influence of their thermal movements. Placing the cell between an optic polarizer and a normally oriented analyzer, the light intensity leaving the combination, within certain limits, is directly proportional to the voltage applied to the condenser. The voltage may be that from a high-frequency radio transmitter.

Later on, Gutton's compatriot Mercier derived a theoretical formula for the ratio between light velocity and the velocities of guided waves. Using a valve oscillator for the high-frequency voltage on a Lecher system and applying his formula to the result, he obtained, in 1921,

$$c = 299\ 782 \pm 30 \text{ km/sec}$$

In the 1870's, Newcomb had introduced a revolving, reflecting multi-surface prism in place of Foucault's mirror. Michelson improved the system further, first in 1879 and finally at Mt. Wilson in 1926, his most accurate measurement. During the time required for the light to cover the distance of 35 km and back, the prism turned the next of its 12 surfaces in place for reflection. Only for exactly correct rotational speed was the position of the image of the suddenly illuminated distant reflector in the field of sight independent of the direction of rotation. The comparison of phase may be said, here too, to have occurred at "coincident maxs," and the high accuracy was due to the great displacement of the image for a turn of the revolving prism. Michelson's value was

$$c = 299\ 796 \pm 4 \text{ km/sec}$$

He overlooked a group correction of +2 km/sec. (Michelson, 1927)

Michelson, Pease and Pearson planned a determination in vacuum. It was completed by Pease and Pearson after Michelson's death in 1931. By multiple reflection in a 1-mile evacuated pipe, the light path was 10 miles. Due to the pipe, the geometry of the measuring device was considerably less symmetrical than in the case of the Mt. Wilson determination. The experiment was much talked about and the result was considered of high quality (Michelson, 1935),

$$c = 299\ 774 \pm 11 \text{ km/sec}$$

In 1928 the German scientists Karolus and Mittelstaedt performed the first direct determination using a Kerr cell. Their result was

$$c = 299\ 778 \pm 20 \text{ km/sec}$$

Here too, the group correction seems to have been overlooked.

Now Michelson's 1926 result was regarded as doubtful, and in 1940 Anderson, an American, tried to arrive at a decision. He used a Kerr cell. For phase comparison a photomultiplier received light from two nearby mirrors, the second of them at a somewhat greater distance in order to obtain intensity maxima from the one mirror coincident with minima from the second. The alternating photo-current then was equal to zero. Thereupon, the second mirror was moved away some 170 meters, and the distance was adjusted anew to yield a photocurrent equal to zero. After the known mirror displacement, the light's travel time had increased an even multiple of the intensity period, known from the frequency. Anderson's value:

$$c = 299\ 776 \pm 14 \text{ km/sec}$$

Thereby the Michelson 1926 value was ruled out. Anderson carefully considered the group correction. Possibly, Anderson on occasions of his apparatus yielding values very different from the evacuated pipe result, might have felt particularly called upon to search for error sources and in that way unconsciously influenced the result. Or it might have been pure chance. In any case, his value superseded the pipe result (Anderson, 1941).

Anderson's value was used for radar systems. Thereby a microwave transmitter emits short pulses (10^{-6} second) which after distant reflection and return are received again. On the screen of a cathode ray tube the rapid sweep of the ray is marked by emitted and received pulses. The difference of mark positions and the sweep speed yields the pulse travel time. By knowing c the distance is obtained. "Oboe" (0.1-meter wave) and "Shoran" (1-meter) applied to known distances gave low values. Was the c-value used too low?

In 1947 Jones and Conford used Oboe in a manner opposite to its usual operation for the determination of c over known distances and got

$$c = 299\ 782 \pm 25 \text{ km/sec}$$

In the case of Shoran the main pulse-giving radar station is in an aircraft traversing the known straight distance between two points. In order to get strong echoes, there are radar slave stations at the points. Immediately after receiving the pulses, the slave stations reemit them on a slightly different wavelength. By that the main station receiver is not disturbed by its own transmitter. The distances to the two slave stations are continuously registered, and the shortest distance and also that used are obtained at the moment of transversing. A typical distance is 300 km. By careful treatment of Shoran results, Aslakson in 1949 obtained a velocity value

$$c = 299\ 792.3 \pm 2.3 \text{ km/sec}$$

In 1951 he used "Hiran," by which errors from varying signal strengths are avoided, and obtained

$$c = 299\ 794.2 \pm 1 \text{ km/sec}$$

(Aslakson, 1951).

Meanwhile Essen attacked the problem in a quite new manner by his indirect determination using a cavity resonator. Microwave guides may be circular tubes of sufficient diameter to let the waves through. If such a tube, whose length is an even multiple of half the wavelength, is closed by plane reflecting covers, the oscillating energy supplied remains in the cavity as a standing wave. This state only occurs in case of an exact, definite resonance frequency. In practice, there are several adjacent resonance frequencies depending on remaining oscillation states, e.g., including different multiples over a diameter or over several symmetrically oriented diameters. Sarbacher and Edson have derived the exact mathematical expression for all these resonance frequencies as functions of the tube length, tube diameter and the inside wave velocity. Essen and Gordon-Smith very carefully measured length, diameter and frequency of the evacuated cavity used. By calculations, they found the vacuum value c. Their result, in 1947, was:

$$c = 299\ 792.2 \pm 4.5 \text{ km/sec}$$

In 1949 Essen repeated the determination using a cavity whose length could be varied by an inserted movable plunger. By the dependence of the results on the cavity length, systematic errors could be rejected. The final value was

$$c = 299\ 792.5 \pm 1 \text{ km/sec}$$

Applying current practices, the error limits of 1 km/sec may be reduced perhaps by half (Essen, 1956).

At this time, Bergstrand performed direct experiments using visible light. The alternating voltage, supplied by a 10-M/Hz radio transmitter, coincidently fed a Kerr cell and a photo tube. In place of "coincident maxs" the phase comparison was carried out in moments of light pulses reaching half of maximum intensity. Then the photocurrent was strongly dependent on the distance to the reflector. By low-frequency phase shift of the emitted light intensity modulation (interchange of maximum and minimum), there were periodically two photocurrents, and by exactly chosen distance, they balanced each other to 0-current on the control instrument. In this way, by known displacement of the reflector through several successive such 0-points, the wavelength of intensity variation, i.e., the group length L_g, could be determined. The group velocity was obtained from $u = \upsilon L_g$, reduced to c by Eqs. (6) and (9). Besides some preliminary results from 1947–48, the 1950 value was:

$$c = 299\ 793.1 \pm 0.3 \text{ km/sec}$$

(Bergstrand, 1957).

Under the name of "Geodimeter," Bergstrand's instrument is used all over the world for measuring distances with high accuracy, c being considered as known. The error in 30 km need not exceed 5 cm. When the geodimeter was used to check the rocket-camera positions around Cape Kennedy, the accuracy turned out to be still better.

Using the geodimeter on known distances, of course, one can obtain c. The experience from recent, improved models now shows that the just related value of 1950 is slightly too high. In 1953 Mackenzie on the Ridge Way and Caithness base lines obtained

$$c = 299\ 792.3 \pm 0.5 \text{ km/sec}$$

Kolibayev performed measurements on many different base lines in the USSR during the years 1958 to 1963, and obtained the value

$$c = 299\ 792.6 \pm 0.1 \text{ km/sec}$$

Likewise, with a geodimeter, Grosse in Germany reported a result in 1967

$$c = 299\ 792.5 \pm 0.1 \text{ km/sec}$$

For the most recent geodimeters, the AGA Ltd. has applied a modulation system more suited for digital display. Also, by introducing a laser as the light source, full daylight measurements are possible.

In several countries nowadays, different forms of electro-optic distance-measuring instruments are manufactured. Intended for the same purpose are instruments using microwave (1 to 10 cm) radiation sources, such as Wadley's Tellurometer of 1957. By this method, a moving wave system is created between two equal instruments, one on each end of the distance, and having slightly different measuring frequencies (10.000 and 10.001 M/Hz). The phase comparison is done by the low-beat frequency of 1000 Hz.

Due to the marked influence of air humidity (Eq. 10) and occasionally occurring side reflections from ground-bound objects, the accuracy of these instruments is somewhat reduced. The results respecting c agree with those of the geodimeter.

One of the most accurate c determinations was that by Froome. In 1950 he started preliminary measurements and in 1958 he used a klystron transmitter delivering harmonics of 0.4 cm wavelength. By guiding pipes the microwave emission was divided into two equal parts. The two pipes terminated in transmitting horns supplied with lenses to form the front surface of the emitted wave as plane as possible. The pipes were bent 180° each in order to get the horns directed opposite to each other. The distance between the horns was 6 to 14 meters. Between the horns there was created a standing wave system, where the nodal points were observed by aid of a movable receiving detector. The displacement of the detector was measured interferometrically. In this way the microwave length was determined with great accuracy. By carrying through the determination for different horn distances, systematic errors were rejected. These errors may depend on disturbing reflections or on the wave fronts not being sufficiently plane or of known shape. The frequency was controlled by aid of an atomic clock. The result of 1958 was

$$c = 299\ 792.5 \pm 0.1 \text{ km/sec}$$

In 1967 Simkin, Lukin, Sikora, and Strelenski used a system very similar to that of Froome. The result was

$$c = 299\ 792.56 \pm 0.11 \text{ km/sec},$$

strongly supporting the Froome value and in excellent accordance with the latest geodimeter results (Simkin, 1967).

A further step towards shorter waves was made by V. Daneu et al. using a laser for the far infrared at $\lambda = 0.1$ mm. In a Michelson vacuum interferometer of 4 m path difference, the laser wave is compared to visible light of accurately known wavelength. The laser frequency is directly determined by comparison with high harmonics of a quartz oscillator. The preliminary results are in concordance with the present accepted value of c (V. Daneu, 1969).

A proposal by Mockler and Brittin is very interesting in two respects:

(1) The use of gamma rays.

(2) Light travels only once over the distance (as Roemer!).

First I refer to the article in this book on the MÖSSBAUER EFFECT. The vertical gable surface A of a quartz rod is directed towards the 3 m distant gable B of an identical rod. Both rods are vibrating longitudinally by stimulation from a common quartz-controlled 10^{10}-Hz oscillator. On A is a film of ^{57}Co, including ^{57}Fe decaying to ground state and thereby emitting gamma rays, marked by the Doppler-variation due to the vibrational movements of A. B is covered with ^{57}Fe, absorbing the emission by excitation from the ground state. Due to the very narrow common bandwidth of emission and absorption, 4 MHz of 4×10^{18} Hz, one will observe absorption at B only when its vibratory movement is in phase with the Doppler variation of the radiation hitting the surface. By then, there is an even number of "Doppler waves" over the known distance from A to B, yielding the "wave length." Again we use Eq. (1) to obtain c. Important for a good result is a strong quartz vibration (Mockler, 1961).

There is an indirect method which does not give such high accuracy: The exactly known frequency of an atomic clock is the ground rotational molecular frequency with quantum number =1 of some diatomic gas. From the quantum spectral formula of the rotational line series, one obtains the frequency at high quantum numbers of visible or infrared light, where the wavelength is known with great accuracy. The connection between wavelength and frequency yields c, and in 1955 Rank, Bennet and Bennet obtained the value 299 791.9 ± 2.2 km/sec.

Finally, E. Richard Cohen in this Encyclopedia quotes a numerical value based on what he considers to be the most accurate and consistent measurements available as of June 1982. The velocity of light was determined by measuring the wavelength and frequency of a methane-stabilized helium-neon laser and taking the product of these two quantities. He quotes a value of 299 792 458 $\mathrm{m \cdot s^{-1}}$ or 299 792.458 km/sec (see CONSTANTS, FUNDAMENTAL).

VIBRATION

There seems to be a reasonable consensus of opinion that, in physics, vibration is a periodic motion—a repeating to-and-fro motion—of a solid body or of the particles of an elastic body. Some examples will illustrate and clarify this definition. However, let us first point out that about us are an endless variety of vibrating systems, including the vibrations of vocal cords, piano and violin strings, bearings, loudspeaker cones, pneumatic drills, organ pipes, bells, woodwinds, and even structures. An historical example of the adverse effects of vibration was the Tacoma Narrows bridge disaster in 1940, in which the amplitude of vibration became so great that the bridge was entirely destroyed.

As a simple example of a vibrating system, let us consider what happens when a body of mass m fastened to a helical spring is moved slightly away from its equilibrium position and let go, assuming that there is no friction and that the mass of the spring is negligible compared with that of the attached body. The force on the body is directly proportional to the displacement x and oppositely directed, so the equation of motion is

$$m\ddot{x} = -kx, \qquad (1)$$

where k, the stiffness of the spring, is a positive constant and $\ddot{x}$ is the second derivative of the displacement with respect to time. The solution of Eq. (1), as may be shown by substitution, is

$$x = A \cos \omega t + B \sin \omega t,$$

where A and B are constants, and ω, the so-called *angular frequency*, is $(k/m)^{1/2}$. If we agree to start counting time from the instant when $x = x_0$, and $v = 0$, the solution reduces to

$$x = x_0 \cos \omega t.$$

This sinusoidal motion is called *simple harmonic motion*. Its period T, the time for one complete vibration, is $2\pi (m/k)^{1/2}$, and its frequency f, is $1/T$, or

$$f = (1/2\pi)(k/m)^{1/2}. \qquad (2)$$

It is important to note that the frequency is independent of the amplitude x_0, and depends only on the mass of the attached body and on k.

Another simple system, somewhat different from the first, is the *simple pendulum*, consisting ideally of a point mass at one end of a massless string, the other end of the string being fastened to a rigid support. Using the idea that the torque is equal to the product of the moment of inertia and the angular acceleration, one gets for the equation of motion:

$$mL^2\ddot{\theta} = -mgL \sin \theta, \qquad (3)$$

where L is the length of the string, g the acceleration of gravity, and θ the displacement angle from the vertical. For θ small enough to enable $\sin \theta$ to be replaced by θ, Eq. (3) has the same form as Eq. (1). Hence, if the boundary or initial conditions are $\theta = \theta_0$ and $\dot{\theta} = 0$ at $t = 0$, the solution is

$$\theta = \theta_0 \cos (g/L)^{1/2}\ t.$$

For this case the frequency is

$$f = (1/2\pi)(g/L)^{1/2}. \qquad (4)$$

In spite of the similarity between this example and the first one, one should note that here the frequency is independent of the mass; dependent on the value of g, which varies from place to place; and dependent on the amplitude—since it is valid only for small values of θ_0. None of these statements is true for a mass vibrating at the end of a spring.

Another—and somewhat more complicated—example of vibratory motion is that of the *transverse vibrations of a stretched string* of constant linear density ρ_L. The string, of length L, is fastened between two fixed supports, and is displaced so little that any displacement y is very small compared with L. Let us consider a small segment of the string of length dx under tension T. The equation of motion is

$$\rho_L\, dx \frac{\partial^2 y}{\partial t^2} = T\left(\frac{\partial y}{\partial x}\right)_{x+dx} - T\left(\frac{\partial y}{\partial x}\right)_x,$$

where x is the distance measured along the string. This reduces to

$$\frac{\partial^2 y}{\partial t^2} = \frac{T}{\rho_L} \frac{\partial^2 y}{\partial x^2}.$$

There are several ways of solving this equation. One is to assume that y may be written as the product of a function of x alone and a function of t alone, i.e., $y = X(x)\,\tau(t)$. This leads to solutions

$$X = C \cos(\omega x/c + D) \quad \text{and} \quad \tau = A \cos(\omega t + B),$$

if we let $c^2 = T/\rho_L$, and $\omega = 2\pi f$. By applying the boundary conditions, namely, that for all values of the time $y = 0$ at the fixed ends of the string (i.e., at $x = 0$ and at $x = L$), we find that $D = \frac{1}{2}\pi$ and $\omega L/c = n\pi$. Hence the possible frequencies with which the string can vibrate are given by

$$f_n = \frac{nc}{2L} = \frac{n}{2L}\left(\frac{T}{\rho_L}\right)^{1/2}, \quad n = 1, 2, 3, \ldots. \tag{5}$$

In contrast to the first two illustrations, where the system could vibrate with only one frequency, this time we have an infinite number of possible frequencies, each an integral multiple of the lowest. The lowest possible frequency is called the *fundamental* or *first harmonic*, the second lowest frequency the *second harmonic*, etc. The general solution is

$$y = \sum_{n=1}^{\infty} \sin\frac{n\pi x}{L}\left\{E_n \cos\frac{n\pi ct}{L} + G_n \sin\frac{n\pi ct}{L}\right\}.$$

Thus, knowing the initial position of the string, one can calculate its position at any future time. It turns out, for example, that if the string is pulled out at a point half-way between its ends and let go, only the odd harmonics are present in the motion.

In the previous example we had a system where there were an infinite number of possible frequencies of vibration, but all those higher than the lowest possible frequency were integral multiples of the lowest frequency. Let us look briefly at a system which vibrates somewhat differently. Let us consider the transverse vibrations of a bar clamped at one end and free at the other—such a bar is often referred to as a *clamped-free bar*. The equation of motion is:

$$\frac{\partial^2 y}{\partial t^2} = -\kappa^2 c^2 \frac{\partial^4 y}{\partial x^4},$$

where $c^2 = Y/\rho$, Y being Young's modulus and ρ the density of the bar. κ is a constant depending on the shape of the bar; for example, for a bar of circular cross section, it is equal to one-half the radius. For such a bar the solution involves both trigonometric and hyperbolic functions. On applying the boundary conditions one finds that the allowed frequencies above the fundamental are not related to one another by a simple relationship. To demonstrate this, let us look at the following Table 1, where the ratio of the six lowest possible frequencies to the fundamental are listed both for the previous example and for this one. Higher frequencies which are not integral multiples of the fundamental a.e known as *overtones*, whereas those which are integral multiples of the fundamental are referred to both as overtones and as *harmonics*. Thus we see from Table 1 that in the case of the string the second lowest frequency is both an overtone and a harmonic, whereas the second lowest frequency in the case of the bar is an overtone but not a harmonic.

Up to now we have been discussing free vibrations in which the system is displaced and then let go. We know that due to friction, etc., the system will eventually come to rest. This process is known as *damping*. There is another kind of vibration, *forced vibration*, in which the system is driven by an external force—frequently a sinusoidal force—and made to vibrate at frequencies which may either be the same as or different from those at which it vibrates as a free system. These vibrations last as long as the force is applied. Perhaps the most interesting case of forced vibrations is that where the system is driven at a frequency close to that at which it vibrates as a free system. This is known as *resonance*. An example frequently cited is the situation where a person demolishes a goblet by singing loudly a note of just the correct frequency, a frequency near the resonant or "natural" frequency of vibration of the goblet. A sharp or narrow resonance may be an advantage, as in the case of tuning a radio receiver, or

TABLE 1. RATIO OF FREQUENCIES TO THE FUNDAMENTAL

	Lowest	2nd	3rd	4th	5th	6th
Transverse vibrations of a string fastened at both ends	1	2	3	4	5	6
Transverse vibrations of a clamped-free bar	1	6.267	17.55	34.39	56.85	84.93

a disadvantage, as in the case of a loudspeaker cone or cabinet.

VISCOELASTICITY

Viscoelasticity is a material property possessed by solids and liquids which, when deformed, exhibit both viscous and elastic behavior through simultaneous dissipation and storage of mechanical energy. The *material constants* linking stress and strain in the theory of elasticity become *time-dependent material functions* in the constitutive equations of viscoelastic theory. At sufficiently small (theoretically infinitestimal) strains the behavior of viscoelastic materials is well described by the *linear theory of viscoelasticity* epitomized by the celebrated *Boltzmann superposition principle.* Expressed in its simplest form

$$\sigma(t) = \int_0^t Q(t-u)\epsilon(u)\,du$$

$$\epsilon(t) = \int_0^t U(t-u)\sigma(u)\,du$$

it states that the stress (or strain) at time t under an arbitrary strain (or stress) history is a linear superposition of all strains (or stresses) applied at previous times u multiplied by the values of a weighting function $Q(t)$ [or $U(t)$] corresponding to the time intervals $t - u$ which have elapsed since imposition of the respective strains (or stresses).

Put another way (see *operator equation* below) the Boltzmann superposition principle expresses the fact that the material behavior can be described by linear differential equations with constant coefficients and time as variable.

Considerable simplification of the viscoelastic relations is achieved by mapping them from the real t axis into the complex s plane through the Laplace transformation. The resulting transforms in s may be manipulated algebraically and then inverted to regain the time-dependent form. Thus the above convolution integrals become

$$\sigma(s) = Q(s)\epsilon(s) \qquad \epsilon(s) = U(s)\sigma(s)$$

and $Q(t)$ and $U(t)$ can be seen to be the material functions representing the response to a unit impulse of strain or stress. The unit step response functions, the material functions under constant strain ϵ_0 and constant stress σ_0, are the *relaxation modulus* and *creep compliance*, obtained as

$$G(t) = \sigma(t)/\epsilon_0 = \mathcal{L}^{-1}\ Q(s)/s$$

$$J(t) = \epsilon(t)/\sigma_0 = \mathcal{L}^{-1}\ U(s)/s$$

where $\mathcal{L}^{-1}$ denotes inversion of the transform. For sinusoidal steady state strain $\epsilon(\omega)$ and stress $\sigma(\omega)$, there result the *complex modulus* and *complex compliance*

$$G^*(\omega) = \sigma(\omega)/\epsilon(\omega) = [Q(s)]_{s=i\omega}$$

$$J^*(\omega) = \epsilon(\omega)/\sigma(\omega) = [U(s)]_{s=i\omega}$$

whose real and imaginary parts are the *storage modulus* $G'(\omega)$, *storage compliance* $J'(\omega)$, *loss modulus* $G''(\omega)$, and *loss compliance* $J''(\omega)$. Their ratio is the loss tangent

$$\tan\delta\ (\omega) = G''(\omega)/G'(\omega) = J''(\omega)/J'(\omega)$$

Any of the above functions (or any other that may be derived, e.g., for constant rate of strain), if known over a sufficiently extended time scale (or, equivalently, over a sufficient range of frequencies), provides complete information on the viscoelastic properties of a homogeneous isotropic material. As formulated above, the equations refer to deformation in simple shear. When dealing with combined stresses, as in viscoelastic stress analysis, the tensorial character of stress and strain must, of course, be taken into account. The equations for other types of deformation, e.g., dilatation or uniaxal extension, are analogous to those for shear. The relations between the frequency-dependent viscoelastic functions in shear, extension, and dilatation are the same as those between the elastic constants, while for the time-dependent functions these relations are valid between the s-multiplied Laplace transforms. Thus the relaxation modulus in extension $E(t)$ is related to $G(t)$ through the *time-dependent Poisson's ratio* $\nu(t)$ by

$$E(s) = 2G(s)\ [1 + s\nu(s)]$$

and for $\nu(t) = 1/2$, $E(t) = 3G(t)$. Data obtained in shear and extension on incompressible bodies are thus readily combined. Moreover, if a viscoelastic function can be formulated analytically, it can be converted into any of the others, allowing combination of measurements made under different stress or strain histories. Use is made of this to extend the experimentally accessible time scale. Thus at short times, dynamic (frequency-dependent) measurements are more convenient than transient (time-dependent) measurements, and *vice versa* for long times.

Another important extension of the time scale is available through *time-temperature superposition*. An increase in temperature generally shortens the time necessary for the molecular rearrangement processes responsible for viscoelastic behavior. If all such processes are affected by temperature in the same way, the material is *thermorheologically simple*, and a change in temperature simply shifts the viscoelastic functions along the logarithmic time or frequency axis. For polymers (the typical viscoelastic materials) above the *glass transition temperature* (at which main chain motion effectively ceases), the shift factor a_T is given by an equation of the form (WLF equation)

$$\ln a_T = -\frac{c_1(T - T_0)}{c_2 + T - T_0}$$

where T_0 is a suitably chosen reference temperature, and c_1 and c_2 are constants. Measurements made at different temperatures can thus be combined to yield a single *master curve*.

