Consider now the case of electrons moving freely ($\omega_0 = 0$) in a crystal-lattice background—while being cognizant of the fact that, except for a change in the sign of θ, similar results hold for positive carriers such as, for example, holes in the valence band of semiconductors. Then the Drude model leads to[3]

$$\epsilon_\pm = \epsilon_l - [\omega_p{}^2/\omega(\omega \pm \omega_c + i\nu)], \qquad (4)$$

where $\epsilon_l = n^2$ is the (real) dielectric constant of the lattice. It follows that, if ω is much larger than the other three frequencies, the Drude model leads to

$$\theta = d\omega_c\omega_p{}^2/2cn\omega^2. \qquad (5)$$

Thus θ is proportional to the magnetic field B and also to m^{-2}, making clear how a measurement of θ can determine the effective mass m. This formula is also used to determine galactic magnetic fields from observations, over a range of frequencies, of the Faraday rotation associated with polarized radio waves from such objects as pulsars.[6] Estimates of primordial magnetic field values have also been made from observations of the θ of a distant extragalactic radio source.[7] Furthermore, a measurement of the Faraday rotation of radio waves emitted by artificial satellites and transmitted