Measurements made under different stress or strain histories are often combined for experimental reasons and the linear theory of viscoelasticity furnishes a number of methods to this end. Interconversion of the viscoelastic functions is faciliated by the introduction of *spectral distribution functions*. The spectral functions may be derived conveniently by rewriting the Boltzmann superposition principle, given above as an integral operator equation, in the form of the *differential operator equation*:

$$[\sum p_m D^m]\,\sigma(t) = \sum\,[q_n D^n]\,\epsilon(t)$$

where $D^r = d^r/dt^r$. The Laplace transformation leads to

$$Q(s) = 1/U(s) = \sum q_n s^n/\;\sum p_m s^m$$

a definition of $Q(s)$ and $U(s)$ which is readily linked with the useful representation of viscoelastic behavior by *models* consisting of series-parallel combinations of springs (elastic or storage elements) and dashpots (viscous or dissipative elements). A parallel combination (Voigt model) is characterized by a *retardance* $U(s) = 1/(G + \eta s) = J/(1 + \lambda s)$, where $\lambda = \eta/G$ is the *retardation time*, η signifies viscosity, and $J = 1/G$. A series combination (Maxwell model) is characterized by a *relaxance* $Q(s) = 1/(J + 1/\eta s) = G\tau s/(1 + \tau s)$ where $\tau = \eta/G$ is the *relaxation time*.

Through the *combination rules*: "relaxances add in parallel, retardances add in series," $Q(s)$ and $U(s)$ are readily derived from a given more complex model as illustrated below.

$Q(s) = \sum G_i \tau_i s/(1+\tau_i s)$
GENERALIZED MAXWELL MODEL

FIG. 1

These models are *conjugate*, i.e., with suitable choices for the parameters, they describe the same viscoelastic material. Representation of viscoelastic behavior by a (small) finite number of elements is often inadequate. Molecular theories of polymer behavior lead to models with an infinite number of parameters, characterized by a *discrete distribution* (or *line spectrum*) *of relaxation or retardation times*. These distributions are normally so closely spaced that they cannot be resolved experimentally. One can therefore define *continuous distribution functions*

$$Q(s) = \int_0^\infty G(\tau)\,\frac{\tau s\,d\tau}{1 + \tau s} = \int_{-\infty}^\infty H(\tau)\,\frac{\tau s\,d\ln\tau}{1 + \tau s}$$

$$U(s) = J + \int_0^\infty J(\lambda)\,\frac{d\lambda}{1 + \lambda s} + 1/\eta s =$$

$$J + \int_{-\infty}^\infty L(\lambda)\,\frac{d\ln\lambda}{1 + \lambda s} + 1/\eta s$$

where $G(\tau)$ and $J(\lambda)$ are distributions of relaxation and retardation times (more properly: modulus and compliance densities on time) respectively, and $H(\tau) = \tau G(\tau)$ and $L(\lambda) = \lambda J(\lambda)$ are their counterparts on the more convenient logarithmic time scale. The spectral functions may be derived from experimentally determined curves of the viscoelastic functions through any of several approximation methods.

The various viscoelastic functions are illustrated above on the example of an uncross-linked amorphous polyvinyl acetate with a molecular weight of about 300 000. Data obtained in extension and shear at different temperatures were combined and interconverted.

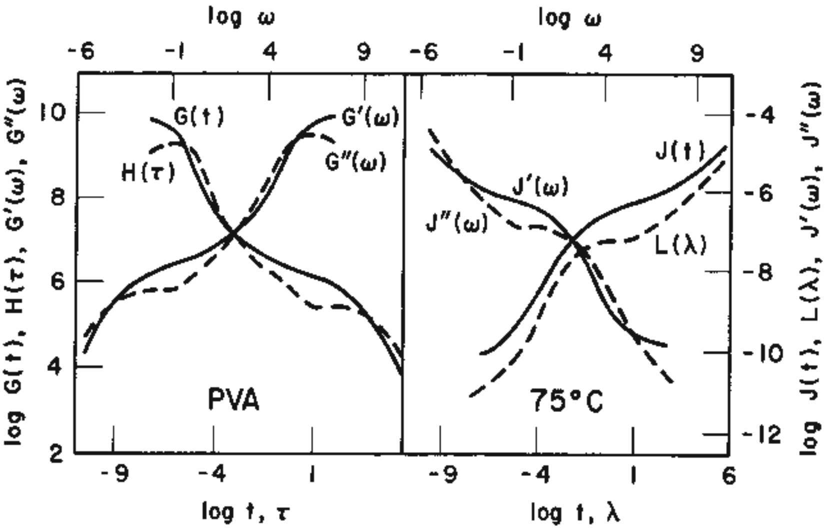

FIG. 2

The functions are grouped to display their qualitative symmetries.

Singling out the relaxation modulus for a broad interpretation of the viscoelastic behavior of an uncross-linked polymer, one sees that at short times (in the *glassy region*), the modulus approaches an asymptotic value, the *glass modulus*. It then drops through the glass-to-rubber transition region and levels out somewhat in the *plateau region* reflecting the effect of molecular entanglements. At still longer times, it decays to zero through the *terminal region*. For cross-linked networks this region is absent (if there is no chemical degradation). In this case, the flow term $1/\eta s$ is missing from $U(s)$ above; an additive constant, the *equilibrium modulus* G_e, characterizing the (level) *rubbery region*, appears in $Q(s)$.

Current efforts in the field of viscoelasticity are directed chiefly towards the development of nonlinear (large deformation) theory, theories of multiphase materials, anisotropic and inhomogeneous (semicrystalline and filled) systems, the solution of viscoelastic boundary problems (viscoelastic stress analysis), and the explanation of viscoelastic behavior on the molecular level (molecular theories).

VISCOSITY

Materials in general show two broad kinds of behavior with regard to their reaction when subject to an applied force. In one type, they deform until a position of equilibrium is reached, when no further change of shape takes place. Many solids show this kind of behavior. Alternatively, there is no permanent resistance to change of shape, and continuous deformation takes place for as long as the force is applied. The material is said to flow. Substances possessing this property are called fluids and may generally be thought of as either liquids or gases. The class also includes some materials, such as glass and pitch, which at room temperature exhibit many of the characteristics normally associated with solids. When flow takes place in a fluid, it is opposed by internal friction arising from the cohesion of the molecules. This internal friction is the property of the fluid known as *viscosity*. It is clearly of great importance in many contexts; we may think, for example, of the flow of blood in the body, the flow of oil in pipe lines, the working of molten glass, and the process of lubrication. It may be used in the discrimination between streamlined and turbulent flow. It is also a useful property in providing information about the structure of complex organic molecules.

Definitions and Units The formal definition of viscosity arises from the concept put forward by Newton that under conditions of parallel flow, the shearing stress is proportional to the velocity gradient. If the force acting on each of two planes of area A parallel to each other, moving parallel to each other with a relative velocity V, and separated by a perpendicular distance X, be denoted by F, the shearing stress is F/A and the velocity gradient, which will be linear for a true liquid, is V/X.

Thus

$$\frac{F}{A} = \eta \cdot \frac{V}{X}$$

The constant η is known as the viscosity coefficient, dynamic viscosity, or viscosity of the liquid. The unit, expressed in dyne second per square centimeter, is known as the "poise," after Poiseuille who worked on viscosity in the early part of the nineteenth century. For practical purposes it is often more convenient to use a smaller unit, known as the centipoise, equal to a hundredth of a *poise*. It is useful to note that water at room temperature has a viscosity of approximately 1 centipoise. In many applications of viscometry, it is useful to note another quantity, called the kinematic viscosity, which is obtained by dividing the dynamic viscosity by the density. It is frequently denoted by the Greek letter ν, and the unit in which it is expressed is the "stokes," after Sir George Stokes, another pioneer worker in viscometry. In practical viscometry, viscosity is sometimes expressed in seconds; this is a measure of the time for a prescribed quantity of liquid to flow through a tube or aperture of defined dimensions.

In considering many problems of fluid motion, an important non-dimensional quantity is vd/ν, where v is the velocity of the fluid, ν its kinematic viscosity, and d a linear dimension, such as the diameter of a tube. This quantity is known as Reynolds' number; when it is less than about 1000, flow is generally streamlined, whereas at values over 1000 it is turbulent.

Values for the viscosity of a number of common substances are given in Table 1.

TABLE 1. COEFFICIENT OF VISCOSITY IN POISES (APPROXIMATE VALUES)

Water at 20°C	0.010
Mercury at 20°C	0.015
Carbon tetrachloride at 20°C	0.009
Olive oil at 20°C	0.84
Glycerine at 20°C	8.3
Golden Syrup at 20°C	1000
Glass at melting temperature	10^3
Glass at working temperature	10^7
Glass at annealing temperature	10^{13}
Air at 0°C	0.00017
Carbon dioxide at 0°C	0.00014
Steam at 100°C	0.00013
Pitch at 15°C	10^{10}

Methods of Measurement In measuring viscosity in the absolute sense, it is necessary to be able to use the basic relationship between shearing stress and velocity gradient in order to derive a relationship between the measurable quantities involved in flow in an apparatus of a particular shape. For example, it can be shown that the volume Q of a liquid of viscosity η flowing per unit time through a tube of length l and internal radius a, when the pressure difference between the ends is P, is given by

$$Q = \frac{\pi P a^4}{8 l \eta}$$

Capillary viscometers enable all the variables in this equation to be measured and the viscosity to be determined.

Similarly, a viscometer can be constructed in which one cylinder rotates inside another with the liquid under test in the annular space between the two. Measurement of the angular velocity and the applied torque, together with a knowledge of the dimensions of the apparatus, enables the viscosity to be calculated.

Another method involves the measurement of the rate of fall of a sphere in a column of liquid. If the liquid has viscosity η and density ρ, and the sphere has radius r and density σ, then the velocity of fall is

$$v = \frac{2gr^2(\sigma - \rho)}{9\eta}$$

a relationship commonly known as **Stokes' law**.

There are also a number of empirical methods that can be used to obtain comparative values, the instruments being calibrated by using liquids of known viscosity.

Variation with Temperature The viscosity of liquids decreases rapidly with increasing temperature. For example, the viscosity of molten glass may be halved by raising the temperature 30°C. On the other hand, the viscosity of gases increases with temperature. This feature is of practical importance in two senses. In all methods of measurement strict temperature control is necessary, and when results are quoted, it is essential to state the temperature to which they refer.

The variation of viscosity with temperature is of great significance in the problem of lubrication, where oils may have to operate over widely different conditions. So-called viscostatic oils have a low temperature coefficient and can thus be used over a wide temperature range. As an indication of this property, the oil industry uses an empirical number known as the "viscosity index"; the higher the viscosity index, the less is the variation of viscosity with temperature.

Molecular Weight Determinations The viscosity of organic materials in solution was suggested by Staudinger as a useful index of their molecular structure, since the flow properties would be influenced by the size and shape of the molecules. For example, some high polymers give appreciable increases of viscosity even at low concentrations on account of the effect of randomly coiled long-chain molecules. Generally speaking, the higher the molecular weight, the greater is the increase in viscosity for a given weight in the solution. The values of molecular weight obtained by this method are not absolute, but they depend on the establishment of empirical relations by measurements on substances of known molecular weight in a given series (see MOLECULAR WEIGHT).

Non-Newtonian Systems A large number of industrially important materials do not obey the simple Newtonian relationship between shearing stress and shearing rate. In some cases the viscosity varies with the shearing rate, and in others, it varies with time when the shearing rate is constant. An important group of such materials is known as thixotropic substances—they become thinner when stirred. Paint, suspensions of clay in water, and many other substances behave in this way, and the property has considerable industrial significance. In the case of paint, for example, the low viscosity when brushed in a thin film makes for easy application, whereas the high viscosity under low shearing stresses enables the film to be retained on vertical surfaces. Some substances thicken up on stirring, and there are a number of other classes of behavior (e.g. VISCOELASTICITY) that constitute departure from Newtonian laws. The study of such anomalous systems is an important branch of modern RHEOLOGY.

VISION AND THE EYE

The meaningful experience of vision requires light, the eye, and a conscious observer (animal or human) having an intact *visual system*. In its gross aspects, the visual system includes the eyes, the *extraocular muscles* which control eye position in the *bony orbit* (eye socket), the optic and other nerves that connect the eyes to the brain, and those several areas of the brain that are in neural communication with the eyes. This summary will stress the informational aspects of human vision; it should be realized however that no visual system could function without its *protective mechanisms* (tears and eyelids, especially) or if its normal metabolism (mediated through the vascular supply of eye and brain) were seriously interfered with.

The visual system is particularly well adapted for the rapid and precise extraction of spatial information from a more-or-less remote external world; it does this by analyzing, in ways that are as yet imperfectly understood, the continuously changing patterns of radiant flux impinging upon the surfaces of the eyes. Much of this light is reflected from objects which must be discriminated, recognized, attended to, and/or avoided in the environment; this ability transcends enormous variations in intensity, quality, and geometry of illumination as well as vantage point of the observer. A block diagram of the visual system is given in Fig. 1.

Although image formation in the eye is importantly involved, the analogy between eye and photographic camera has been badly overworked and tends to create the erroneous impression that little else is needed to explain how we see. Image formation is greatly complicated by the movement of the eyes within the head, and of both eyes and head relative to the external sea of radiant energy. Such visual input is ordinarily sampled by discrete momentary pauses of the eyes called *fixations*, interrupted by very rapid ballistic motions known as *saccades* which bring the eyes from one fixation position to the next. Smooth movements of the eyes can occur when an object having a predictable motion is available to be followed.

Each eye controls many important functions within one mobile housing: it is a device to form an image upon a vast array of light sensitive *photoreceptors*, but it also contains systems to dissect, encode, and transmit information derived therefrom. A cross section of the human eye is shown in Fig. 2. The primary refracting surface is the *cornea*, a complex yet transparent structure which admits light through the anterior part of the outer surface of the eye. The *iris* contains muscles which alter the size of the entrance port of the eye, the *pupil*. The *crystalline lens* has a variable shape, under the indirect control of the *ciliary* muscle. Since it has a refractive index higher than the surrounding media, it gives the eye a variable focal length, allowing *accommodation* to objects at varying distances from the eye. The iris muscles and the ciliary muscle, known collectively as the *intra-*

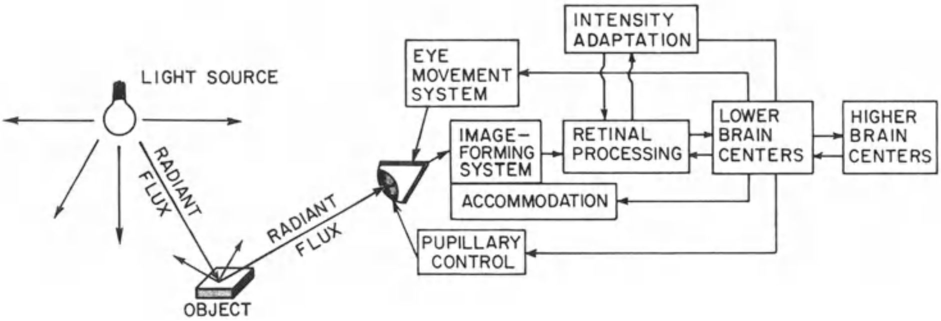

FIG. 1. Block diagram of the functional components of the visual system.

ocular muscles of the eye, are controlled by impulses having their origins in separate but interacting centers in the brain stem. These brain centers also receive nerve impulses from the eye. These loops, and those involving the extraocular musculature and thus eye position, have some of the properties of nonlinear servosystems, and have been actively investigated as such.

Much of the remainder of the eye is filled with fluids and materials under pressure, which help the eye maintain its shape. The *aqueous humor*—thin, watery, and continuously being replaced—fills the *anterior* chamber between cornea and lens. The *vitreous humor*—thinly jellylike and of very low metabolism—fills the majority of the eye's volume. The image produced through these structures is formed upon the *retina* at the back of the eye. The retinal image is very small, because the eye itself is small and has a short posterior focal length of about 19 to 23 mm, depending upon accommodative state. The retinal image has a point-spread function on the order of two to three minutes of arc, corresponding to about 10μ on the retina for ideal conditions. These conditions include a 2 to 3 mm pupil, monochromatic light, optimal accommodation and a normal, young, and healthy eye. This quality approaches, but is somewhat worse, than that produced by diffraction-limited imagery in an ideal optical system. The retinal image is always in motion: even during the best efforts at steady fixation, there exists an irreducible tremor of the eye whose high-frequency components are in the 20 to 30 seconds-of-arc range, with larger drifting and saccadic movements up to 5 minutes of arc. It is possible to eliminate this residual motion by various optical techniques; such stabilization usually results in a total loss of vision, providing an elegant demonstration that the visual system responds primarily to *changes* in light patterns, rather than to steady states. Electrophysiological evidence from animals amply confirms this.

The *retina* is a thin structure of extreme com-

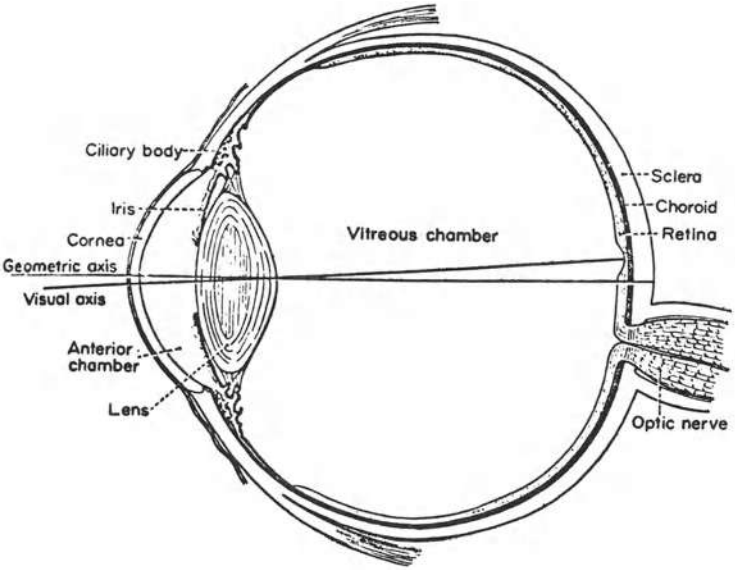

FIG. 2. Horizontal cross seuuon of the right eye of the human.

plexity. It is considered embryologically to be a displaced part of the brain, and it is of clinical importance as the only part of the central nervous system that can be directly observed in the intact living subject. The receptors, the *rods* and *cones*, line the back surface of the retina, in immediate contact with dark layers (including the pigment epithelium and choroid) which help to nourish the receptors and to prevent multiple reflection of light. There are about 125 000 000 receptors in each human eye, of which only about 5 per cent are cones. The cones are however of an importance disproportionate to their relative number: in particular there is a small central bouquet of about 2000 of them, located in a rod-free depression of the retina known as the *fovea centralis* where they are packed together into a hexagonal array having a density of about 150 000/mm^2; these are capable of dissecting the finest details of the optimal retinal image. This process is aided by the lateral displacement of other retinal structures through which light must pass to reach the cone receptors. Moreover, this is the area of the retina where images have the highest attention value and which "projects" to a disproportionately huge area of the visual brain; the extraocular muscles move the eye more or less automatically, in the act of fixation, to put objects of interest into this region where their details can be most critically appreciated, while the accommodative mechanism alters the shape of the lens to produce the sharpest possible image in this region. The cones, including those in the fovea, function only at high luminance levels (approximately, above .01 candela/m^2), below which they are functionally blind and the rods take over. Thus the retina contains two systems intermixed: (a) the cone system (photopic), good for high-acuity vision, which also mediates all color vision; (b) the achromatic rod system, which has relatively poor spatial resolving power, but very high sensitivity.

The rods and cones are synaptically connected to the *bipolar cells*, which in turn relate to the *ganglion cells*, whose axons constitute the optic nerve fibers. There are also rich horizontal connections among the receptors, among the bipolar cells, and among the ganglion cells. In addition, there is a high degree of convergence: the 125 000 000 receptors ultimately feed into only 1 000 000 nerve fibers of the flexible optic nerve, which therefore constitutes the principal "bottleneck" of information flow in the visual system. The convergence ratio for the fovea is about 1:1, helping to preserve the high-detail vision of this region, while in the peripheral retina this ratio is many thousands to one, leading to high sensitivity at the sacrifice of resolving power.

The pathways from retina to brain are by no means independent, including those emerging from the central fovea. The horizontal interconnections are utilized to allow inhibitory processes to sharpen the "neural image" by a process of border enhancement, but much more complicated preprocessing of information occurs also. It is abundantly clear that the brain does not receive a replica of what is on the retina, although a spatial isomorphism between retina and brain does exist; rather, the messages sent to the brain tend to carry information that is already processed in complex ways to make efficient use of the limited communications pathways between eye and brain in an adaptively significant manner.

Horizontal cells form synaptic connections with receptors and bipolar cells, and by connecting with one another they integrate signals over long retinal distances. They probably play an important role in adaptation by providing inhibitory feedback to reduce the responses of receptors whose signals otherwise would saturate. In addition, horizontal cells are involved in the generation of opponent signals that relate to sums and differences of receptor outputs, and which are important both for spatial and color vision. *Amacrine cells* lie deeper in the retina, where they interconnect with bipolar and ganglion cells, as well as with other amacrines.

Cells in the visual system exist in a very wide variety of specialized types. This is true both within and between levels of visual processing, including the cells of the retina, the *lateral geniculate nucleus* (LGN) of the thalamus (to which the optic nerve fibers project) and the *visual cortex* of the brain, which receives its input from the LGN. Many other regions of the brain are also concerned with vision; most, but not all, receive their input from the LGN.

All of the cells of the retina except the ganglion cells (and to a limited extent the amacrines) exhibit graded potentials which carry information by means of an amplitude code. Most cells of the visual system, including the ganglion cells of the retina, show the classical all-or-none behavior according to which information is encoded in terms of impulse frequency for transmission over relatively long distances.

Visual cells have been extensively studied using microelectrodes, and the visual pathways have been traced using an ever expanding variety of techniques. At all levels of the visual system, the responsiveness of a cell relates to a restricted region of the visual field, but not to just a point. A ubiquitous feature of a visually responsive cell is its *receptive field*. This is defined as the region of visual space to which it responds. The reaction of a cell within such a region is not uniform. For example, ganglion cells exhibit a concentric center-surround organization: the output of the cells is increased by delivering stimuli to the center of its receptive field, but is inhibited by light in the surrounding region (or vice versa). In the visual cortex, cells respond instead to more complex stimuli, such as bars, lines, or gratings, depending upon such variables as orientation, movement, and length. Thus individual cells differ markedly in their responsiveness to important stimulus properties related to time, space, and color. Despite rapidly expanding knowledge of how the visual system analyzes the visual environment, as reflected in the activity of its constituent cellular components, almost nothing is known about the mechanisms of synthesis that presumably must underlie our integrated sensory experiences.

Because the two eyes are located in slightly different places in space, a disparity of the two retinal images results. Rather than to produce a blurred or confused picture, this *retinal disparity* results in the appearance of *stereoscopic depth*. Such depth judgments are remarkably precise, consistent with the findings that all but the smallest eye movements and accommodative adjustments are highly correlated between the two eyes, and that neural units in the visual brain are precisely connected, by way of intermediate synapses, to optically corresponding areas.

The normal eye exhibits a large amount of chromatic aberration which is not normally noticeable. There are at least two reasons for this: (a) the cone receptors exhibit a directional sensitivity which reduces the visual effectiveness of light entering the marginal zones of the pupil; (b) the visual system has a remarkable capacity to adapt to systematic distortions of almost any kind which do not carry useful information from the external world. For example, observers learn with practice to compensate for the effects of gross visual displacement caused by prisms placed before the eyes, and are no longer able to see the chromatic fringes produced by such prisms. Removal of the prisms produces reappearance of chromatic fringes and an apparent displacement in the opposite direction. The explanation of such effects is not simple: in this example, the adaptation to displacement is probably kinesthetic rather than visual, but the adaptation to fringes is almost certainly confined to the visual system. Related to this are many entoptic phenomena that are seldom preceived: (a) the shadows of the retinal blood vessels, which are in front of the receptors; (b) the blind spot in the visual field, caused by the receptor-free optic disc, large enough to contain 200 images of the moon; (c) "floaters," usually shadows of debris in the vitreous humor, clearly visible if attended to against bright, uniform surfaces such as the sky; (d) fleeting specks of light probably caused by the movements of corpuscles within the retinal blood vessels; (e) Maxwell's spot, probably corresponding to the region of the macular pigment, and many others.

The initial nonoptical event in the visual process is the absorption of single light quanta by single molecules of visual photopigment, of which millions are located in each rod or cone. Under ideal conditions, as few as a half-dozen of these elemental events within fairly broad bounds of time and area, are sufficient to lead to a visual sensation. The visual photopigment contained in the rods is *rhodopsin*, having a peak sensitivity at about 505 nm. It has been much studied and is found in most animals including man. Absorption of light by rhodopsin probably produces graded potentials at the receptors that trigger all-or-none nerve impulses by the time the ganglion cells are activated, if not before. The exact mechanisms whereby light absorption gives rise to receptor potentials (and these to nerve impulses), although under active investigation, cannot be said yet to be satisfactorily understood.

Color vision depends upon the existence of three classes of visual photopigment, all different from rhodopsin, housed in different proportions in different classes of cone receptors. When two fields of light that are physically different look exactly alike in color (*metameric* matches), it is probable that the rate at which light is being absorbed in the three classes of cone photopigment is the same from both fields, although this is not yet definitely established. The perception of color clearly involves the higher levels of the visual system as well.

Another important property of the eye is its adaptation to intensity by means of which the eye changes its gain and other characteristics, enabling it to respond discriminatively over a stimulus intensity range of about ten billion to one. At one time, it was felt that the bleaching of photopigments was primarily involved in this process; recent evidence indicates that this plays only a minor role and the true mechanisms are numerous and include changes in the organizational properties of retinal networks.

VITREOUS STATE

The vitreous state, or the glassy state, is a special metastable condition in which a substance can exist. A material in the vitreous state may be termed a noncrystalline solid or a rigid liquid. The attainment of the vitreous state is illustrated by the volume-temperature relationship of an ideal system in Fig. 1. When a liquid is cooled slowly, crystallization will usually occur when the temperature reaches the melting point T_m as described by the path a-b. In the case of a complex liquid, crystallization will similarly commence when the temperature reaches the liquidus. Crystallization is generally considered to take place by a two-step mechanism, namely, nucleation and then crystal growth. In the absence of crystallization, a liquid can be supercooled below T_m, and the cooling path is now described by a-c. Since the fluidity of a liquid generally exhibits an exponential dependence on temperature, progressive undercooling along a-c will be accompanied by a rapid increase of viscosity. If crystallization has still not occurred when point d is reached, the viscosity of the liquid will have reached 10^{13} poises. (By comparison, the viscosity of glycerol at room temperature is only 10 poises.) For a particular cooling rate, say 5 deg/min, the cooling curve will now follow d-e. At any temperature below that corresponding to the point d, the material is said to be in the vitreous state. It now has the rigidity of the corresponding crystalline solid, but its structure is still devoid of long-range order similar to that of the parent liquid. A substance in the vitreous state is called a glass.

At the point d, the viscosity of the supercooled liquid is 10^{13} poises. At such high viscosity, molecular motions are retarded since the relaxation times are of the order of minutes and hours. The time taken for experimental measurements may now be actually less than the time needed to attain internal equilibrium. Thus for a particular cooling rate, an inflection will occur at d. For a slower cooling rate, d-e will be displaced to the first dashed line below it. For an even slower cooling rate, the inflection will occur at point f; the cooling curve will now be described by the lowest dashed curve. Similar behavior is shown by the heat content-temperature relationship of the system. The inflection points d and f, and hence the specific volume of a glass at the lower temperatures, are dependent on the cooling rate. The temperature region over which this inflection occurs is termed the glass-transition temperature T_g. Although

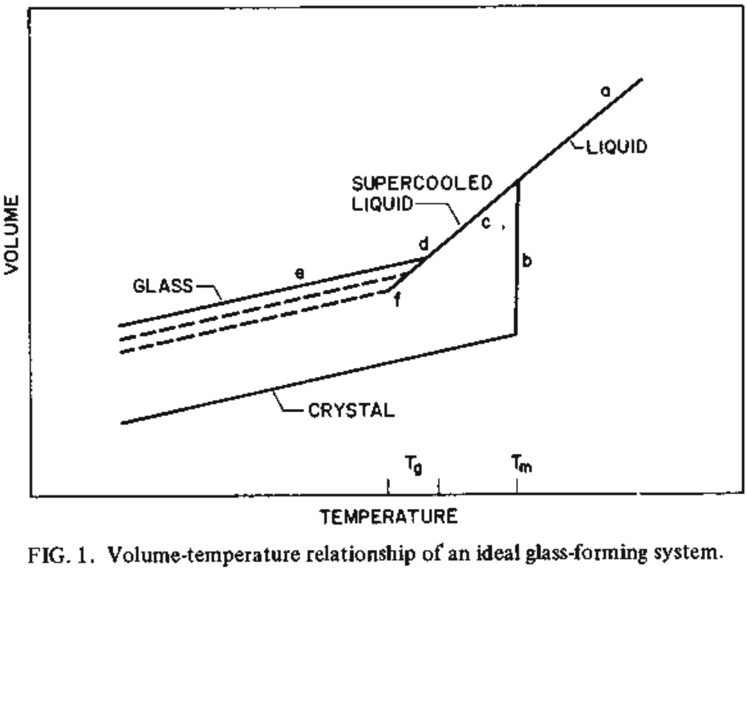

FIG. 1. Volume-temperature relationship of an ideal glass-forming system.

the supercooled liquid at above T_g is metastable with respect to the crystalline phase, it is in internal thermodynamic equilibrium. A glass, however, is generally considered not to be in internal thermodynamic equilibrium.[1]

Many substances are easily rendered into the vitreous state by supercooling the melt. These include organic liquids such as toluene and the alcohols, polymeric materials, fused salts such as $Ca(NO_3)_2$-KNO_3, ZrF_4-BaF_2, and many silicates, borates, phosphates, and their mixtures.[2] In general the ease of glass formation via the liquid is dependent on the crystallization kinetic constants as well as the cooling rate. Although the crystallization kinetic constants of metallic systems, for instance, are not favorable for glass formation, the vitreous state is attainable by very rapid cooling. Many metallic glasses are now known. The condensation of vapor at low temperatures can also yield noncrystalline solid phases and so can precipitation from solutions. Little is known about the relationship between such phases and the more common glassy phase obtained from the cooling of the melt. Present theoretical interests are centered on the nature of the glass transition at T_g. Two important questions are: (a) Is the glass-transition region an iso-free volume state for all substances? (b) Is there a theoretical lower temperature limit to T_g? No unambiguous answers to these questions are at present available.

VOLCANOLOGY

Volcanology is the science of volcanoes. Volcanologists, however, are generally geologists, geophysicists, or geochemists who specialize in studying volcanoes. With their roots in the Earth's mantle, volcanoes often explode their products into the stratosphere. This diversity of pheonomena requires the combined studies of many disciplines, physics being one of the more important with regard to the structure and processes of volcanoes.

Volcanic Activity An active volcano is defined as one that has a historic record of eruption, i.e., emission of lava flows or solid volcanic fragments. There are 529 active volcanoes known on Earth, and about 50 of these erupt during any one year. An active volcano can be either dormant or erupting. A volcano with no historic record of eruption may be considered potentially active if its record of prehistoric eruptions in geologically recent time implies that it has a moderate to high probability of future eruptions. An extinct volcano is one with very low probability of future eruptions. Life spans of volcanoes vary from 1 to 10,000,000 years and dormant periods from days to millions of years; thus it is difficult to distinguish potentially active from extinct volcanoes.

Types of Volcanoes Volcanoes have been classified by location, topographic form, general character of their eruptions, rock type, and tectonic setting. Most active volcanoes occur around the rim of the Pacific Ocean Basin. These often erupt explosively and build steep conical peaks known as *strato-volcanoes*, which are mixtures of lava and explosive debris (pyroclastic fragments). Hawaiian volcanoes, in contrast, are built mainly by lava flows poured out in gently sloping forms called *shield volcanoes*. Pacific rim volcanoes have rock types ranging from basalts (~50% SiO_2) through andesites (~55–60% SiO_2) and dacites (~60–65% SiO_2) to rhyolites (~65–75% SiO_2), whereas Hawaiian volcanoes are mainly basalts. As SiO_2 content increases, Fe and Mg generally decrease, and Na and K increase. The amount of dissolved gases in a magma (subsurface molten rock) and the viscosity of magma generally increase with SiO_2 content, and these both increase the potential for explosive eruptions.

Rift volcanoes occur along the separating edges of diverging tectonic plates. (See Fig. 1.) Iceland and the Mid-Atlantic Ridge are of rift volcanic origin. The products are generally basaltic lavas and most are nonexplosive submarine eruptions in water depths too great to allow explosive boiling of the dissolved magmatic gases or the contact water. The bedrock of the world's ocean basins, 70% of the Earth's area, is formed by the progressive rift volcanism which heals the spreading gap between the separating plates.

Subduction volcanoes occur on the overriding edges of converging plates, about 100–200 km from the oceanic trenches which mark the actual plate boundaries. (See Fig. 2.) These volcanoes form important components of island arcs like Japan and coastal mountain chains like the Andes. The rock name *andesite* comes from its common occurrence in the Andes Mountains. Subduction volcanoes, which comprise about 80% of the world's known volcanoes, typically erupt explosively and produce a variety of rock types. Thick viscous lava flows do occur, but most of their products are exploded pyroclastic fragments which range from fine volcanic ash to large blocks of pumice (rapidly cooled frothy volcanic glass).

The eruptions of Mount St. Helens (MSH) in

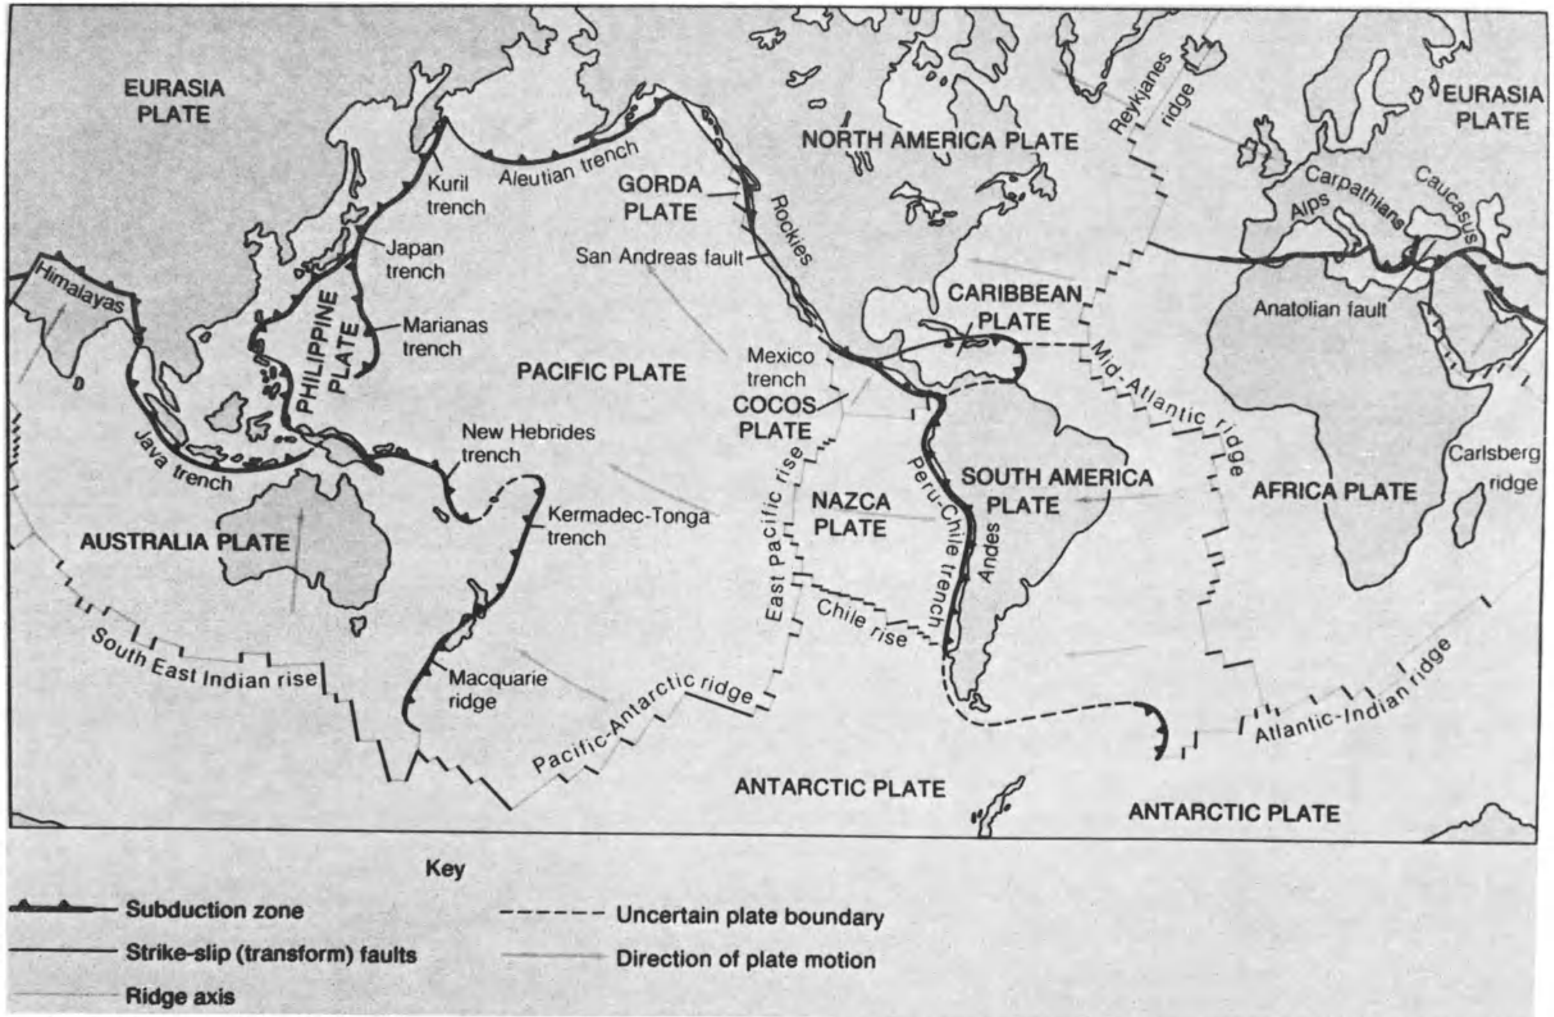

FIG. 1. Rigid plates of the Earth's surface are slowly moving horizontally away trom and toward one another. The arrows shown assume that the Africa plate is not moving. Plates separate along the crests of mid-ocean ridges, slide past each other along strike-slip faults, and converge at subduction zones. (After J. F. Dewey, "Plate Tectonics," copyright © 1972 by Scientific American, Inc. All rights reserved.)

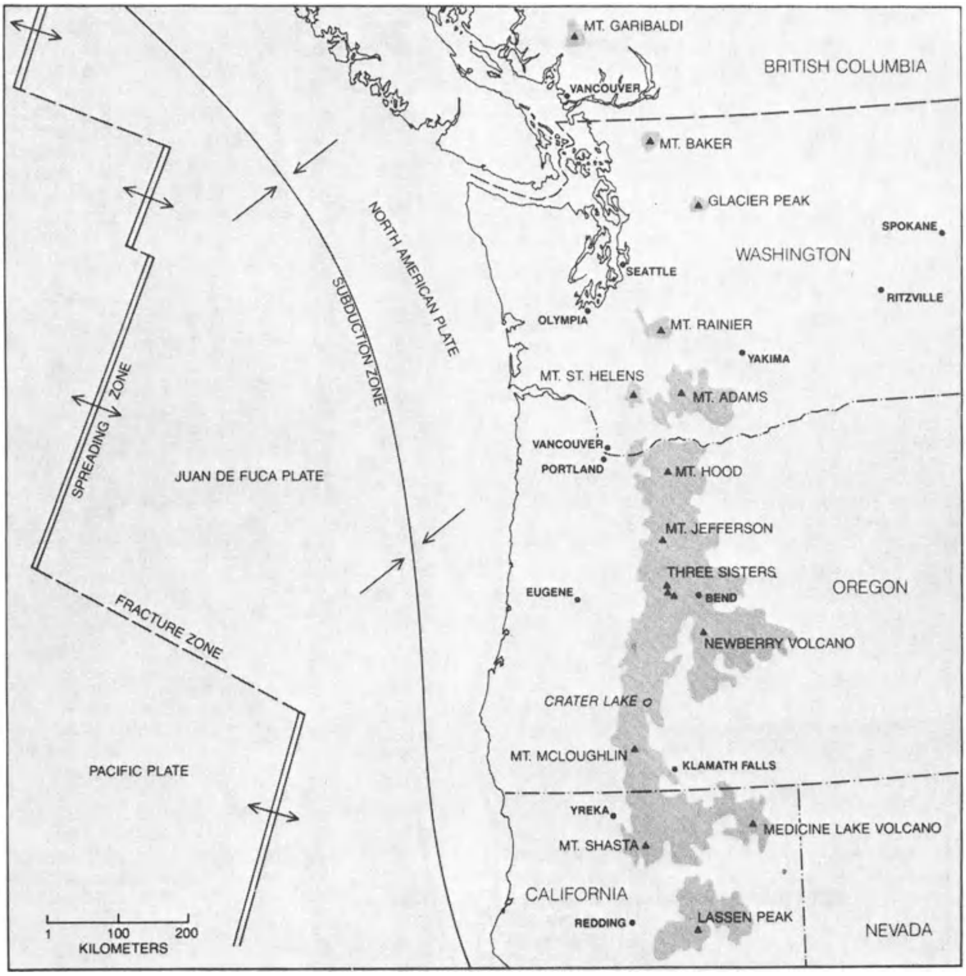

FIG. 2. Tectonic map shows the relation between the North American tectonic plate and the Juan de Fuca and Pacific plates to the west. At the subduction zone the Juan de Fuca plate is plunging under the North American plate, giving rise to the volcanoes of the Cascade Range (small black triangles). Shaded areas are volcanic deposits less than two million years old. (Data from U.S. Geological Survey. Copyright © 1981 by Scientific American, Inc. All rights reserved.)

northwestern United States provide a good case study of explosive volcanism. (See Figs. 3–7.) MSH was dormant from 1857 until March 20, 1980, when a magnitude 4 earthquake at shallow depth beneath MSH heralded the start of a major earthquake swarm that continued for 60 days. The eruption began on March 27 with a small steam explosion and formation of a crater in the ice-covered summit. These small explosions continued intermittently during April and early May, dusting the snow-clad peak with old rock particles but no new volcanic fragments. During this period of earthquakes and small explosions, a major topographic bulge was forming high on the mountain's north flank. Repeated aerial photographs and direct measurements showed that an area about 1.5 by 2 km was moving outward at about 2 m per day. The volume increase of the bulge was close to 1,800,000 m^3 per day, and the bulge and shallow earthquakes were interpreted as being caused by the shallow injection of magma beneath MSH. On May 18 at 8:32 AM local time a magnitude 5.1 earthquake triggered a 2.3 km^3 avalanche of the over-steepened bulge. This suddenly released the pressure on the shallow magma intrusion and surrounding heated groundwater, and generated a massive explosion that was directed northward by the collapse of the north flank of the cone. This lateral blast was a fluidized mixture of hot expanding gases, mostly steam with some car-

bon dioxide (CO_2) and sulfur dioxide (SO_2), and fragmental debris from the old volcanic edifice as well as hot fragments of the newly intruded magma. The ratio of solids to gases in the mixture was high enough that much of the hot expanding blast cloud surged along the ground surface. The blast cloud had temperatures from 100 to 300°C; traveling at velocities from 100 to 325 m/sec it devastated 550 km^2 of forested mountain terrain. The mechanical energy of the blast was derived from explosive boiling, and was estimated at 3×10^{16} joules. The huge avalanche that preceded and accompanied the blast was probably partly fluidized by expanding pore gases, and accelerated rapidly to velocities as high as 80 m/sec. Some lobes swept into Spirit Lake and over a ridge 360 m high, but the bulk of the debris funneled down a valley, forming a hummocky deposit 22 km long, 1–2 km wide, and up to 195 m deep. The gravitational energy of the avalanche was about 5×10^{16} joules.

Following the initial avalanche and lateral blast, which lasted only a few minutes, the eruption produced a vertical jetting eruption lasting about 9 hours that generated a high ash cloud of volcanic gases (mostly steam), fractured silicate crystals and fine volcanic glass shards. Fallout from this ash cloud caused major nuisance, but little long-term damage, along a downwind path across central and eastern Washington, northern Idaho, and western Montana. The high jetting eruption from the boiling of the gases in the newly exposed magma caused progressively deeper coring of the crater until temporary exhaustion of the heat energy and slumping of the crater walls finally terminated the eruption. During this period of jetting eruptions, intermittent pyroclasic flows of fluidized mixtures of hot but solid volcanic rock fragments and gases spilled from the crater and down the north slopes of MSH onto the earlier avalanche and lateral blast deposits.

Mud flows, mixtures of water and the newly erupted volcanic and avalanche debris, flooded valleys well beyond the limits of the area devastated by the avalanche and lateral blast, and added greatly to the overall destruction. The count of dead and missing persons was 60, but it could have been 100 times worse if the

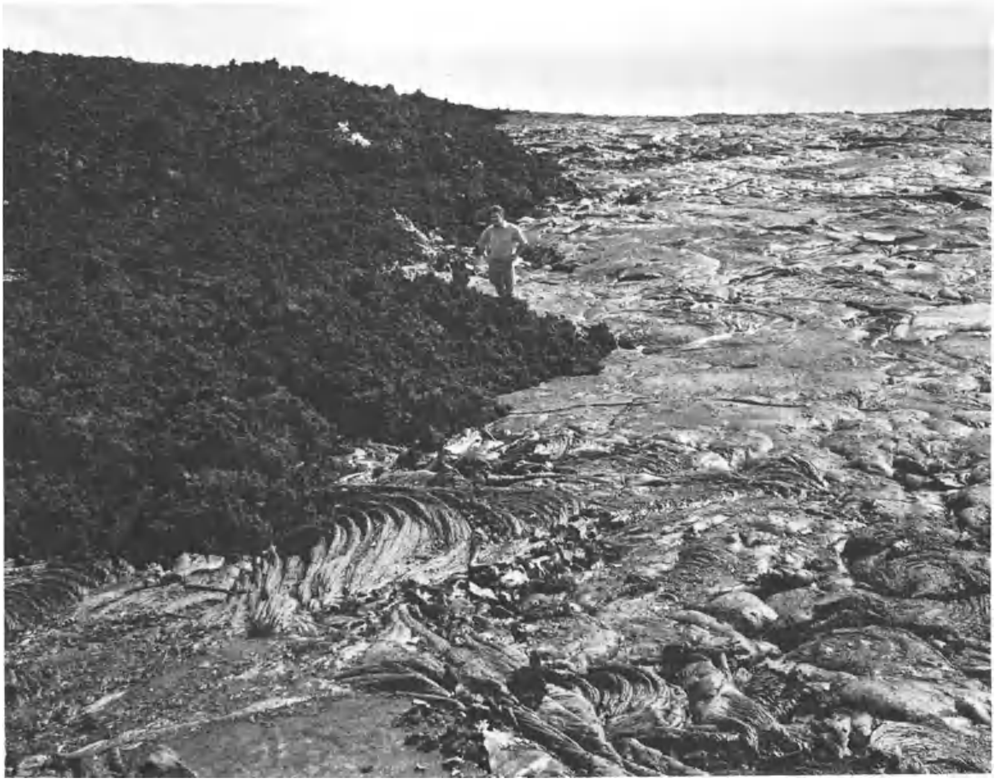

FIG. 5. Lava flows of aa (left) and pahoehoe both issued from Kilauea Volcano in Hawaii in 1974. The dark, rough aa is ~3–4 meters thick; it was covering the smoother, glistening pahoehoe when the flow stopped. (Photograph by Barbara Decker.)

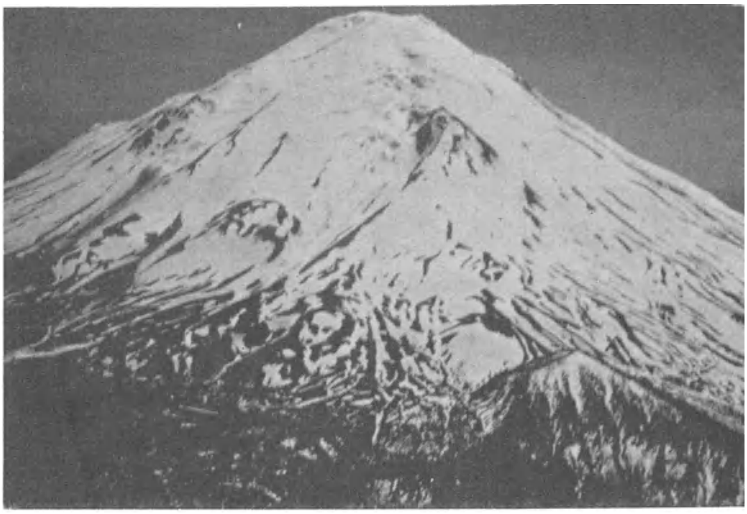

FIG. 6. Mount St. Helens in June, 1970. The elevation of the summit, seen here from the north-northeast, was 2950 meters, rising from a base with an elevation of about 1000 meters. (Photograph by Robert Decker.)

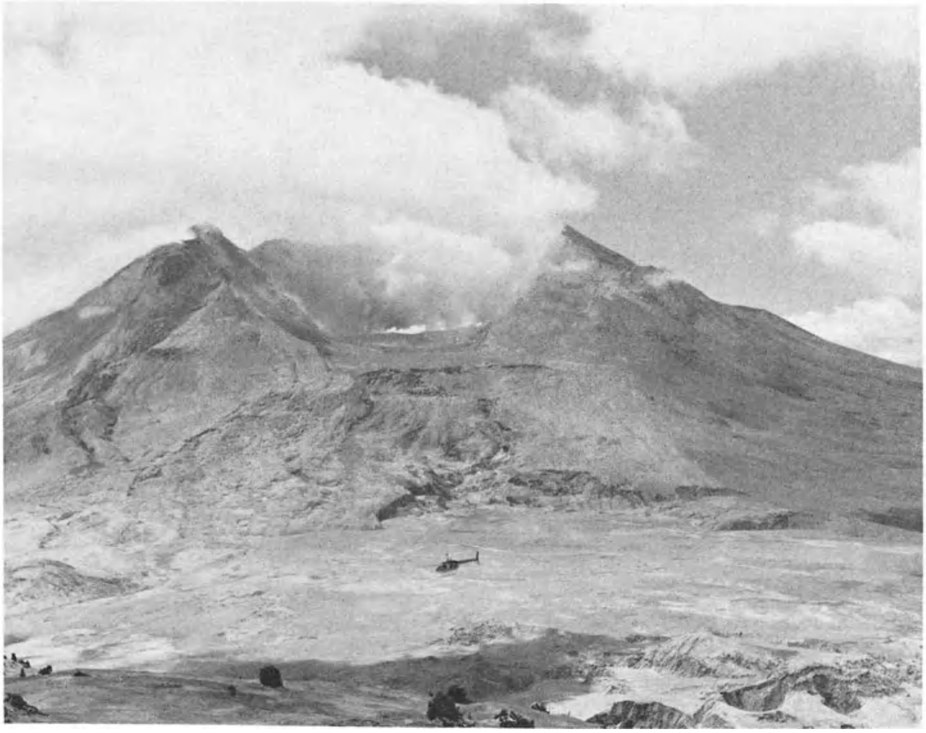

FIG. 7. Mount St. Helens in July, 1980. The crater, seen here from the north, is 2 kilometers across. The elevation of the rim of the crater is between 2400 and 2550 meters, that of the floor of the crater between 1800 and 1900 meters. Pyroclastic flows cover much of the foreground. (Photograph by Ray Foster, Sandia Laboratories.)

general area north of the volcano had not been under restricted access. The total energy of the eruptions was largely contained in the thermal energy of the new magma involved (about 0.4 km^3 at 900–1000°C) and is estimated to be 1.7×10^{18} joules. Fortunately, it is typical of volcanic explosions that only a small fraction of thermal energy is converted to mechanical energy. Eruptions on the scale of the May 18, 1980, event at MSH occur somewhere in the world about every 20 years. Several much smaller eruptions at MSH involving ash explosions, pyroclastic flows, and extrusions of a viscous lava dome in the new crater have occurred since the major explosion.

Hot-spot volcanoes occurring within tectonic plates comprise only 5% of the world's active volcanoes. They are considered to be caused by some sort of melting anomalies in the Earth's upper mantle. The magma formed at hot spots is less dense than the overlying rocks, and forces and melts its way to the surface through the overlying lithospheric plate. As the plate slowly moves over the hot spot, a chain of volcanoes is formed that becomes progressively older in the direction of plate motion. The Island of Hawaii with its active volcanoes Mauna Loa and Kilauea lies over a hot spot, and the other Hawaiian Islands which once formed over the same hot spot have moved away to the northwest. The Island of Kauai which has volcanic rocks about 5 million years old is 500 km northwest of the Island of Hawaii, giving an average plate velocity of 10 cm/year. Yellowstone National Park is another volcanic area that is apparently caused by a mantle hot spot. Hot-spot volcanoes in oceanic settings generally produce basaltic lava flows, but in continental settings hot-spot volcanoes produce varied rock types from basalts to rhyolites, and are often explosive. A major explosive eruption in the Yellowstone region about 600,000 years ago expelled 1000 km^3 of pyroclastic flows. This eruption was 2000 to 3000 times larger than the 1980 eruption of Mount St. Helens.

Volcanic products are classified by their chemistry, mineralogy, texture, and structure, or some combination of these characteristics. A basic goal in studying prehistoric volcanic products is to identify their origin as lava flows, air-fall deposits, pyroclastic flows, or mud flows. Air-fall deposits generally are well sorted and layered, whereas pyroclastic flows and mudflows are more poorly sorted and massive in appear-

TABLE 1. FORM OF VOLCANIC PRODUCTS.

Form	Name	Characteristics (dimensions)
Gas	Fume	
Liquid	Lavas	
	Aa	rough, blocky surface
	Pahoehoe	smooth to ropy surface
Solid	Airfall fragments	
	dust	$<\frac{1}{16}$ mm
	ash	$\frac{1}{16}$–2 mm
	cinders	2–64 mm
	blocks	>64 mm solid
	bombs	>64 mm plastic
	Pyroclastic flows	hot fluidized flows
	Mudflows	flows fluidized by rainfall, melting ice and snow, or ejected crater lakes

ance, like concrete. Table 1 shows the forms of some volcanic products and their textural and structural characteristics.

Volcanic landforms are quite variable. Stratovolcanoes and shield volcanoes have already been mentioned. Either of these volcanoes may have massive collapse basins on their summits, called *calderas*, which are larger than craters formed by volcanic vents. *Cinder cones* are angle-of-repose piles of loose volcanic fragments around vents, and *volcanic plateaus* are thick or multiple layers of low-viscosity pyroclastic flows or lava flows. Lava domes formed from high-viscosity magma build large steep-sided masses directly over their vents. Some volcanic vents are long lived and build complex volcanoes composed of several volcanic forms.

Roots of Volcanoes The deep structure and dynamics of volcanoes are of fundamental importance to the understanding of volcanic processes, but most data on these topics are indirect. Melting temperatures of rock in the 1200°C range occur at depths of 50 to 100 km beneath the Earth's surface. The source of heat is from radionuclides such as U^{238}, thorium^{232}, and potassium^{40}, or from other sources such as viscous dissipation from shear stresses in the Earth's mantle. Upward mass transfer of plastic material in the mantle could also cause melting from pressure reduction. Once enough molten rock has formed at depth it makes its way upward from bouyant forces by diapiric penetration or through fractures toward the surface. In volcanoes like Kilauea in Hawaii there is good evidence that magma accumulates in shallow reservoirs 2–6 km beneath the surface. Continuing accumulation in this shallow magma reservoir uplifts the ground surface and eventually causes fracturing upward or horizontally outward from the chamber. If the injection of magma into newly formed fractures reaches the surface, there is an eruption. Sometimes, particularly in lateral injections into the volcano's flanks, the magma stays beneath the surface and causes growth of the volcano by widening and uplift rather than by surface eruption. These shallow injections of magma are accompanied by earthquake swarms caused by progressive rock failure along the crack tip, and by rapidly changing stress gradients adjacent to the magma-filled fracture (*dike*). Geophysical monitoring of the local seismicity and ground-surface deformation on active volcanoes is a topic of active research, and much is being learned about the dynamics of magma movement beneath volcanoes.

Origin of Atmosphere and Hydrosphere The eruptions of volcanoes on Earth over geologic time have contributed significantly to the formation of the Earth's hydrosphere and atmosphere. The common gases from volcanoes contain oxygen, hydrogen, nitrogen, chlorine, and sulfur. Except for sulfur, their emissions from current volcanism can account for much of Earth's water and air if integrated over geologic time. Sulfur appears to be fifty times more abundant in volcanic gases than needed in this accounting. Probably it is recycled back to the mantle by precipitation as FeS_2 (pyrites) and subducted in oceanic trench sediments.

Geothermal Power and Mineral Deposits The heat energy contained in the upper 10 km of rock beneath the United States is estimated to be 3.3×10^{25} joules; however, in only a few places can drill holes into steam or hot water reservoirs make power extraction economically possible. Nearly all of these places are areas of geologically recent volcanism where the shallow emplacement of magma into or near subsurface water reservoirs has occurred. Normal heat flux from the Earth's interior is 0.06 watts per m^2 of the surface. In contrast, some geothermal steam wells can produce 6 megawatts of thermal power, equal to the normal heat flux from 100 km^2 of land surface. The key to this difference is the mass transfer of heat from deeper levels to near surface by volcanism, conductive and convective heat transfer from shallow magma bodies into subsurface water reservoirs, and finally mass transfer of heat by hot water or steam from drill holes. At The Geyers geothermal field north of San Francisco, superheated steam is directly tapped from porous underground reservoirs; but in most geothermal fields, water at or near its subsurface boiling temperature—about 300°C at 1 km depth—is allowed to flash into a steam and water mixture at reduced pressures in the bore hole. This two-phase fluid is separated at the well head, and the steam phase is used to drive a turbine. Exploration and development of geothermal-power fields is a young but rapidly expanding industry.

Many mineral deposits, including gold and silver, have been precipitated by the natural circulation of hot subsurface-water systems during geologic history. In most cases, shallow emplacements of magma provided the heat source for these natural distilleries, and in some cases, the valuable elements were themselves expelled from cooling magma as the more common rock-forming minerals crystallized and concentrated the excluded elements. In terms of geologic time, yesterday's geothermal fields are some of today's mineral deposits.

Other Research Topics There is some evidence that stratospheric aerosols, particularly sulfuric acid droplets, from violent volcanic explosions can lower the Earth's average surface temperature. Joint efforts by meteorologists and volcanologists are currently seeking to understand this effect. Forecasting volcanic eruptions is also a topic of active research. Local seismicity, ground-surface deformation, gas emissions, and electrical and magnetic fields often show anomalous behavior preceding eruptions at time scales of months to minutes. Finally, it is becoming evident that volcanism is a pervasive planetary process. Ancient volcanism on the moon, Mars, Mercury, and Venus, and active sulfur volcanism on Io, indicate that volcanic phenomena are not unique to our Earth.

WAVE MECHANICS

Introduction It has been known since the early part of the present century that systems of atomic dimensions do not obey the laws of classical mechanics, as formulated by Newton. A new mechanics has had to be constructed, and this is called *quantum mechanics*.

There were initially two apparently different formulations of quantum mechanics, one called MATRIX MECHANICS and the other *wave mechanics*. It was ultimately shown that the two formulations are completely equivalent and complicated quantum mechanical problems are nowadays usually solved by a combination of both. However, there are still many applications of quantum mechanics which can be treated by purely wave mechanical methods, and as these generally make a more direct appeal to physical intuition, it is perhaps worth while to give an account of wave mechanics quite separate from matrix mechanics.*

Waves and Particles The work of Planck, in 1900, on thermal radiation, and of Einstein, in 1905, on the photoelectric effect, suggested that light must, for some purposes, be regarded as consisting of particles, called *light quanta* or *photons*. The energy of a photon is given by

$$E = h\nu \qquad (1)$$

and its momentum by

$$p = h/\lambda \qquad (2)$$

where ν is the frequency and λ the wavelength of the light, and h is Planck's constant, which has the value 6.624×10^{-27} erg sec. On the other hand, diffraction phenomena, for example, can only be explained on the assumption that light consists of waves, so that neither the corpuscular nor the wave theory is completely satisfactory. In fact, it must simply be accepted that light can behave *either* as particles *or* as waves. The nature of a given experiment will emphasize one aspect or the other, and the relations between the two aspects are given by Eq. (1) and (2).

In 1924, de Broglie went further and suggested that *any* moving particle, with mass m and speed v, will in some experiments display wave-like properties, the wavelength being given by Eq. (2), with $p = mv$. This purely theoretical suggestion received experimental confirmation in 1927, when Davisson and Germer observed the diffraction of a beam of electrons by a crystal of nickel, and similar results have since been obtained with beams of other kinds of particles, including atoms and molecules.

De Broglie's theory was the beginning of wave mechanics, but its further development was due to Schrödinger, who showed, in 1926, how the theory could be used to account for the existence of stationary states of atoms.

In 1911, Rutherford had proposed that an atom consists of a small nucleus surrounded by a planetary system of electrons. The electrons are continually accelerated; hence, according to classical electromagnetic theory, there should be a continual emission of radiation, accompanied by a diminution in the size of the electronic orbits and consequent increase in frequency. The existence of line spectra, that is, the emission of radiation in a discrete series of frequencies, and indeed the stability of matter itself, proves that this is not the case, and in 1913 Bohr suggested that an atom can exist in any one of a set of so-called *stationary states*, each with a definite energy, and with a finite energy difference between one and the next. Radiation is emitted only when an atom passes from a stationary state with energy E_1 to a state of lower energy E_2, and the frequency ν of the radiation is given by

$$h\nu = E_1 - E_2 \qquad (3)$$

Bohr attempted to graft this idea on to the classical picture of electrons describing planetary orbits about the nucleus by postulating that only certain orbits were permissible. This theory successfully explained the line spectrum of hydrogen and had several other partial successes, but it was soon superseded by the more revolutionary but also more versatile quantum mechanics.

The Schrödinger Equation According to de Broglie's theory a freely moving particle should be represented by a wave of the form

$$\Psi(x,t) = A \exp\left[2\pi i\left(\frac{x}{\lambda} - \nu t\right)\right]$$

*According to Dirac (1964), the validity of wave mechanics does not extend to quantum field theory, but it remains perfectly adequate in the domain of atomic and molecular physics.

where A is a constant. Using Eq. (1) and (2), this becomes

$$\Psi(x,t) = A \exp\,[i(px - Et)/\hbar]$$
$$= \psi(x) \exp(-iEt/\hbar) \qquad (4)$$

where $\hbar = h/2\pi$ and

$$\psi(x) = A \exp(ipx/\hbar) \qquad (5)$$

is the time-independent part of the wave (we shall deal with the time-dependent factor later).

Differentiation shows that

$$\frac{d^2\psi}{dx^2} = -\frac{p^2}{\hbar^2}\psi \qquad (6)$$

However, the energy of the particle is

$$E = \frac{p^2}{2m} + V$$

the first term on the right-hand side being the kinetic energy and the second term the potential energy, which is constant if the particle is moving under no forces. Equation (6) thus becomes

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2}(E - V)\psi = 0 \qquad (7)$$

Although this equation has been plausibly derived only for a free particle, Schrödinger assumed that it also applies to a particle moving under a force, so that the potential energy V is a function of x. It is known as the *Schrödinger equation* or the *wave equation* for a particle moving in one dimension, and the function $\psi(x)$ is called the *wave function*. We will consider the interpretation of ψ below, but meanwhile let us note that ψ is to be *single-valued*, *continuous*, *smooth* [except at infinities of $V(x)$] and *finite everywhere*. Also, although $\psi = 0$ is always a solution of Eq. (7), it is not permitted as a wave function.

Particle in a One-dimensional Box That the Schrödinger equation does lead to discrete energy values, at least when classical mechanics would predict a limited range of motion or a *bound* particle, can easily be seen by considering a particle moving in one dimension between infinite potential barriers–this is known as a one-dimensional box.

Suppose that the potential energy is zero from $x = 0$ to $x = L$, and infinite everywhere else. In the region of zero potential energy, Eq. (7) becomes

$$\frac{d^2\psi}{dx^2} + \frac{2mE}{\hbar^2}\psi = 0 \qquad (8)$$

with the general solution

$$\psi = A \cos\sqrt{\frac{2mE}{\hbar^2}}\,x + B \sin\sqrt{\frac{2mE}{\hbar^2}}\,x \qquad (9)$$

The condition of finiteness on ψ (which we will not consider in detail) demands that it vanish in the region of infinite potential energy and because of the condition of continuity, we must then have $\psi(0) = \psi(L) = 0$. The only solutions in the region of zero potential energy satisfying these boundary conditions are of the form

$$\psi_n = B_n \sin\frac{n\pi x}{L}, \qquad n = 1, 2, 3, \cdots \qquad (10)$$

corresponding to the energy values E_n given by

$$\sqrt{\frac{2mE_n}{\hbar^2}} = \frac{n\pi}{L}$$

or

$$E_n = \frac{n^2\pi^2\hbar^2}{2mL^2} \qquad (11)$$

($n = 0$ gives $\psi \equiv 0$, which is not allowed).

The energy E can thus have any one of an infinite set of discrete values, corresponding to the integral values of n, but no other value. These values are called the *eigenvalues* of the Schrödinger equation or *energy levels* of the system, and the corresponding wave functions are called the *eigenfunctions* of the equation and represent the stationary states of the system.

Operators The Hamiltonian $H(x,p)$ of the one-dimensional system we have been considering is simply the energy expressed in terms of the momentum p and coordinate x, and the *equation of energy* is

$$H(x,p) \equiv \frac{p^2}{2m} + V(x) = E \qquad (12)$$

If we formally convert this into an *operator* equation by letting

$$p = \frac{\hbar}{i}\frac{d}{dx} \qquad (13)$$

(the coordinate x becomes the operator "multiply by x", but this is trivial), and allow both sides to operate on a function $\psi(x)$, we obtain

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} + V\psi = E\psi \qquad (14)$$

which, when rearranged, is seen to be the Schrödinger equation [Eq. (7)].

The representation of dynamical variables by operators is fundamental to quantum mechanics, but the choice of operators made above is not unique. It may be confirmed by differentiation that

$$\frac{\hbar}{i}\frac{d}{dx}(x\psi) - x\frac{\hbar}{i}\frac{d\psi}{dx} = \frac{\hbar}{i}\psi$$

and using Eq. (13), this gives the operator equation

$$px - xp = \frac{\hbar}{i} \qquad (15)$$

The operator on the left is called the *commutator* of p and x, and is generally written $[p, x]$. Equation (15) is the basic equation of matrix mechanics and existed before Schrödinger's equation, p and x then being represented by MATRICES. This shows in an elementary way the close connection between wave mechanics and matrix mechanics.

Particles in Three Dimensions Equation (13) gives the clue to the extension of Schrödinger's equation to systems of one or more particles moving in three dimensions. We first write down the Hamiltonian of the system and transform each Cartesian component of momentum into a differential operator like Eq. (13) with respect to its corresponding (canonically conjugate) coordinate. For example, for a single particle moving in three dimensions, the Hamiltonian is

$$H(x, y, z, p_x, p_y, p_z) = \frac{1}{2m}(p_x{}^2 + p_y{}^2 + p_z{}^2) + V(x, y, z)$$

where p_x, p_y, p_z are the Cartesian components of the momentum, and the equation of energy is

$$H(x, y, z, p_x, p_y, P_z) = E \qquad (16)$$

If we transform the latter into an operator equation by writing

$$p_x = \frac{\hbar}{i}\frac{\partial}{\partial x}, \quad p_y = \frac{\hbar}{i}\frac{\partial}{\partial y}, \quad p_z = \frac{\hbar}{i}\frac{\partial}{\partial z} \qquad (17)$$

(partial derivatives are now required as several variables are present), and operate upon a function $\psi(x, y, z)$, we obtain the equation

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2}\right) + V(x, y, z)\psi = E\psi \quad (18)$$

which is the Schrödinger equation of the system. The essential correctness of this equation has been amply demonstrated by many successful applications (this is, of course, the *only* justification of any of the postulates of quantum mechanics). In particular, in the case of the hydrogen atom, where there is a single electron moving under the Coulomb attraction of a single proton (which may as a good approximation be considered to be at rest), the equation can be solved analytically, and the energy levels so found, together with the Bohr frequency rule [Eq. (3)], correctly give the line spectrum of hydrogen.

The extension to many particles is straightforward; in the Hamiltonian of the system, the substitutions of Eq. (17) are made for the momentum components of each particle of the system, and the equation of energy is thus transformed into the Schrödinger equation. Again the equation has had many successful applications, an early one being the calculation of the energy of the normal helium atom by Hylleraas in 1930, which the earlier Bohr theory failed to do. Unfortunately, owing to the interaction of the electrons, the equation cannot be solved analytically for many-electron systems and resort must be made to approximate methods of solution which have become extremely complicated in recent years [see e.g., Raimes (1972)].

Interpretation of the Wave Function Let us consider the Schrödinger equation for a single particle moving in three dimensions. This is a linear equation, so that if ψ is a solution, so also is $C\psi$, where C is any constant. This means that (in most cases) we can choose ψ so that

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} |\psi(x, y, z)|^2 dx\, dy\, dz = 1 \qquad (19)$$

The function ψ is generally complex and $|\psi|$ is its *modulus* ($|\psi|^2 = \psi^*\psi$, where ψ^* is the complex conjugate of ψ). If it satisfies Eq. (19), the function ψ is said to be *normalized*.

The interpretation of ψ demands that it be normalized. If this is not possible, owing to the divergence of the integral in Eq. (19), as is the case with a free particle, then normalization has to be affected artificially by enclosing the system in a large box.

It was proposed by Born, in 1926, that if the particle is in a stationary state, with normalized wave function ψ, then $|\psi|^2$ may be interpreted as a *probability density*, such that

$$|\psi(x, y, z)|^2\, dx\, dy\, dz$$

is the *probability* of finding the particle in the small volume element $dx\, dy\, dz$ at the point (x, y, z).

It is clear from this why normalization is necessary—Eq. (19) expresses the fact that the probability of finding the particle *somewhere* is unity.

An important extension of this interpretation, which we will not justify in detail, relates to the *average* or *expectation value* $\langle f\rangle$ of a dynamical variable f (such as momentum) for a system in a state ψ, i.e., the average of a large number of measurements of f made on a system in this state. It is found that

$$\langle f\rangle = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \psi^* f_{\text{op}}\psi\, dx\, dy\, dz \qquad (20)$$

where f_{op} is the quantum mechanical operator representing f. Here we have restricted ourselves to a single-particle system, but the same applies to systems of any number of particles, so long as the integral is a multiple integral taken throughout the full range of all the variables appearing in ψ.

The interpretation of ψ, or rather of $|\psi|^2$ (ψ itself has no physical significance), which we have presented above, gives rise to a fundamental and important difference between classical mechanics and quantum mechanics. According to the latter, there is a finite probability of finding a particle in regions of space where its presence would be forbidden by classical mechanics—regions where its kinetic energy would be negative.

Let us take as an example the linear harmonic oscillator. Suppose a particle of mass m is moving along the x axis under the action of a force $-kx$ (k is positive) directed towards the origin. Classically, the particle executes simple harmonic motion with frequency $\omega/2\pi$, where $\omega = \sqrt{k/m}$. It is easy to see that the potential energy is $V(x) = \frac{1}{2}m\omega^2x^2$, if the zero of potential energy is taken to be at $x = 0$, so that the Schrödinger equation [Eq. (7)] becomes

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2}\left(E - \frac{1}{2}m\omega^2x^2\right)\psi = 0 \qquad (21)$$

It may be verified by substitution that the function

$$\psi_0 = \exp\,(-\,m\omega x^2/2\hbar) \qquad (22)$$

satisfies this equation, provided E has the value

$$E_0 = \tfrac{1}{2}\hbar\omega \qquad (23)$$

This is, in fact, the *ground state* of the oscillator, that is to say, E_0 is the lowest energy level.

Now according to classical mechanics, the particle, having energy E_0, would be confined to a region of the x axis whose limits are given by setting $V(x) = E_0$, that is, $x = \pm\sqrt{\hbar/m\omega}$. However, ψ_0 tends to zero asymptotically as x tends to $\pm\infty$, so that, according to the interpretation of $|\psi|^2$, there is a finite probability of finding the particle at very large distances from the origin. This is known as the *tunnel effect* and has an important application in the theory of radioactive decay.

The foregoing example demonstrates another point in which quantum mechanics differs from classical mechanics. According to the latter, the oscillator could have zero energy (when the particle is at rest at the origin), but this is not permitted in quantum mechanics—the *lowest* energy the oscillator can have is $\frac{1}{2}\hbar\omega$, which is called its *zero-point energy*.

Time-Dependence So far we have only considered the stationary states of a system and, furthermore, only of a *conservative* system, i.e., one whose energy is constant. However, if a system is subject to a disturbance which varies with time, for example, due to the passage of a charged particle or a light wave through it, there is a probability that the system will in a certain time make a transition from its initial stationary state to some other stationary state. In order to calculate such *transition probabilities*, it is necessary to consider explicitly the time dependence of wave functions, which we have so far neglected, and this entails the use of a modified Schrödinger equation.

Differentiation of the function $\Psi(x, t)$, Eq. (4) gives

$$E\Psi = i\hbar\,\frac{\partial\Psi}{\partial t} \qquad (24)$$

which suggests that the energy E should in general be represented by the operator

$$E = i\hbar\,\frac{\partial}{\partial t} \qquad (25)$$

If we convert the equation of energy [Eq. (12)] for a one-dimensional system into an operator, using Eqs. (13) and (25), and if we allow both sides to operate upon a function $\Psi(x, t)$, we obtain

$$-\frac{\hbar^2}{2m}\frac{\partial^2\Psi}{\partial x^2} + V\Psi = i\hbar\,\frac{\partial\Psi}{\partial t} \qquad (26)$$

[the derivative in Eq. (13) has been replaced by a partial derivative as we now have two variables, x and t]. This is known as the *time-dependent Schrödinger equation*; it applies even when the potential energy function V depends explicitly upon the time. If more than one dimension or several particles are involved, it is only necessary to use the appropriate quantum mechanical Hamiltonian operator on the left-hand side. It should be emphasized that this equation has *not* been rigorously derived, but only plausibly suggested. No such derivation exists, either for Eq. (26) or for Eq. (7)—their justification lies entirely in their successful application.

If we are, in fact, dealing with a conservative system, so that V does not depend explicitly upon t, it is easy to verify by substitution (and indeed this is obvious from the way in which the equation was derived) that Eq. (26) has solutions of the form

$$\Psi(x, t) = \psi(x)\exp\,(-\,iEt/\hbar) \qquad (27)$$

where $\psi(x)$ is an eigenfunction of Eq. (7) and E is its corresponding eigenvalue. The function $\psi(x)$ is the time-independent wave function of a stationary state, and $\Psi(x, t)$ is the time-dependent wave function. Since it is not ψ but $|\psi|^2$ which has physical significance, and Eq. (27) shows that $|\Psi|^2 = |\psi|^2$, it is clear that so long as we are dealing with the stationary states of a conservative system, the time dependence of the wave function is of no importance.

Conclusion The foregoing account has been confined to the elementary ideas of wave mechanics, due to de Broglie and Schrödinger. No mention has been made, for example, of the relativistic wave equation, due to Dirac, or of the important concept of electron spin. Further information on wave mechanics, its applications, and its relationship with the rest of quantum mechanics can be obtained from the article on MATRIX MECHANICS in this book and from a vast number of books of which those listed in the references are a very small sample.

WAVE MOTION

Wave motion can be said to be the most common and the most important type of motion that we know. It is through wave motion that sounds come to our ears, light to our eyes, electromagnetic waves to our radios and television sets, and tidal waves and earthquakes to our cities. Wave motion can be defined as that mechanism by which energy is transported from a source to a distant receiver without the transfer of matter between the two points.

Waves can be classified according to the manner of their production, namely, a vibrating material object or, in the case of electromagnetic waves, sources such as electrical oscillations in an aerial. The wind blowing across water causes surface waves; a piezoelectric quartz crystal vibrating under an applied electric field generates underwater wave motion. Or, waves could be classified according to the medium in which they travel. The most useful classification, however, involves the direction of motion of the particles of a medium (or of an electric or magnetic field in the case of electromagnetic waves) relative to the direction in which the energy of the wave is itself propagated. Such a classification is useful because wave motions falling into the same class according to the selected criterion will have other similar properties.

Wave motion can be most easily understood if one considers first, as an example, wave motion in a horizontal, stretched string and then, by analogy, other types of wave motion. If one end of such a string is moved up and down, a rhythmic disturbance travels along the string. Each particle of the string moves up and down, while, at the same time, the wave motion moves along the length of the string. It is the state of the particles that advances, the medium as a whole returning to its initial condition after the disturbance has passed. Such a wave motion, one in which the vibratory motion of the medium is at right angles, or essentially at right angles, to the direction of propagation, is called transverse. Surface waves on liquids are transverse; so also are electromagnetic waves (x-rays, visible light, radio waves, and so forth), but here, since electromagnetic waves can travel in a vacuum, we must think of the electric and magnetic fields associated with such waves as changing in intensity in a direction at right angles to the direction of propagation.

Another type of wave motion, one termed longitudinal or compressional, can occur only in material media and has the particles of the medium moving forward and backward along the direction of propagation of the wave. Compressional waves are exemplified by sound waves in air, in which a volume in the path of the wave is alternately compressed and rarefied. These variations in pressure are very small. Even for the loudest sounds that an ear can tolerate, the pressure variations are of the order of 280 dyne/cm^2 (above and below atmospheric pressure of about 1 000 000 dyne/cm^2).

Yet another type of wave motion is the torsional wave, which can take place only in solids. Less frequently seen, this type can be demonstrated by a long helical spring supported on a flat surface. As one end of the spring is given a quick, momentary twist about the axis of the spring, a pulse travels down the spring.

Whatever the type of wave, certain useful definitions can be set forth and general statements made. Phase describes the relative position and direction of movement of a particle in its periodic motion as it participates in wave motion, or the relative intensity at a point of the electric field accompanying electromagnetic waves. Frequency is the number of complete vibrations performed per unit of time by a particle (or field) through which a wave passes. Period is the time required for one complete vibration of a particle participating in wave motion. Wavelength is the distance between any two points that are in phase on successive waves or pulses. The velocity of a wave is the product of the frequency and the wavelength. All waves except electromagnetic waves require a medium for their propagation.

Wave motions may vary in the energy they transport per unit of time. This property depends on the amplitude. The amplitude of a wave in a string, to take again an example, is the maximum displacement experienced by the particles of the string as they move from their equilibrium positions. The intensity of the wave is the power (energy per second) passing through a square centimeter perpendicular to the wave front, and it is related to the square of the amplitude. In the case of sound, intensity is related to loudness.

Two or more waves crossing one another's paths will not cause any change in the direction, frequency, or intensity of any of them. The displacement effects of two or more waves of the same kind passing through a medium are additive at any point; and at any moment, the displacement at a point is the vector sum of the separate displacements caused by the separate waves. Two transverse wave motions passing at right angles through a point in a medium cause a particle at that point to perform a path called a Lissajous figure, whose form depends upon the amplitudes and frequencies of the two waves and upon their phase relationship.

Standing (stationary) waves are produced by combining two similar wave trains moving in opposite directions. Not themselves waves, they are patterns of vibration that simulate waves standing still. An example is exhibited by a string one end of which is fastened rigidly and the other vibrated transversely at a constant frequency. Waves traveling down the string from the source meet waves reflected from the fixed end. If the tension in the string is adjusted properly, the string can be made to display nodes, points where the string does not move transversely because at those points the two waves cancel the effects of one another. Between the regularly spaced nodes are found the antinodes or loops where the two waves reinforce one another.

Wave motion also experiences the phenomena of absorption, reflection, refraction, interference, diffraction, beats, resonance, and polarization. However, longitudinal waves do not exhibit the property of polarization.

Complex waves can be analyzed into sets of simple waves according to the principles of Fourier analysis, where by "simple waves" are meant waves whose variations of displacement with time can be represented by sine curves.

Compressional waves require about 5 seconds to travel a mile in air, 1 second to travel a mile in water, and 1/3 second to travel a mile in iron. Though varying in speed from material to material, low-frequency compressional waves travel with the same speed in a particular medium, i.e., they do not exhibit dispersion. Small variations in speed sometimes found at high frequencies are due to relaxation phenomena.

Compressional waves in a fluid have a speed v that depends only on the density ρ and the adiabatic bulk modulus β of the medium according to the relation

$$v = \sqrt{\frac{\beta}{\rho}}$$

In solids, the speed of compressional waves is given by the relation

$$v = \sqrt{\frac{Y}{\rho}}$$

where Y is Young's Modulus. Thus it may be seen that a study of the propagation of waves in a medium gives important information about the medium.

Transverse waves on the surfaces of liquids do not travel with a fixed speed dependent only on the properties of the liquid. Their speed depends upon their wavelength and amplitude, the depth of the liquid, and whether the surface is confined, as in a canal. Surface tension waves on the surface of water have wavelengths less than 1.7 cm, while gravity waves on the surface of water have wavelengths greater than 1.7 cm. Ripples on water often move only 30 cm/sec. They have higher velocity as their wavelength becomes smaller. In contrast, for example, ocean waves measuring 244 m (800 feet) from crest to crest have been found to travel 20 m/sec (45 mph).

Transverse waves in strings (or wires) travel with a speed that depends only on the tension in the string T and the mass per unit length of the string m, according to the formula

$$v = \sqrt{T/m}$$

Electromagnetic waves of all frequencies travel with the same speed in a vacuum (2.9979×10^{10} cm/sec). In a particular medium, however, different frequencies (colors in the case of visible light) travel with different speeds. The speeds at particular frequencies also vary with the media.

The observed wavelength of a wave motion, whether it be longitudinal or transverse, depends on whether the source and the receiver are moving relative to one another, a phenomenon known as the Doppler effect. In the case of electromagnetic waves, the Doppler effect depends only on the relative velocity; in the case of a compressional wave, as for instance, sound, the magnitude of the effect depends not only on the relative velocity of the source and receiver but upon which is in motion with respect to the transmitting medium. In both cases the wavelength of the wave is increased if the source and receiver move away from one another and decreased if they move toward one another.

In some uses of wave motion, care must be taken to differentiate between "phase" and "group" velocity. The group velocity of a wave is the velocity usually observed, and the energy in a wave is transmitted with the group velocity. For example, measurements of the speed of light wherein the time for "chopped" pulses to travel a known distance is determined, result in values of the group velocity. On the other hand, again for example, if one carefully observes the expanding group of ripples when a stone is dropped into water, the group travels with one velocity, the group velocity, while a particular wave crest will advance through the group to the outer leading edge and exhibit the phase velocity. The difference in the two velocities depends on the wavelength in the material medium and on the dispersion, i.e., on the change in phase velocity with wavelength. In a vacuum—interstellar space for instance—the two velocities are the same for light, whatever the color.

WEAK INTERACTIONS

The weak interactions present a fascinating aspect of the problem of elementary particles. They appear at first to be totally unrelated to the other interactions that we know; nonetheless there have been discovered striking regularities among them, which have led to major advances in our knowledge of the laws of nature. We present here a brief history of the subject, which has been marked by many surprises.

To avoid the difficulties found in understanding processes of β-decay (see RADIOACTIVITY), in 1931 Pauli suggested that the emission of a β-particle from a nucleus is always accompanied by that of a spin-$\frac{1}{2}$ neutral particle of small mass, which takes account of energy and angular momentum conservation in β-decay. Calorimetric measurements of the average energy release in a β-decay transition agree quite well with the value calculated from direct measurement of the β-decay spectrum, indicating that the hypothetical particles, which were called *neutrinos*, must interact extremely weakly with matter, since they escape from the apparatus without giving up any measurable energy. A quantitative theory of β-decay, incorporating the neutrino hypothesis (see NEUTRINO), was formulated in 1934 by Fermi, who wrote down the simplest relativistic expressions that would describe the basic β-transition: the transformation of a neutron into a proton accompanied by the creation of an electron and a neutrino. This theory has been strikingly successful in describing all aspects of β-decay—with one qualification to be described later—and is the one employed to this day. It could be anticipated from the weakness of the neutrino's interaction with matter that the coupling constant characteristic of β-decay would be small; it is in fact extremely small.* Adopting a simile of Lord Rutherford, one may say that from the point of view of the nucleus, β-decay practically never happens! To judge the scale, we note that lifetimes for β-decay are commonly several minutes, whereas γ-transitions of similar energy occur in nanoseconds or less.

The success of Fermi's theory in accounting for the shapes of β-spectra and the dependence of the lifetimes on the available energy release could be regarded as indirect evidence for the existence of the neutrino; there were also other indications, such as the occurrence of the predicted nuclear recoil after processes of orbital electron capture, a phenomenon predicted by the theory. Nonetheless, there was considerable satisfaction when the existence of the neutrino was directly demonstrated by Cowan and Reines in 1955 (for Reines' discussion, see NEUTRINO). They used the intense neutrino flux arising from free neutron decays near a reactor to induce inverse β-decay, i.e., the conversion of a proton into a neutron with the emission of a positron, at roughly the expected rate. A similar experiment by Davis gave a negative results. In Davis' case, however, the reaction sought was the inverse of a β^+-decay transition, although the neutrinos available to him were the same as those used by Cowan and Reines, i.e., neutrinos arising from the β^--decay of neutrons. The nonoccurrence of the Davis reactions demonstrates that the neutrinos emitted in β^--decays cannot be identical with the neutrinos associated with β^+-decay. This conclusion is supported by the absence of neutrinoless

*An average β-decay neutrino must pass through a thickness of matter of the order of 10^{20} g/cm^2 before suffering an interaction.

double β-decay, a process in which the neutrino from the β-decay of one nucleon could be reabsorbed within the same nucleus to induce the β-transition of a second nucleon. Davis subsequently enlarged his apparatus (using 600 tons of dry-cleaning fluid, C_2Cl_4!) to obtain the extreme sensitivity at which he should expect to see reactions induced by neutrinos emitted together with β^+-particles in fusion reactions in the interior of the sun. The rate of events which he finds[4] is about one-third of that expected from current solar-model calculations. Whether this reflects our ignorance of the solar interior or a failure in our understanding of weak interactions is not certain at the moment.

Universal Fermi Interaction The μ-mesons, or muons (see ELEMENTARY PARTICLES), which were originally identified with Yukawa's mesons, were found to interact only very weakly with matter. In fact, it was noted that their absorption could be regarded as a process exactly like electron capture, i.e., by an interaction just like that of β-decay, with even the same coupling constant! The decay of a muon into an electron and two neutral particles, presumably neutrinos, was also accounted for by assuming a Fermi coupling of these four particles, again with a coupling constant of the same magnitude. This led to the hypothesis of a *universal Fermi interaction* between fermions, and after the discovery of "strange" particles (see STRONG INTERACTIONS), the natural extension of this hypothesis to include hyperons led to a qualitative understanding of all strange-particle decays. The relatively meager data available on hyperon β-decays could be accounted for quite adequately by the Fermi theory, provided one used coupling constants somewhat smaller than for nuclear β-decay. This can be explained in terms of a universal Fermi interaction by modifying the definition of universality, in a way suggested by Cabibbo.

After the discovery of parity nonconservation in 1957, it was verified that the detailed space-time forms of the μ-decay interaction and the β-decay interaction are also very similar, lending further support to the idea of a universal Fermi interaction. Experiments showed that the form of the Fermi interaction is that of a current-current coupling, just as the electromagnetic interaction between two objects may be regarded as the interaction between their currents. It was therefore suggested that the Fermi Interaction may arise as a result of the interaction between currents which generate a vector field, similar to the electromagnetic field, which mediates the weak interaction. The currents appearing in the Fermi interaction induce a transfer of electric charge, therefore the intermediary W-field must carry electric charge. To account for the short range of the Fermi interaction, the quanta of this W-field must be very massive, which would account for the fact that these W-particles have not been seen so far. The selection rules for weak interactions could be understood by assigning suitable properties to the generating currents. Gell-Mann's suggestion that these currents form a certain algebra codified these selection rules and also led to a mathematically precise definition of universality. It also led to the remarkable Adler-Weisberger relation between vector and axial-vector β-decay constants.

Fermi's theory predicts that the cross section for neutrino interactions increases quadratically with neutrino energy. For the reaction

$$\nu + n \to \begin{pmatrix} e^- \\ \mu^- \end{pmatrix} + p,$$

this growth is not expected to continue after the neutrino wavelength becomes smaller than nucleon dimensions, but the cross section at the corresponding energy, about 1 GeV, is already sufficient for experiments using high-energy accelerations. One of the first results of such experiments was to demonstrate the striking fact that the neutrino associated with muon capture, which is the one predominantly produced in meson decays, is unable to produce electrons, proving that it is physically distinct from the neutrino of β-decay. It now appears that there is at least one other neutrino associated with the heavy lepton τ found in e^+e^- annihilation. The *total* neutrino cross section continues to increase as the square of the neutrino energy, as measured in the neutrino-nucleon c.m. system, to the highest neutrino energies studied thus far, about 400 GeV at the Fermi National Accelerator Laboratory. This supports the idea of "pointlike" constituents (*partons*) in the nucleon, previously suggested by Feynman to explain the pointlike cross sections found in the inelastic scattering of high-energy electrons. All observations are consistent with the hypothesis of current-current interactions; the currents are simply described as those carried by quarks and leptons (see QUARKS and ELEMENTARY PARTICLES).

The similarity of form of the weak and electromagnetic interactions is a strong hint that the two are related. The principal difficulty with this notion was that while the carrier of electromagnetic interactions, the photon, has zero mass, the postulated W-meson must be very massive. Subsequently, it was realized that this extreme difference of masses can be understood in a gauge theory of weak and electromagnetic interactions if one is dealing with a situation of *spontaneous symmetry violation*, through a mechanism discovered by Higgs. A unified gauge theory of weak and electromagnetic interactions incorporating these ideas was proposed by Weinberg and also published by Salam. This scheme also possesses the advantage that calculations of higher-order effects of weak interactions, which previously yielded meaningless infinities, can be made finite in the same sense as in quantum electrodynamics. Earlier, Glashow had proposed a specific model identical in form to the Weinberg-Salam theory without, however, explaining why the intermediary quanta of the weak interactions should be massive. A particular feature of this theory is that, in addition to the weak interactions mediated by charged $W^{\pm}$ bosons, there should be *neutral current* interactions transmitted by massive neutral Z bosons. The neutral current interactions of neutrinos were discovered in 1973, those of electrons in 1978, and of electrons with muons in 1981.

A difficulty in accepting the idea of weak neutral currents had been the absence of such interactions in strange particle decays. The problem was brilliantly solved by Glashow, Iliopoulos, and Maiani, who simultaneously explained the absence of $\Delta S = 2$ interactions by postulating the existence of a fourth, *charmed* quark which would be paired in weak interactions with the quark combination orthogonal to the one corresponding to Cabibbo's choice. Incorporation of this idea allows the Weinberg-Salam theory to be applied to hadrons as well as to leptons, and is now generally considered to provide the basic description of weak interactions. Glashow et al. were also able to deduce that charmed particles could not be too much more massive than "ordinary" hadrons, and the discovery of charmed particles as predicted, in 1974–76, must be regarded as one of the signal triumphs of theoretical physics. The intermediate bosons $W^{\pm}$ and Z^0 are yet to be detected. Their observation would be important discoveries in themselves. If they are found to have their predicted masses—slightly over 80 GeV/c^2 and 90 GeV/c^2, respectively—the confirmation of the Weinberg-Salam theory would be virtuall complete.*

The success achieved by the hypothesis that weak and electromagnetic interactions are related, naturally encouraged speculation about further unification of the forces of nature. A gauge theory called quantum chromodynamics, similar to the one used to describe electroweak interactions, is found to give an excellent qualitative account of strong iterations, although exact calculations cannot yet be performed for this theory. This led to the idea that both strong and electroweak interactions may be described by a gauge theory involving a larger symmetry group which encompasses both. The apparent difference in strength between the two classes of interactions must again be attributed to spontaneous symmetry breaking, which is expected to occur at a mass scale much higher than 100 GeV/c^2. Common to most such theories of grand unification is the idea that quarks and leptons may transform into each other just as one kind of lepton or quark transforms into another in weak interactions. If this is so, protons would no longer be absolutely stable as previously believed, but decay into leptons and radiation. The high mass scale of strong-electroweak symmetry breaking would assure that the X bosons which mediate such decays are extremely massive, causing the effective proton decay interaction to be exceedingly weak, consistent with the present experimental lower limit of 10^{30} years for the proton lifetime. Experiments to search for such extremely rare proton decays are currently in progress in many parts of the world.

As aspect of the weak interactions which we have not emphasized thus far is that they possess fewer space-time symmetries than the strong interactions. Until Lee and Yang pointed out the possibility in 1956, it was not generally suspected that any interaction could distinguish between right and left. It was then found that weak interactions disciminate between them very strongly; in the case of β-decay and related processes, this preference for a certain handedness could be attributed to the previously unknown fact that neutrinos are handed objects, a concept which can be given a relativistically invariant meaning only for massless particles. For other weak processes, the failure of reflection invariance remains totally unexplained; a new explanation is required even for neutrinos, which certain grand unified theories allow to have a small mass.

An answer to the question of how a left-handed coordinate system could be preferred over a right-handed one was offered by Landau's principle of symmetry under combined inversion CP. According to this principle, the apparent spatial asymmetry in a given experiment is predicted to be exactly the mirror image of that to be expected in an experiment performed with the corresponding antiparticles. This prediction has been verified in many experiments, and for several years all observations were in agreement with this hypothesis, until the discovery of K_L decays in 1964 proved that combined inversion CP could not be an exact symmetry. A consequence of the CPT theorem (see ANTIPARTICLES) is that, if CP-invariance fails, T-invariance must also fail; although this has not been directly observed in any phenomenon, there is indirect evidence from neutral K-meson decays that this is so. Many speculations have been advanced regarding the nature of the CP noninvariant interaction. All existing information is consistent with the hypothesis that CP noninvariance is confined to interactions much weaker than the usual weak interactions, which have observable consequences only in neutral K-meson decays, which are the only phenomena where CP noninvariance has been conclusively established. It is pos-

*Editor's note: The bosons W^+, W^-, and Z^0 were observed at CERN in 1938. Masses as determined experimentally matched those obtained from theory suprisingly well. See *Physics Today* 37, S-30 (Jan. 1984).

sible that CP noninvariance may be associated with the existence of a third pair of quarks, composed of the b quark and its hypothetical partner. In that case, there is no chance of seeing possibly larger CP noninvariant effects outside the neutral K-meson system.

There is still much to learn about weak interactions.

WORK, POWER, AND ENERGY

In the strict physical sense, work is performed only when a force is exerted on a body while the body moves at the same time in such a way that the force has a component in the direction of motion. In the simplest case where a constant force is applied in the same direction as the motion, it may be stated that work equals force multiplied by distance, or

$$W = Fs.$$

An example could be the raising of mass m from elevation h_1 to elevation h_2 in a constant gravitational field where the acceleration of gravity is g. The work performed would be

$$W = mg\,(h_2 - h_1).$$

To generalize for more complex situations, the amount of work done during motion from point "a" to point "b" can be expressed by:

$$W = \int_a^b F \cos\theta \, ds$$

where F is the total force exerted and θ is the angle between the direction of F and the direction of the elemental displacement ds. In the cgs system the unit of work is the dyne-centimeter or erg, in the mks system the newton-meter or joule, and in the English system the unit of work is the foot-pound.

In rotational motion, the definition just given can be exactly applied, but it is often convenient to express the force as a torque and the motion as an angular displacement. The work done will be:

$$W = \int_a^b \tau \cos\theta \, d\omega$$

where in this case θ is always the angle between the torque τ expressed as a vector quantity and the elemental angular motion $d\omega$, also expressed as a vector. The units of work performed in angular motion will, of course, be the same as in the case of linear motion. Notice that the definition of work involves no time element.

Power is defined as the rate at which work is performed. The average power accomplished by an agent during a given period of time is equal to the total work performed by the agent during the period, divided by the length of the time interval. The instantaneous power can be expressed simply as

$$P = \frac{dW}{dt}.$$

In the cgs system, power has the units of ergs per second; in the mks system, units of joules per second (or watts), and in the English system, units of foot-pounds per second. A common engineering unit is the horsepower, defined as 550 foot-pounds per second, or 33 000 foot-pounds per minute.

Energy may be defined as the capacity for performing work. This definition may be better understood when stated as: the energy is that which diminishes when work is done by an amount equal to the work so done. The units of energy are identical with the units of work, previously given.

Energy can exist in a variety of forms, some more recognizable as being capable of performing work than others. Forms in which the energy is not dependent upon mechanical motion are generally referred to as forms of potential energy. The most common example in this category is gravitational potential energy. A body near the earth's surface undergoes a change in potential energy when it is changed in elevation, the amount being equal to the product of the weight of the body and the change in elevation.

Potential energy may also be stored in an elastic body such as a spring or a container of compressed gas. It may exist in the form of chemical potential energy, as measured by the amount of energy made available when given substances react chemically. Potential energy also exists in the nucleii of atoms and can be released by certain nuclear rearrangements.

Kinetic energy is the energy associated with mechanical motion of bodies. It is quantitatively equal to $\frac{1}{2}mv^2$ where m is the mass of a body moving with velocity v. In the case of rotational motion, the kinetic energy is more easily calculated using the expression $\frac{1}{2}I\omega^2$, where I is the moment of inertia of the body about its axis of rotation and ω is the angular velocity. Kinetic energy, like all forms of energy, is a scalar quantity. In a system made up of an assembly of particles, such as a given volume of gas, the total kinetic energy is equal to the sum of the kinetic energies of all the molecules contained in the volume. Calculation of the energy of such systems is very successfully treated theoretically on the basis of statistical averages.

Within a given system, energy may be transformed back and forth from one form to another, without changing the total energy in the system. A simple example is the pendulum, in which the energy is periodically converted from gravitational potential energy to kinetic energy and then back to gravitational potential energy. A similar situation, but on a submicroscopic scale, occurs in solid materials where the atoms are vibrating under the effect of interatomic rather than gravitational forces. As the temperature of a solid increases, the energy associated with the vibration of the atoms increases.

The example just given illustrates how, on a macroscopic scale, heat can be considered a form of energy. Regardless of the material involved, any amount of heat absorbed or released may be quantitatively expressed as an amount of energy. A gram-calorie of heat is equivalent to 4.19 joules, and in the English system a British thermal unit (Btu) is equivalent to 778 foot-pounds.

Potential energy is also present in electric and magnetic fields. The energy available in a region of electric field is equal to $E^2/8\pi$ per unit volume, where E is the electric field strength. Within a given volume, the total energy represented by the electric field is the integral of $E^2/8\pi$ over the volume. Similarly, the energy represented by a magnetic field may be independently calculated by integrating $H^2/8\pi$ over any given volume, where H represents the magnetic field strength. In the case of an electrically charged capacitor, the total energy in the electric field, and hence in the capacitor, can be shown to be $\frac{1}{2}CV^2$. Here C is the capacitance and V the electric potential to which the capacitor is charged. Similarly the total energy in the magnetic field associated with an inductor carrying an electric current is $\frac{1}{2}LI^2$, where L is the inductance and I the current.

Electromagnetic radiation is a combination of rapidly alternating electric and magnetic fields. Energy is associated with these fields and is exchanged between the electric and magnetic forms. This energy in a quantum of electromagnetic radiation, such as light or gamma radiation, can be represented in different ways, but is commonly expressed as $E = h\nu$. Here h is Planck's Constant and ν is the frequency of the radiation.

For particulate radiation or any very rapidly moving mass, the expression previously given for the kinetic energy, $\frac{1}{2}mv^2$, is not accurate when the velocity approaches that of the velocity of light. The theory of relativity requires a correction be made, and the exact kinetic energy, T, may be calculated in terms of mass, m_0, of the body measured when at rest, and the speed of light in vacuum, c, as follows:

$$T = m_0c^2 \left[\left(1 - \frac{v^2}{c^2}\right)^{-1/2} - 1\right]$$

Notice that this formula may also be written:

$$T = (m - m_0)c^2$$

where m is the variable quantity $m_0 \left(1 - \frac{v^2}{c^2}\right)^{-1/2}$. This quantity represents the mass of the body, reducing to m_0 when v is zero, and approaching infinity as v approaches the speed of light.

This example illustrates another result of the theory of relativity, namely, the equivalence of mass and energy. Rewriting the last equation,

$$m = m_0 + \frac{T}{c^2}$$

The mass is seen to increase linearly with the kinetic energy of the body, the proportionality factor being c^2. Indeed, even the rest mass, m_0, represents an amount of energy equal to m_0c^2. The total energy of a body of mass, m, can be generally given as:

$$E = mc^2 \text{ or } E = m_0c^2 + T$$

In dealing with radiation, whether particulate or electromagnetic, it is customary to express energy in terms of electron volts. An electron volt is equal to the amount of work done when an electron moves through an electric field produced by a potential difference of one volt. One electron volt is equivalent to 1.60×10^{-12} erg. When charged particles such as electrons or protons are given kinetic energy by an accelerator, their kinetic energy is stated in terms of electron volts (eV) or million electron volts (MeV). In addition, any such particle will have a rest mass which can also be specified as an energy. For an electron,

$$m_0 = 9.11 \times 10^{-28} \text{ gram}$$

which is equivalent to 8.18×10^{-7} erg or 0.515 MeV.

A basic principle of physics is known as conservation of energy. This principle requires that within any closed system, the total energy must remain a constant. Energy can be changed from one form to another; but the total, so long as no energy is added to or lost from the system, must be constant. In the case of the swinging pendulum, decreases in kinetic energy reappear as increases in potential energy and vice versa. Eventually, of course, the pendulum will stop due to the effect of frictional forces. At that time, all of the kinetic and gravitational potential energy will have been converted to heat.

In another example involving a radioactive atom, the total energy represented by the atom and the emitted radiation must be constant. If a gamma ray is emitted, the rest mass of the atom will be decreased by an amount equivalent to the sum of the energy of the gamma ray and the recoil kinetic energy of the atom, which will be very small. If a beta ray is emitted, the rest mass of the atom will be decreased by an amount equivalent to the sum of the rest mass of the emitted electron, the kinetic energy of the electron, and the recoil kinetic energy of the atom.

X

X-RAY DIFFRACTION

X-rays are electromagnetic radiations, and, like visible light, they can be diffracted (see OPTICS, PHYSICAL and DIFFRACTION). If a diffraction grating is used, the situation is as shown in Fig. 1. The points, B, B′, B″, · · · along OX represent the lines of the grating seen end-on, and ABC, A′B′C′, · · · are typical incident and scattered rays of a parallel incident beam. If D′ is the foot of the perpendicular dropped from B on to A′B′ and D is the foot of the perpendicular from B′ to BC, the extra distance traveled by the ray A′B′C′ is clearly D′B′−DB. This path difference can be expressed in terms of the grating space a, the angle of incidence ϕ_1, and the angle of scattering ϕ_2. From the triangle BB′D′, D′B′ = $a \cos \phi_1$, and from the triangle BB′D, DB = $-a \cos \phi_2$. If there is to be appreciable intensity diffracted in the direction BC, the path difference must be an integral multiple of the wavelength λ, say $h\lambda$. Then

$$h\lambda = a(\cos \phi_1 + \cos \phi_2) \tag{1}$$

In order to obtain any appreciable scattering of x-rays from a grating it is necessary in practice to use very small angles of incidence, so that total external reflexion occurs. (The refractive index of matter for x-rays is very slightly less than unity, so that under suitable conditions they exhibit total external reflexion, whereas light exhibits total internal reflexion.) The points B, B′, · · · thus correspond to the centers of the smooth reflecting portions of the grating. From measurements of the angles of incidence and diffraction under such conditions, the absolute values of the x-ray wavelengths have been derived.

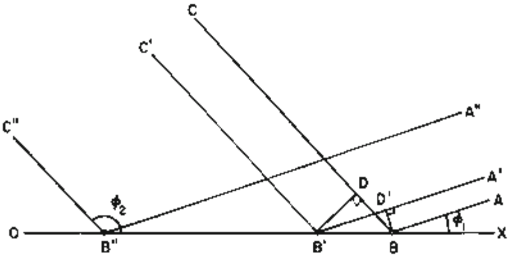

FIG. 1. Diffraction by a linear grating or line of scattering centres.

A geometrical representation of Eq. (1) is helpful in extending the theory of diffraction by a grating (an object with a one-dimensional variation of scattering power) to diffraction by a crystal (an object with a three-dimensional variation of scattering power). Equation (1) can be rewritten:

$$\frac{\cos \phi_1}{\lambda} + \frac{\cos \phi_2}{\lambda} = \frac{h}{a} \tag{2}$$

In Fig. 2, OP is a line of length $1/\lambda$ drawn parallel to BA, so that the angle XOP = ϕ_1, and PQ is a line of the same length drawn parallel to BC, so that it makes an angle ϕ_2 with OX. The projection of OP on OX, OP′, is clearly of length $\cos \phi_1/\lambda$, and the projection of PQ, P′Q′, is of length $\cos \phi_2/\lambda$. If Eq. (2) is satisfied, the length of OQ′ = OP′ + P′Q′ must be h/a. Clearly, fixing h is not sufficient to fix the angles ϕ_1 and ϕ_2. If we imagine that the lines XO, OP and PQ are jointed together at O and P, Q is free to slide up and down the line GQ′H within wide limits without affecting the equality of Eq. (2), and so giving considerable freedom to the directions of incident and diffracted rays having a constant path difference $h\lambda$. Different values of h lead to different lines GH, G′H′, · · · spaced at integral multiples of the distance $1/a$ along OX. All possible mutual relationships between the incident and strongly diffracted rays are represented

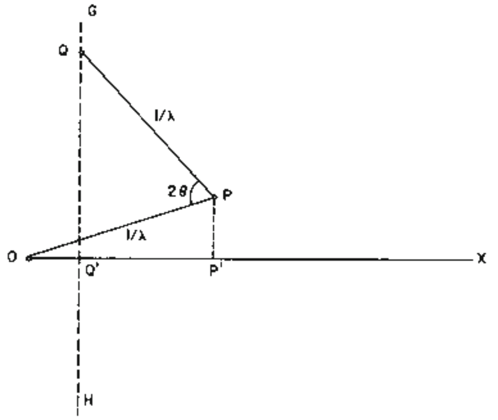

FIG. 2. Geometrical representation of the condition for strong reflection.

by those portions of the set of parallel lines of spacing $1/a$ that lie within a circle with radius $2/\lambda$ and center O.

The exterior angle between AB and BC is generally denoted by 2θ. From Fig. 1 it is clear that

$$2\theta = \phi_2 - \phi_1 \tag{3}$$

and from Fig. 2

$$\begin{aligned} \text{OQ} &= \text{OP} \sin\theta + \text{PQ} \sin\theta \\ &= (2 \sin\theta)/\lambda \end{aligned} \tag{4}$$

With a little reinterpretation, Figs. 1 and 2 can be used to derive the condition for strong diffraction by a crystal. A crystal is a three-dimensionally periodic object, with a certain arrangement of atoms repeating indefinitely at intervals of a in one direction, b in another, and c in a third. The intervals a, b, c are not generally equal to each other, nor necessarily at right angles to each other. They define a parallelepiped called the *unit cell* of the crystal. For determining the geometrical conditions for the existence of a strong diffracted beam, the manner in which the atoms are arranged in the cell is not important, and for the moment we may think of them as forming a single scattering center at the corner of the cell. In Fig. 1, the points B, B′, · · · now represent a row of scattering centers parallel to a, and ABC, A′B′C′, · · · represent a sequence of incident and diffracted rays. The difference is that for a ruled grating one can expect constructive interference between the various scattered rays only if OX, AB, BC, A′B′, B′C′, · · · are coplanar, whereas an arrangement of atoms can scatter out of the plane of OX and AB, and hence BC need not lie in this plane. The condition for reinforcement, however, remains

$$\text{D}'\text{B}' - \text{DB} = h\lambda \tag{5}$$

and its geometrical representation in Fig. 2 is changed only in that Q does not necessarily lie in the plane of OX and OP. With this relaxation, the condition for reinforcement is fulfilled if Q lies anywhere on a plane perpendicular to a and distant h/a from O. Different values of h lead to a set of parallel planes, and as far as the repetition of scattering centers in the direction of a is concerned, reinforcement will occur if Q lies anywhere on any of the planes within a sphere with center O and radius $2/\lambda$.

It is, however, necessary to satisfy similar conditions for the repetition of scattering centers in the directions of b and c. These conditions are exactly analogous: reinforcement for repetition along b will occur only if Q lies in one of a set of planes that are perpendicular to b and spaced $1/b$ apart, and reinforcement for repetition along c will occur only if Q lies in one of a set of planes perpendicular to c and spaced $1/c$ apart. There can be a strong beam diffracted by the crystal only if Q satisfies these three conditions simultaneously. Two sets of planes intersect in a set of parallel lines, and the third set of planes will intersect these lines in a lattice of points. This is called the lattice reciprocal to the crystal lattice, or the reciprocal lattice for short. A strong diffracted beam can occur, then, only if Q coincides with one of the points of the reciprocal lattice, and only those points within a sphere of radius $2/\lambda$ are possible, since the maximum length of OQ is $2/\lambda$. This sphere is called the *limiting sphere*.

The repeat distances in the reciprocal lattice are usually called a^*, b^*, c^*. They have the same general directions as a, b, c, but are actually parallel to them only in those crystal systems that have their axes at right angles. There are a number of "reciprocal" relations between the two sets of axes, some obvious from the way in which the reciprocal lattice has been constructed, others obtainable only by analysis. For further details the article on CRYSTALLOGRAPHY should be consulted.

For a given wavelength λ, a given direction of incidence PO, and a fixed position of the crystal, the loci of possible positions of Q is a sphere with center P and radius $1/\lambda$. This sphere is called the *sphere of reflexion*, since strong diffraction can take place only if one of the points of the reciprocal lattice lies in or passes through its surface. With all parameters fixed, this is an unlikely coincidence, and in the practical study of x-ray diffraction, provision must be made for variation of either λ (the Laue method), or the orientation of the crystal (most types of single-crystal and crystal-powder cameras and diffractometers), or the direction of the incident x-rays (some special-purpose techniques). Space does not permit discussion of the practical details.

In the preceding treatment diffraction has been considered from the viewpoint of adding contributions scattered by centers arranged in a regular lattice. It can also be considered as reflexion from sets of parallel planes of atoms, the rays reflected by successive planes in a set being added. It can be shown that the connection between the two views is that (1) the line OQ joining the origin of the reciprocal lattice to the point hkl is perpendicular to the corresponding set of reflecting planes, and (2) its length is the reciprocal of their spacing d. From the second viewpoint, then, Eq. (4) may be rewritten

$$\lambda = 2d \sin\theta \tag{6}$$

a relation known as *Bragg's law*.

The arrangement of atoms within the unit cell influences the intensity of the various orders of diffraction hkl, just as the shape of the ruling influences the intensities of the different orders produced by an optical diffraction grating. It is easy to see that x-rays diffracted by an atom at the position xa, yb, zc within the unit cell travel a shorter distance than those diffracted at the hypothetical scattering center at the origin, and that the corresponding phase difference is $2\pi(hx + ky + lz)$. If the cell contains n atoms whose scattering factors (the ratio of the actual scattered amplitude to the amplitude scattered by a free electron under the same conditions) are $f_1, f_2, \cdots, f_n$, the total amplitude scattered by the cell will thus have an in-phase component of

$$A = f_1 \cos 2\pi(hx_1 + ky_1 + lz_1) + \cdots + f_n \cos 2\pi(hx_n + ky_n + lz_n) \quad (7)$$

and an in-quadrature component of

$$B = f_1 \sin 2\pi(hx_1 + ky_1 + lz_1) + \cdots + f_n \sin 2\pi(hx_n + ky_n + lz_n) \quad (8)$$

the scattering by an atom at the origin of the cell being taken as the reference phase. The total intensity of scattering is thus proportional to

$$F^2 = A^2 + B^2 \quad (9)$$

The quantity F is called the *structure factor*; it is sometimes convenient to regard it as a complex quantity $F = A + iB$. It can vary in magnitude from zero to $f_1 + f_2 + \cdots + f_n$, with a root-mean-square value of $\sqrt{(f_1{}^2 + \cdots + f_n{}^2)}$. The total intensity of the order hkl is proportional to NF^2, where N is the number of unit cells in the crystal. The scatter of the actual values of the intensity above and below the mean value depends on the symmetry of the atomic arrangement. Although the relationship is statistical, a study of the scatter can often provide evidence about the *point group* of the crystal when other methods are not available. From Eq. (7) through (9) it is clear that for any hkl the actual intensity of diffraction depends on the atomic positions $x_1y_1z_1 \cdots x_ny_nz_n$. Measurement of the intensities of a sufficient number of diffraction maxima thus makes it possible to infer the atomic positions. Unfortunately there is no single procedure that can be guaranteed to lead from the measured intensities to the atomic coordinates, but there are many that are successful in appropriate cases: trial-and-error, isotypic (isomorphous) substitution, so-called "direct" methods. Direct methods make heavy demands on computing facilities, as they require statistical manipulation of a great body of data, but they succeed almost routinely for crystals whose unit cells contain up to about a hundred atoms (plus hydrogen, if the substance is organic).

Up to this point there has been a tacit assumption that the scattered intensity is a negligible fraction of that incident on the crystal. This assumption is justified for crystals that warrant the paradoxical description "ideally imperfect." In practice this covers most of the fine powders used in powder diffractometry and powder photography (see final paragraph below) and most of the reflections from organic crystals used in single-crystal investigations, but there are exceptions for inorganic crystals and for the stronger reflections from organic crystals. The observed effect is that the total intensity of the reflection is *less* than that calculated from (7)-(9) above, because the incident beam is weakened by the intensity diffracted out of it, and thus the parts of the crystal far from the source have less opportunity to diffract than parts close to the source. This effect is known as *secondary extinction*, and can be allowed for on a semiempirical basis for most crystals used in structure determination.

The treatment of x-ray diffraction outlined above is known as *kinematical theory*, and is adequate for most problems. It does not apply, however, for crystals that are approaching genuine perfection in atomic arrangement. Until recently such perfection was found only in rather rare mineral specimens, but it is now possible to grow practically perfect crystals of silicon and other substances in commercial quantities. In such crystals the incident beam is almost perfectly reflected once, the once-reflected beam is reflected back into parallelism with the incident beam, the twice-reflected beam is reflected back into parallelism with the once-reflected, and so on indefinitely. The parallel beams interfere with one another, and the mathematics, known as *dynamical theory*, becomes difficult. The most obvious result is that if the x-ray beam is incident at the correct angle it is almost totally reflected (there is a small reduction associated with absorption), but if the angle of incidence is wrong by more than a few seconds of arc the intensity of reflection is practically zero. One thus has the peculiar situation that a perfect crystal reflects perfectly while it is reflecting, but the total amount that it reflects when it is rotated through the reflecting position is very much less than that reflected by an ideally imperfect crystal of the same material. There are other peculiar phenomena associated with perfection, one of the most spectacular being transmission of the incident beam through a thickness of crystal that would completely absorb it if the angle of incidence were slightly altered.

At the opposite end of the scale there are crystals that are really imperfect, not merely ideally. The observed effect is that the intensity of reflection is appreciable over quite a range of Bragg angles; kinematical theory suffices to describe the phenomenon. In most cases [there are some exceptions, particularly for case (2) below], the maximum intensity of diffraction occurs when the point Q, defined above, coincides with one of the points hkl of the reciprocal lattice. As the point Q moves away from its ideal position, the intensity of diffraction does not drop instantaneously to zero, but falls off gradually in a manner depending on the size and perfection of the crystal. The study of the manner in which the falling off occurs is a fascinating exercise both experimentally and theoretically, but space permits only the quotation of a few qualitative results. The main varieties of imperfection considered are (1) the crystal is too small to give sharp diffraction maxima, (2) there are "mistakes" in the arrangement of atoms in the sequence of unit cells, and (3) the crystal is twisted, bent, or affected by dislocations. In case (1) the regions round each reciprocal-lattice point are identical except for variations in F, and extend in any direction to a distance that is roughly the reciprocal of the thickness of the crystal in the corresponding direction. In case (2) the size and shape of the regions may vary in a complex manner with hkl, but they show no general increase in size with increasing distance from the origin of reciprocal space. In case (3) the size of the regions shows a general increase in direct proportion to their distance from the origin of reciprocal space, as well as varying with hkl.

The intensity of many diffraction maxima may be recorded simultaneously on a photographic film with a suitable emulsion, and later measured with a densitometer, or individual diffraction maxima may be investigated one by one with a counter diffractometer. In spite of the complexity of the mechanism the latter is becoming the preferred method; various methods of automation, including on-line computer control, have removed the tedium associated with early diffractometric measurements. For determination of the atomic arrangement only the total ("integrated") intensity of each maximum is required, but for investigations of crystal imperfection much more detailed information about the variation of intensity with position in reciprocal space is needed. Often the material exhibiting imperfections is not available in crystals large enough to be examined individually, and the specimen has to take the form of an aggregate of many small crystallites in a more or less random orientation. In such cases measurement of the three-dimensional variation of intensity in reciprocal space is not possible, but by the use of a powder diffractometer the one-dimensional variation of intensity with Bragg angle [θ in Eq. (6) above] can be measured with considerable precision, and there is an extensive theory for the interpretation of such "line profiles."

X-RAYS

The portion of the electromagnetic spectrum known as x-rays has been recognized for nearly a century, yet radiation in this area continues to find new applications in many fields of science and technology. It seems unlikely that Wilhelm Conrad Roentgen could possibly have foreseen the impact that these rays would have when he discovered them in 1895 at the University of Wurzburg. He received the first Nobel prize (1901) in physics in recognition of the discovery. For seventeen years the exact nature of x-rays was obscure. They certainly deserved their designation of x- (or unknown) rays. In 1912, M. von Laue and his associates showed that x-rays could be diffracted from crystals which simulated three-dimensional gratings. This historic experiment not only proved the wavelike nature of x-rays, but also showed the regular three-dimensional arrangement of atoms in a crystal lattice. Two new fields of science were thus launched, namely, x-ray spectroscopy and x-ray crystallography. The crystal spectrometer was developed by W. L. Bragg; then Bragg, H. G. J. Moseley, M. Siegbahn, and others began the laborious task of cataloging lists of characteristic x-ray wavelengths. It was Moseley who recognized the simplicity and periodicity of the K series, for instance, whose main four lines varied step by step in going from one element to the next in the periodic table. The power of the technique is illustrated by the fact that spectral gaps were noted which indicated that certain elements were missing from the then known elemental scheme. In each case the missing elements were found and their x-ray spectra fell into the predicted places.

X-rays may be produced by a variety of methods, but the general method employed by Roentgen, that is, using electrons, continues to be the most popular. Roentgen operated his discharge tube at high voltage and with sufficient gas pressure to allow the cathode rays (electrons) to travel through the tube and collide with the walls to produce x-rays. Today, most x-ray tubes use a hot filament with electrons produced by the Edison effect. The fast-moving electrons convert their energy to an x-ray photon according to the law,

$$h\nu = E_1 - E_2$$

where E_1 and E_2 are the initial and final energies of the electron, h is Planck's constant, and ν is the frequency of the x-ray photon created. The radiation thus produced consists of a continuum of radiations, corresponding to the many possible energy losses that the electrons can undergo on striking the target of the x-ray tube. Such a continuum is represented in Fig. 1. When the electron loses all of its energy in a single collision, then $E_2 = 0$ and the x-ray photon of the highest energy is produced. This energy corresponds to the shortest possible wavelength or λ_{min}. Upon introduction of appropriate constants, λ_{min} in angstroms may be approximated by

$$\lambda_{\text{min}} = \frac{12{,}400}{E\ (\text{volts})}$$

where E is the x-ray tube voltage. Ten angstroms equal one nanometer. Therefore, if an x-ray tube is operated at 40 kV, then the shortest possible wavelength λ_{min} will be about 0.3 Å. The peak of the "white" or continuous radiation will be about $\frac{3}{2}$ times λ_{min}.

Superimposed on the continuum is a simple line and band spectrum characteristic of each element such as that shown in Fig. 1. These spectral features are produced by ejection of an electron in an inner energy level followed by the filling of this vacancy by an electron from a higher energy state. The energy of the x-ray quantum is the difference between the energies of the two levels involved. The x-ray series are named according to the final energy state involved in the transition with the familiar notations K, L, M, N, etc., as devised by Barkla in 1905 to emphasize the analogy with optical spectral series. It is not easy to place exact limits on the position of x-rays in the electromagnetic spectrum, since they overlap with γ-rays on the short-wavelength end and with vacuum ultraviolet radiation on the long-wavelength end. Generally, however, they are classified as ultrahard (<0.1 Å), hard (0.1–1.0 Å), soft (1–10 Å) and ultrasoft (>10 Å).

As the wavelength of x-rays is increased (or as they become "softer"), they are as a rule more easily absorbed by all materials. The decrease in intensity of a beam of x-rays passing through matter follows the law

$$I = I_0 e^{-\mu x}$$

where I_0 is the incident intensity, I the reduced intensity after a thickness x (cm) of homogeneous matter has been transversed, and μ the linear absorption or attenuation coefficient for the materials traversed.

In addition to this general attenuation in matter, there occur sharp absorption discontinuities in the x-ray spectrum corresponding to the energy necessary to just eject an electron from a given level, as shown in Fig. 2, where the structure near the K edge is shown for metallic iron. The large discontinuity suggests the use of metal foils to act as filters for various purposes. The edge is designated as K, L_I, L_{II}, L_{III}, etc., which indicates where the initial vacancy has occurred. The emission lines of a given element fall at longer wavelengths compared to the corresponding absorption edge. The absorption edge position and the fine

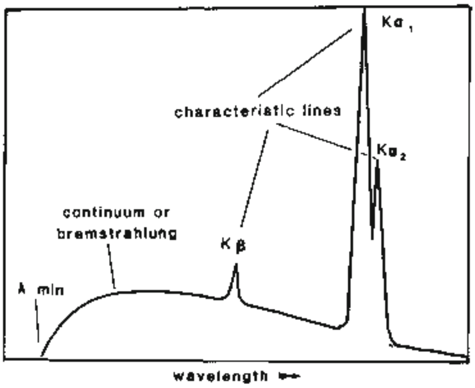

FIG. 1. Typical x-ray spectrum, showing continuum and characteristic radiation.

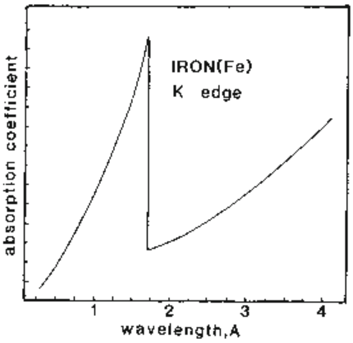

FIG. 2. Plot of absorption coefficient of iron against wavelength, showing characteristic K edge at 1.74 A.

structure on the edge depend strongly on the state of chemical combination of the emitting element, and detailed study of edge structure provides a powerful tool for the determination of chemical bonding.

The major uses of x-rays are in the areas of x-ray emission, x-ray diffraction, and x-ray absorption (to include interaction, such as ionization, with matter). X-ray emission analysis is a precision technique for elemental analysis which uses a high-intensity beam of x-rays from a primary source to excite characteristic x-rays in a sample. These x-rays are dispersed by a crystal spectrometer and detected by a scintillation or proportional detector which measures the angle at which the x-rays are diffracted by the analyzing crystal. The familiar Bragg equation

$$n\lambda = 2d \sin \theta$$

is used to deduce the wavelength λ of the secondary x-rays from the sample. θ is the angle that the x-ray beam makes with the crystal and is measured by the spectrometer, d is the lattice or interplanar spacing of the single-crystal analyzer, and n is the order of diffraction. This technique, commonly called *x-ray fluorescence*, is generally applicable to qualitative and quantitative analysis of all elements higher than atomic number 11 in the periodic table. With special instrumentation, the technique can be extended to low-atomic-number elements such as carbon and oxygen.

An extraordinary development in x-ray emission analysis has occurred with the development of the *electron microbeam probe* which collimates a beam of electrons to produce characteristic x-rays from a total sample volume of about one cubic micrometer. In addition to elemental analysis, the method provides a map of elemental distribution on a highly magnified image of the specimen. Scanning spectrometers and nondispersive Si (Li) detectors on scanning electron microscopes allow elemental distribution mapping in addition to the extremely high-resolution scanning pictures which are obtained from low-energy secondary electron emission from the sample surface.

An important new development in x-ray emission spectroscopy is the use of the fine features on x-ray lines and bands to deduce chemical bonding and the effects of chemical combination. Another significant use of monochromatic characteristic x-rays is to produce photoelectrons in the newly emerging technique known as ESCA (electron spectroscopy for chemical analysis), pioneered by Kai Siegbahn at Uppsala. The development of this technique, which is so closely related to x-ray spectroscopy, recently earned Siegbahn a Nobel prize in physics. This honor was especially fitting because his father was also honored for early pioneering work in x-ray spectroscopy.

X-ray diffraction is a widely used technique for characterization of solid crystalline materials in single-crystal analysis, powder diffraction analysis, and texture or topographical analysis. The same Bragg law mentioned earlier for x-ray emission analysis also applies to diffraction analysis, since it is a diffraction technique which is used to analyze or disperse the x-rays in the x-ray emission scheme. In x-ray diffraction, however, the wavelength λ is known, the angle θ (or 2θ) is measured, and the d spacing is calculated. Each crystalline material produces a diffraction pattern unlike that of any other material, and this pattern identifies each material unambiguously. An extensive file of diffraction patterns is provided by the American Society for Testing and Materials, which permits quick identification of crystalline materials. The reader is referred to the articles in this volume on X-RAY DIFFRACTION and DIFFRACTION BY MATTER AND DIFFRACTION GRATINGS for further details of the theory of diffraction phenomena, and to CRYSTALLOGRAPHY for applications to single-crystal analysis.

Perhaps the most familiar use of x-rays concerns the absorption (attenuation) and interaction with matter of an x-ray beam, since these phenomena provide the basis for radiography and uses in medical technology. *Radiography* is the registration on film or a fluorescent screen (fluoroscopy) of the differential absorption of a beam passing through a heterogeneous sample. This technique is used in medical diagnosis and to determine the soundness and perfection of manufactured products such as castings and forgings. An important development has been in cineradiography, where extremely high fluences of x-rays are pulsed to give sequential radiographs of transient phenomena lasting 10^{-9} sec or less. Microradiographic techniques are used to obtain magnifications of 100× to 200× of radiographs resulting from passage of monochromatic x-rays through a sample which is in direct contact with the recording film. Magnification is then realized by photographic enlargement. An improvement over contact microradiography is point projection radiography, where a fine point source of x-rays registers the sharp absorption discontinuities from a sample which is placed at varying distances from the film to achieve different sharp magnifications of the image. A further use of the absorption phenomenon is in absorptiometry, where measurement is made of the attenuation of a beam passing through a sample to determine, for instance, density, porosity, and coating thickness. Chemical analysis is also achieved by measuring characteristic absorption edges with a crystal spectrometer. Fine structure on these edges may also be used in certain cases to deduce bonding and chemical combination.

The areas of radiation chemistry, physics, biology, genetics, therapy, and protection all depend on the effects and changes produced when x-ray quanta are absorbed in matter. X-rays are, of course, ionizing radiations, and induce chemical reactions by formation of intermediate species, free radicals, and ions. These reactions may be used profitably for dosimetry, to produce mutations, and to irradiate selectively cancerous tissue, among many of the possible uses.

Because of space limitations, this review only sketchily refers to some of the numerous uses of x-rays. For further information it is suggested that the reader consult the references.

ZEEMAN AND STARK EFFECTS

Introduction The Zeeman and Stark Effects refer, respectively, to effects of external magnetic and external electric fields on the structure of atoms or molecules. In most cases the effects are observed through the modification of spectral features such as strength, polarization, width and position of emission or absorption lines. The Zeeman effect is named after Pieter Zeeman, who in 1896 observed a magnetic-field-induced broadening of the *D* emission lines in sodium vapor. (Zeeman's observed broadening was later found to be a small splitting.) The Stark effect is named after Johannes Stark, who in 1913 observed the electric-field-induced splitting of the Balmer transitions in atomic hydrogen.

Both the Stark and Zeeman effects have received extensive study since their discoveries. During the period of the development of the early quantum theories the effects played an important role by helping to stimulate the development of new ideas and computational techniques. In modern times the effects have enjoyed continued interest due to newly discovered aspects of the intermediate and strong field problems. To a degree, much of the recent interest is also connected with the technological developments of tunable lasers and digital computers.

This article will examine the effects of external magnetic and electric fields on hydrogen and hydrogenlike atoms. The discussion has been limited to such atoms for the sake of simplicity but not at the cost of completeness. All the essential features of external field effects are brought out by the discussion of this simple example. It will be shown that the Zeeman and Stark effects are traceable to the interaction between the magnetic and electric dipole moments of atoms and the external fields. Dipole moments in atoms occur naturally or are induced by external fields.

Zeeman Effect *Introduction.* The Zeeman effect is the result of the interaction between the magnetic moment of the atom and the external magnetic field. The leading term to the interaction energy is,

$$W = -\boldsymbol{\mu} \cdot \mathbf{B}, \tag{1}$$

where $\boldsymbol{\mu}$ is the magnetic dipole moment and **B** is the magnetic field. Magnetic dipole moments in atoms arise either from internal currents due to electron orbital motion, or from the natural (intrinsic) magnetism associated with the electron and the atomic nucleus. In the following discussions three well known cases of the Zeeman effect are considered: the normal effect, the anomalous effect, and the diamagnetic effect. (The terms "normal" and "anomalous" were coined before the Zeeman effect was well understood and unfortunately are misleading. The normal effect is actually a special case of the anomalous effect.) The magnetic moment associated with each case has a unique origin. The normal effect is caused by the interaction with the orbital magnetic moment. The anomalous effect is caused by the interaction with the combined orbital and intrinsic magnetic moments. The diamagnetic effect is caused by the interaction with the field-induced magnetic moment.

Normal Zeeman Effect. Figure 1 displays the simplest example of the normal Zeeman effect, that is, the effect on the *s–p* transition. (Spectroscopic notation is used to label quantum states. The letters *s*, *p*, *d*, *f*, . . . designate the orbital angular momentum, *l*, corresponding to values of 0, $\hbar$, $2\hbar$, $3\hbar$, . . . , $2\pi\hbar$ is Planck's constant.) The *p* level splits into three equally spaced sublevels under the influence of the external field. The central *p* sublevel and the *s* level do not shift in response to the field. The energy spacings between the *p* sublevels increase linearly with the applied field. (An observation that applies to all normal-effect transitions is that the magnitude of the rate of separation between adjacent sublevels is a constant that is the same for all members of a Rydberg series. Thus, the

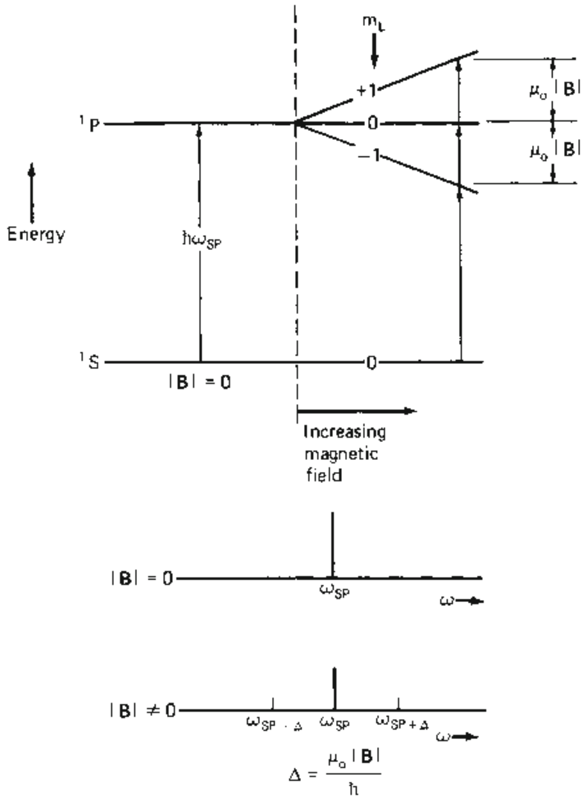

FIG. 1. Normal Zeeman effect for ^1S-^1P transition. Above is energy level diagram; below is spectrum with and without an external field.

appearance of the effect does not depend upon the principal quantum numbers of the states in question. This last observation is Preston's rule.) The spectrum, which is due to transitions between the s and p states, appears as a triplet as indicated in the lower portion of Figure 1. (The normal-effect triplet for the s–p transition is named after Lorentz, who described the effect in terms of his theory of electrons. Lorentz's explanation helped to support the notion of orbiting electrons in atoms.)

As indicated in the introduction, the normal effect is the result of the interaction between the magnetic moment due to the orbiting electron and the external field. From electromagnetic theory, the magnetic moment due to an electron circulating in a closed loop and having angular momentum $\boldsymbol{l}$ is,

$$\boldsymbol{\mu}_l = \frac{-e}{2m_eC}\,\boldsymbol{l}, \tag{2}$$

where $-e$ is the electron charge, m_e is the electron mass, and c is the speed of light. (Unless otherwise noted all quantities are expressed in cgs units.) The interaction energy follows from Eq. (1),

$$W = \frac{e}{2m_eC}\,\boldsymbol{l}\cdot\boldsymbol{B}. \tag{3}$$

According to quantum mechanics the projection of $\boldsymbol{l}$ about an axis, here the magnetic field axis, assumes discrete values $m_l\hbar$, where m_l is an integer that ranges between $+l$ and $-l$. The expression for the interaction energy is, thus,

$$W = m_l\mu_0\,|\boldsymbol{B}|, \tag{4}$$

where μ_0 is the Bohr magneton constant defined by,

$$\mu_0 = \frac{e\hbar}{2m_ec} \simeq 1.4 \times 10^6 \text{ Hz/Gauss.}$$

The triplet spectrum in Figure 1 is thus completely described given that m_l for the p state has values +1, 0, and −1, while m_l for the s state has the value 0.

It happens that the normal effect does not actually occur for ordinary one-electron atoms because of the complication of electron spin.

The discussion above is thus strictly correct only if one assumes that the electron has no intrinsic magnetic moment of its own. The triplet does occur, however, in certain many-electron atoms (e.g., helium) where because of pairing of spins, the effects of intrinsic moments can be ignored.

Anomalous Zeeman Effect. Figure 2 diagrams examples of the anomalous Zeeman effect on a number of different atomic transitions. (One-electron atoms fall into the doublet category.) It is evident that the structure of the anomalous effect is more complicated than that of the normal effect. In addition, the field dependence is also more complicated. In weak fields, the levels separate linearly with the strength of the applied field as they did for the normal effect; however, the rates of separation of levels are different than those observed for the normal effect. In moderate fields, the levels shift in a complicated way that is not easily described by any simple power law. In strong fields, the levels again shift in proportion to the field strength but this time with rates of separation that are the same as those of the normal effect.

The anomalous effect was a mystery until 1925 when S. Goudsmit and G. Uhlenbeck introduced the concept of electron spin. Electron spin was conceived to explain why the fine structure separation of the ^2P levels of alkali metal atoms were so much larger than the corresponding levels of hydrogen. Goudsmit and Uhlenbeck suggested that electrons have both an intrinsic angular momentum and an intrinsic magnetic moment. Following this assumption, the fine structure splitting was shown to be the result of the magnetic interaction between the intrinsic magnetic moment of the electron and an internal magnetic field produced by the electron's orbital motion. This effect is referred to as the spin-orbit interaction. (Note that the spin-orbit effect in many-electron atoms is much more difficult to model because one must consider the magnetic couplings of all of the electrons with each other. These include, for example, the interaction between the magnetic field produced by the orbit of one electron with the magnetic moment of another electron. The problem is sufficiently complex that even sophisticated modern techniques have failed to reliably calculate the absolute magnitude and, in certain extreme cases, the sign of the spin-orbit interaction for the bulk of the atoms in the periodic table.)

Given the postulate of spin to explain fine structure, it became evident that spin could also be used to explain the anomalous effect. The only way that it was possible to reconcile both effects, however, was to assume that the maximum projection of the intrinsic angular momentum of an electron was $\hbar/2$ and that the intrinsic electron magnetic moment was,

$$\boldsymbol{\mu}_s = g_e \frac{-e}{2m_e C} \boldsymbol{s} \qquad (5)$$

where $\boldsymbol{s}$ is the electron spin angular momentum and g_e is an arbitrary factor added to preserve the form of the classical relationship between magnetic moment and angular momentum [Eq. (2)]. Early agreement with experiment was obtained by guessing that $g_e = 2$. (The Dirac equation, which combines quantum mechanics and relativity, justifies the ersatz of Eq. (5) and pre-

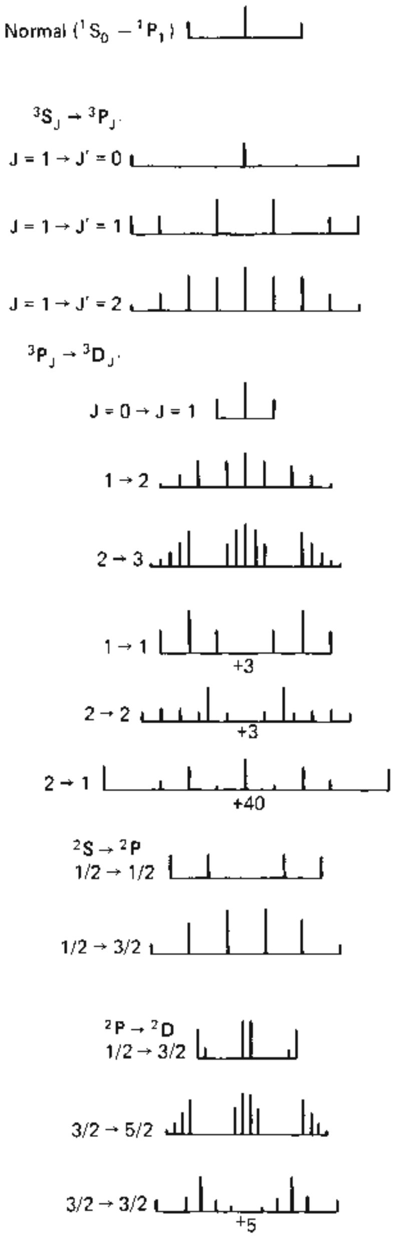

FIG. 2. Anomalous Zeeman spectra for numerous transitions. The normal Zeeman spectrum is shown for comparison. (After Condon and Shortley, 1971.)

dicts that g_e is exactly two. It is now known that g_e has a value that is a fraction of a percent larger than two. One of the important successes of modern quantum electrodynamic field theory, which treats both particles and fields quantum mechanically, is the correct prediction of this constant.)

With the introduction of electron spin it is straightforward, although nontrivial, to explain shifts associated with the anomalous effect. The energy of the quantum state of a one-electron atom follows from the expression for the interaction energy between a magnetic moment and an external field,

$$W = -(\boldsymbol{\mu}_l + \boldsymbol{\mu}_s) \cdot \boldsymbol{B} + a\boldsymbol{l} \cdot \boldsymbol{s}. \qquad (6)$$

The additional term here, $a\boldsymbol{l} \cdot \boldsymbol{s}$, represents the spin-orbit interaction. In the absence of external fields the spin and orbital angular momenta are coupled by the spin-orbit term such that the conserved quantity is $\boldsymbol{j}$, which is defined as the sum of $\boldsymbol{l}$ and $\boldsymbol{s}$, that is,

$$\boldsymbol{j} \equiv \boldsymbol{l} + \boldsymbol{s}. \qquad (7)$$

The complete characterization of the anomalous effect is complicated because the external field interaction affects the internal coupling of $\boldsymbol{l}$ and $\boldsymbol{s}$. In light of this, only the weak and strong field cases, which are the two cases most easily described, are to be considered. These two cases represent the extreme situations where $\boldsymbol{l}$ and $\boldsymbol{s}$ are either completely coupled or completely decoupled.

In weak fields, where the interaction terms in Eq. (6) due to the external field are small compared with the spin-orbit term, $\boldsymbol{l}$ and $\boldsymbol{s}$ are completely coupled. In this case the dominant contribution of the magnetic moment is due to the portion of the moment that is parallel to $\boldsymbol{j}$. (Since $g_e \neq 1$, the magnetic moment does not point along $\boldsymbol{j}$. As a consequence of the coupling, however, the contribution of the portion not parallel to $\boldsymbol{j}$ is generally negligible.) Therefore the net effective magnetic moment is

$$\boldsymbol{\mu}_j \simeq g_j \frac{-e}{2m_eC} \boldsymbol{j}, \qquad (8)$$

where the expression for g_j,

$$g_j = 1 + \frac{j(j+1) + s(s+1) + l(l+1)}{2j(j+1)}, \qquad (9)$$

is derived from angular momentum coupling relations assuming $g_e = 2$. Here j, s, and l are the maximum projections of $\boldsymbol{j}$, $\boldsymbol{s}$, and $\boldsymbol{l}$ in units of $\hbar$. Eq. (9) was obtained first empirically by Landé in 1921 based on studies of the experimental data of Back. (Landé's observations extended the earlier rule of Runge, which expressed the fact that the weak-field anomalous effect splittings are related to the normal effect splittings by a rational fraction.) With the above value for $\boldsymbol{\mu}_j$, the interaction energy for the weak-field anomalous effect according to Eq. (1) is,

$$W \simeq m_j g_j \mu_0 \, |\boldsymbol{B}|, \qquad (10)$$

where m_j is an integer or half-integer ranging from $+j$ to $-j$ in unit steps. (Besides explaining this aspect of the anomalous effect, the comparison between the quantum mechanical derivation of g_j and the empirical results of Landé served to show that the norms (lengths) of the vectors $\boldsymbol{l}$, $\boldsymbol{s}$ and $\boldsymbol{j}$ were $\sqrt{l(l+1)}\,\hbar$, $\sqrt{s(s+1)}\,\hbar$, and $\sqrt{j(j+1)}\ \hbar$ rather than $l\hbar$, $s\hbar$, and $j\hbar$ as predicted by the Bohr model.)

In strong fields, where the interaction terms in Eq. (6) due to the external field are large compared with the spin-orbit term, $\boldsymbol{l}$ and $\boldsymbol{s}$ are completey decoupled. The decoupling of $\boldsymbol{l}$ and $\boldsymbol{s}$ by the field is referred to as the *Paschen–Back effect*. As a result of the Paschen–Back decoupling, $\boldsymbol{l}$ and $\boldsymbol{s}$ are separately conserved so that the interactions associated with the orbital and spin moments contribute separately. Thus the expression for the strong-field anomalous effect is,

$$W \simeq (m_l + g_e m_s)\, \mu_0 \, |\boldsymbol{B}|, \qquad (11)$$

where m_s is an integer or half-integer that ranges from +s to −s in unit steps.

The weak and strong field cases are best summarized by means of an example. In Figure 3 the anomalous Zeeman effect of a ^2P level is shown. In zero field, where $\boldsymbol{l}$ and $\boldsymbol{s}$ are coupled, there are two groupings of sublevels which correspond to states having $j = \frac{3}{2}$ and $j = \frac{1}{2}$. In weak fields, all of the j groupings split up according to their m_j values. The relative slopes of the levels are governed by the values of $g_j\mu_0$, which for $j = \frac{3}{2}$ is $4\mu_0/3$, and for $j = \frac{1}{2}$ is $2\mu_0/3$. In strong fields there are five groupings of sublevels which separate with relative slopes of μ_0. In intermediate fields the low and high field states connect smoothly with one another.

Up to this point the effect of the intrinsic magnetism of the atomic nucleus has been ignored. This is not a major omission, since nuclear moments are typically a few thousand times smaller than electronic moments. (This is due primarily to the differences in mass between nucleons and electrons.) The intrinsic nuclear moment enters into the anomalous effect in a way that is completely analogous to that in which the intrinsic electronic moment did. Here, instead of $\boldsymbol{l}$ and $\boldsymbol{s}$ coupling to form $\boldsymbol{j}$, we have $\boldsymbol{j}$ and the nuclear spin angular momentum $\boldsymbol{i}$ coupling to form $\boldsymbol{f}$. The coupling is the result of the interaction between the magnetic moment of the nucleus and the magnetic field produced both by the orbital motion and the intrinsic magnetism of the electrons. The so-called hyperfine splitting associated with this interaction leads to an energy term proportional to $\boldsymbol{i} \cdot \boldsymbol{j}$.

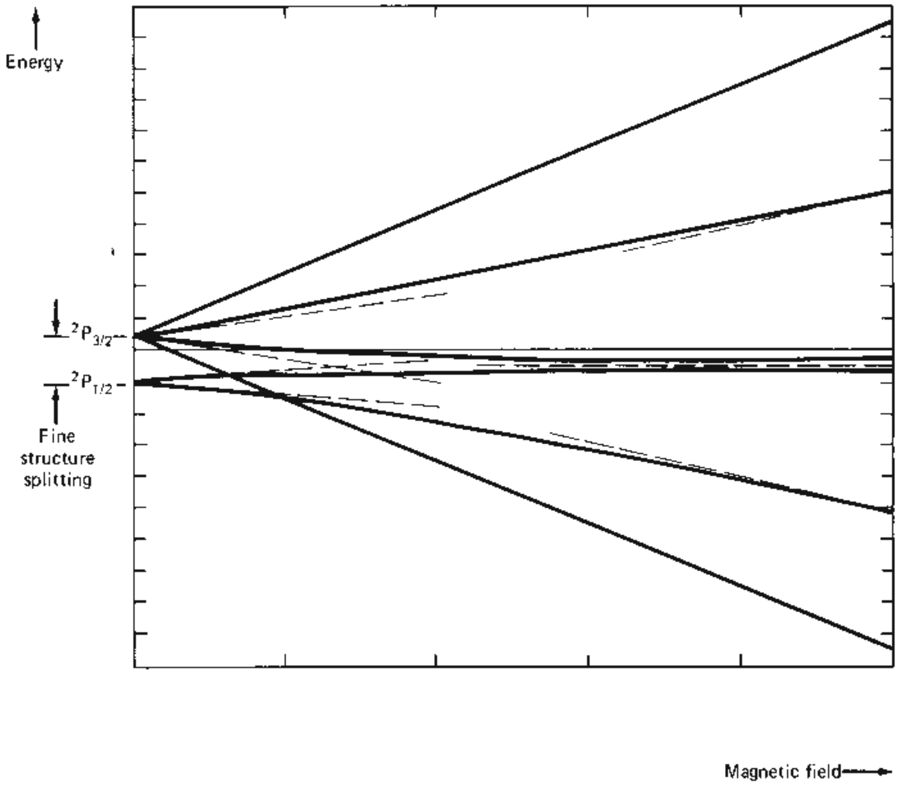

FIG. 3. The energy level diagram for ^2P level, showing anomalous Zeeman effect in weak to strong external fields. (After Condon and Shortley, 1971.)

As with the case involving electron spin, there are two field regimes in which nuclear spin effects are easily described, that is, the weak field regime and the strong field regime. In weak fields a Landé-like g-factor is introduced, g_f, and the levels split up according to values $g_f m_f$. Likewise, in strong fields i and j are decoupled such that the interactions associated with the nuclear moment and the electron moment contribute separately and the levels shift according to their values of $g_j m_j$ and $g_i m_i$. The strong field decoupling is the Back–Goudsmit effect, which is the analog of the Paschen–Back effect.

The complete picture of the anomalous effect now is that as the field increases from zero the contributions to the magnetic moment change from the case where l, s, and i, are completely coupled, to that where l and s are coupled but not i, to the final case where l, s, and i are completely decoupled.

Diamagnetic Effect. Even when all the angular momenta are zero so that there is no orbital or intrinsic magnetic moment, there is still a shift due to external fields. The shift is quadratic in its dependence on field strength and corresponds to an increase in internal energy. The effect is due to an induced moment and the increased energy indicates that the moment opposes the field. The opposition to the field means that this effect is inherently diamagnetic.

The diamagnetic shift can be understood simply as the result of the Larmor precession of an electron orbit when a magnetic field is applied. Here we consider the effect on an electron in a circular orbit. Larmor precession of the frame of reference due to the external field ($\omega_L = eB/2\ m_e C$) leads to a change in the orbital velocity of the electron when viewed in the laboratory frame. The changed orbital velocity results in a change in the net magnetic moment of an amount

$$\Delta\mu = -\frac{e^2 A}{4\pi m_e c^2}\,\mathbf{B}. \qquad (12)$$

where A is the orbital area projected on the plane perpendicular to $\boldsymbol{B}$. It is a bit surprising that the change in the moment is not dependent on the direction of electron circulation. (This fact is actually connected with Lenz's law of electromagnetism which expresses the tendency of electrical conductors to set up countercurrents that produce fields which oppose an externally applied magnetic field.) The energy shift due to diamagnetism follows from Eq. (12) by integrating the differential form of Eq (1) to give,

$$W = \frac{1}{2}\,\frac{e^2 A}{4\pi m_e c^2}\;|\mathbf{B}|^2. \qquad (13)$$

The magnitude of the interaction energy associated with the diamagnetic effect can be estimated for an arbitrary state of principal quantum number n, by recognizing that the orbital area for a typical atom is $\pi(n^2 a_0)^2$, where a_0 is the Bohr radius, 0.5×10^{-8} cm. Thus according to Eq. (13) a frequency shift of $1.3 \times 10^{-4} n^4 |\boldsymbol{B}|^2$ Hz is expected. (For 100 kG the $n = 1$ level is expected to shift 1.4 MHz. For the ground ${}^1S$ level of helium the observed shift is 2.4 MHz. Given that there are two $n = 1$ electrons in helium, 2.8 MHz might be expected. The agreement here is remarkably good.) The n^4 scaling of this effect means that for states of high n, the diamagnetic shift can be significant, especially in view of the fact that the Zeeman shifts due to the orbital and intrinsic moments are independent of n. The large relative size of the diamagnetic shift is one of the reasons that modern laser spectroscopists have studied this effect in the context of highly excited atoms.

Current Status. In recent years the Zeeman effect has received renewed interest due to the development of new experimental and theoretical techniques. One aspect of the problem that has received most of the recent attention is the case where the external fields cannot be considered as weak in comparison to the internal Coulomb field. This situation has been realized in the laboratory through the use of intense magnetic fields and high states of atomic excitation. It also occurs naturally in the atmospheres of certain collapsed stars for low states of excitation.

In a classic series of experiments on photoabsorption to the continuum (i.e., photoionization) by R. Garten and F. Thompkins, the transition from weak fields, where the electron is bound to the atom, to strong fields, where the electron is bound to the field, has been observed. The experimental evidence for the changeover from one regime to the other has been seen through the emergence of the so-called quasi-Landau resonances in the energy region near the threshold for photoionization. (A free electron in a magnetic field is bound in the plane perpendicular to the field axis by the Lorentz force. This binding gives rise to cyclotron orbits. Quantized cyclotron orbits are the basis for the discrete Landau levels.)

Considerable attention has recently been focused on measurements of the diamagnetic effect for highly excited atoms. One of the potentially important findings observed by Kleppner and co-workers are sharp crossings of sublevels. Such sharp crossings suggest the possibility of the existence of an unidentified symmetry of the magnetic field problem.

Spurred on by experiments such as the ones mentioned above, theorists have been making marked progress towards developing a general theory of magnetic effects in fields of arbitrary strength. The problem, however, is still far from being solved.

Stark Effect *Introduction.* The Stark effect is due to the interaction between the electric moment of the atom and the external electric field. The leading term to the interaction energy is,

$$W = -\mathbf{p} \cdot \mathbf{E}, \qquad (14)$$

where $\boldsymbol{p}$ is the electric dipole moment and $\boldsymbol{E}$ is the external field. Electric dipole moments in atoms arise as a consequence of the way that charge is distributed within atoms. In the following discussions two aspects of the Stark effect are to be considered: the linear effect and the quadratic effect. It will be shown that the linear effect is due to a dipole moment that arises from a naturally occurring nonsymmetric distribution of electron charge, while the quadratic effect is due to a dipole moment that is induced by the external field. For simplicity the effects of fine and hyperfine structure will be ignored.

Linear Stark Effect. Figure 4 diagrams the simplest case of the linear effect, that is, the transition from the ground level ($n = 1$) to the first excited level ($n = 2$) of atomic hydrogen. The excited level splits into three equally spaced sublevels under the influence of the external field. The spacings between sublevels increase linearly with the applied field. The central sublevels of $n = 2$ and the ground level do not shift in response to the field. (In the general case, an arbitrary n level splits into $2n - 1$ sublevels that separate in the field at a rate that scales with n. Thus the higher n states are more sensitive to the external field.)

As indicated above, the linear effect is the result of the interaction between the electric dipole moment due to the distribution of charge within the atom and the external field. The dipole moment can be understood by considering an eccentric elliptical orbit as shown in Figure 5. Here the nucleus is at one focus and the electron follows a Kepler orbit that sweeps out equal areas in equal times. It is evident that the further the electron is from the nucleus the slower it moves, and as a result the electron's position averaged over an oribt is not centered on the nucleus. The separation between positive and negative charge centers here necessarily leads to a dipole moment.

The size of the naturally occurring dipole moment corresponding to a highly eccentric orbit can be estimated, given that the mean radius of an atom in a state of principal quantum number n is on the order of $n^2 a_0$, where a_0 is the Bohr radius. Thus the dipole moment, which is the product of the charge and the charge separation, is $en^2 a_0$. This crude estimate is actually comparable with the observed moment

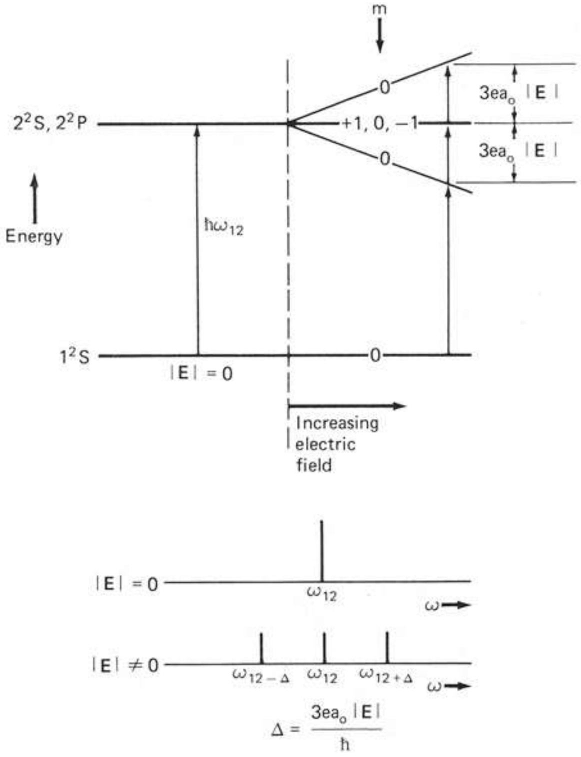

FIG. 4. Linear Stark effect for $n = 1$ to $n = 2$ transition. Above is energy level diagram; below is spectrum with and without external field.

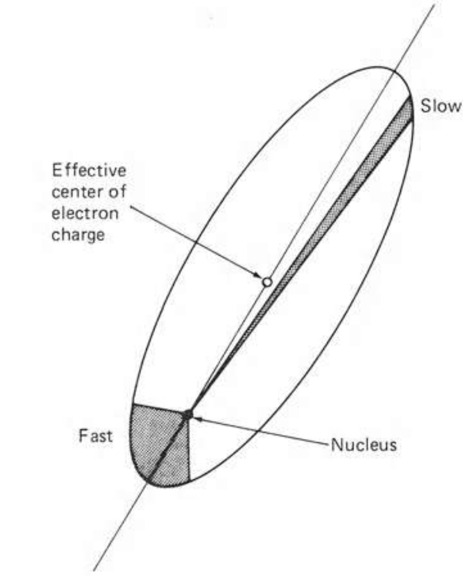

FIG. 5. Elliptical electron orbit. According to Kepler's law the electron is moving quickly when it is near the nucleus and slowly when it is far from the nucleus.

of the extreme-most Stark level, $3en(n - 1)a_0/2$. The general result according to nonrelativistic quantum theory is that the linear shift is

$$W = \tfrac{3}{2}\, enka_0, \tag{15}$$

where k is the electric quantum number, which ranges in value from $+(n - |m| - 1)$ to $-(n - |m| - 1)$ for all possible values of m, which ranges from $+(n - 1)$ to $-(n - 1)$.

The quantum mechanical predictions of charge distribution that correspond to the states described by Eq. (15) are most interesting. The charge distributions reveal parabolic symmetry. This symmetry is evident in Figure 6 from maps of the charge distributions corresponding to the eight $m = 0$ sublevels of the $n = 8$ level in atomic hydrogen. The ridges of charge are intersecting parabolas that open along and against the electric field axis. (This is most easily noted for the central states, $k = \pm 1$, which have the smallest dipole moments and correspond to nearly circular orbits.) The parabolic nature of the Stark problem is reflected in its usual analytical treatment, where the three-dimensional Schrödinger equation is separated into three one-dimensional equations in a parabolic coordinate system. (Incidentally, by comparison the magnetic field

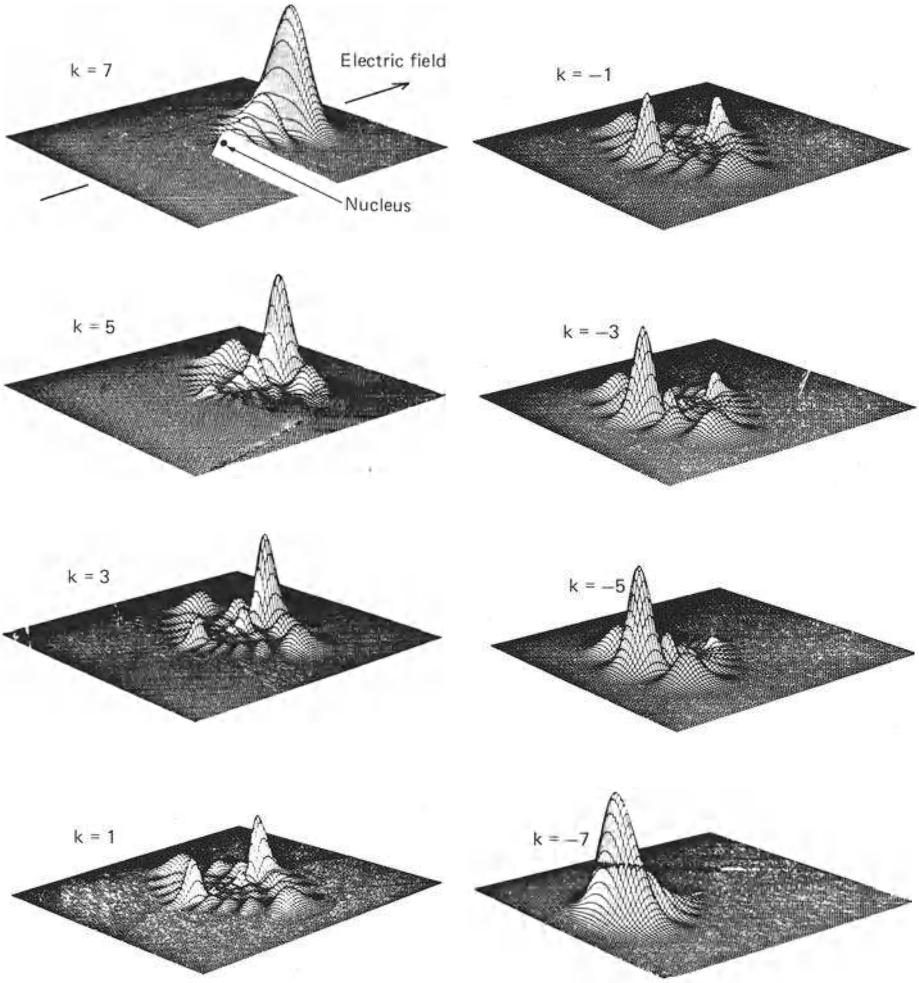

FIG. 6. Charge distribution for the eight $m_L = 0$ sublevels of the $n = 8$ level of hydrogen. The $k = +7$ and $k = -7$ sublevels are the extreme-most Stark states which display the largest dipole moments. The nucleus is in the center of the mesh. (Adapted from Kleppner, Littman, and Zimmerman, 1981.)

problem is more difficult to model analytically than the electric field problem because no similar separation of variables has ever been accomplished.)

Up to this point the discussion has concerned the linear effect for atomic hydrogen. More complex atoms also display linear effects, however, they can only do so when two or more states of different angular momentum have the same energy in zero field. Because of the high level of degeneracy in hydrogen this condition is met for all excited levels. In complex atoms, this condition is usually met only for the high angular momentum states. Isolated angular momentum states of a well defined parity cannot display linear shifts because of their inversion symmetry. (This is because the charge distribution must be the same when $\boldsymbol{r}$ is relaced by $-\boldsymbol{r}$ so that the center of electron charge for these states must coincide with the nucleus.)

The linear Stark effect has the distinction of being the first problem to which the well known perturbation method was applied. (Perturbation theory allows for the approximation of a solution of one problem in terms of an expansion of the solutions of another.) In this first application, the wavefunction for an atom in an electric field was expressed in terms of an expansion of wavefunctions for an atom in the absence of external fields. The linear shift was given by the first order term in the expansion for the energy.

Quadratic Stark Effect. For states with no linear shift, such as the ground state of hydrogen, there is still a shift due to external fields. The shift is quadratic in its dependence on field strength.

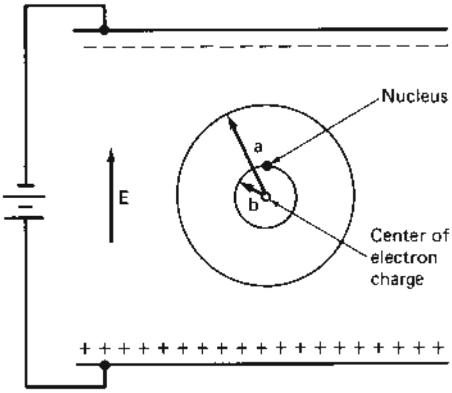

FIG. 7. The idealized effect of an external field on a uniform spherical charge distribution of radius *a*. The electron cloud and the nucleus separate by distance *b*. (After Purcell, 1965.)

As was the case with the quadratic shift in magnetic fields, the quadratic shift in electric fields is due to an induced moment. The induced moment can be understood by considering the external field effect on a uniform sphere of negative charge centered on a positive nucleus. The external field pulls the positive and negative charges in opposite directions which sets up an opposing force due to the displacement of charge centers. The magnitude of the displacement can be estimated by imposing the condition that the two forces be balanced. Figure 7 depicts the situation here. The charge outside of the inner sphere of radius b does not contribute to the net attractive force because the field inside a uniform spherical shell is zero. (This is the same phenomenon that causes the gravitational field at the center of the earth to be zero.) Thus, only the charge inside the inner sphere contributes. The amount of charge inside is $e(b^3/a^3)$, so that the force balancing condition is

$$e|\mathbf{E}| = \left(e\,\frac{b^3}{a^3}\right)\frac{e}{b^2}\,, \qquad (16)$$

or alternatively,

$$|\Delta \mathbf{p}| \equiv eb = a^3\,|\mathbf{E}|. \qquad (17)$$

Thus the strength of the induced dipole moment is roughly proportional to the field strength times the volume of the charge cloud. (The constant of proportionality is known as the *scalar polarizability*.) Given this expression for the induced moment, the interaction energy is obtained by integrating the differential form of Eq. (14), which gives

$$W = \tfrac{1}{2}\,a^3\;|\mathbf{E}|^2. \qquad (18)$$

The magnitude of the interaction energy associated with the quadratic effect can be estimated given that the mean radius for an arbitrary state of principal quantum number n is n^2a_0. Thus, according to Eq. (18), a frequency shift of $11.2n^6\;|E|^2$ Hz is expected, where $|E|$ is in units of stat-Volt/cm. For the ground state of hydrogen this estimate is low by a factor of 5, but for highly excited states it is correct to within a few percent.

At this point an example is appropriate. The linear and quadratic shifts that have been discussed thus far are evident in the laser spectroscopic data of sodium excited states near $n = 15$, as shown in Figure 8. The levels which enter from above and below here correspond to states from neighboring $n = 14$ and $n = 16$ levels. The grouping of states near the $15d$ level corresponds to the $n = 15$ high-angular-momentum states, and these display linear shifts. The $16p$ level, on the other hand, is far from any other states of differing angular momentum, and so it displays a quadratic shift.

Current Status. In recent years the Stark effect has received renewed interest due to the development of new experimental and theoretical techniques. Much of the recent interest has been in the situation where the external fields are comparable or stronger than the internal fields that hold the atom together. This condition has been realized in the laboratory through the use of fields of moderate strength and high states of excitation.

One of the interesting effects of intense fields on atoms that has received recent study is the field-induced ionization of the neutral atom. Field ionization is interesting because the purely quantum mechanical effect of tunneling is known to play an important role. One of the significant observations of recent field ionization studies is that the ionization threshold for virtually all complex atoms occurs near the threshold energy that one would predict classically.

Another topic that has received recent attention is the lack of rigorous convergence of the Stark perturbation expansion. The convergence difficulty is connected to the fact that, in the presence of an electric field, bound states do not strictly exist because of a finite probability that any given state will spontaneously ionize via tunneling. (This problem is most important in strong fields.) Using a technique developed by Leibnitz and a digital computer, H. Silverstone and co-workers have calculated the perturbation expansion to 150th order and demonstrated explicitly the nature of the divergence. They also have shown how the convergence can be improved using the technique of Padé approximants.

Yet another topic that has drawn much attention is the observation of oscillations in the photoionization spectrum of an atom in an electric field. Here R. Freeman and co-workers have

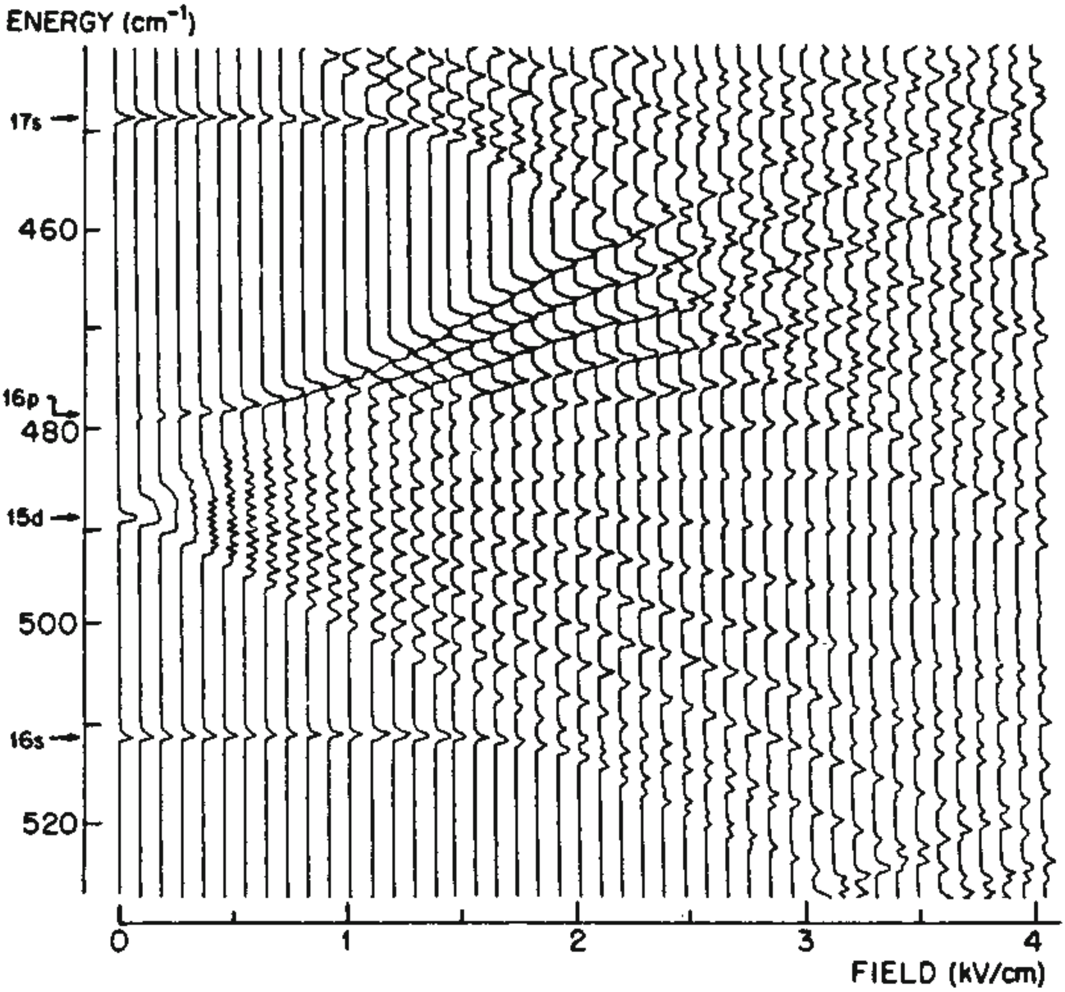

FIG. 8. Spectroscopic study of Stark effect on excited levels of sodium near $n = 15$. This is a composite map of data accumulated at many different values of applied field. [From M. G. Littman, M. L. Zimmerman, T. W. Ducas, R. R. Freeman, and D. Kleppner, *Phys. Rev. Lett.* 36, 788 (1976).]

studied what appears to be the electrical analog of the quasi-Landau levels discussed previously (see the section of this article on Zeeman Effect—Current Status).

In spite of the fact that the Stark effect is an old topic, recent activity has shown that the area is indeed still vital.
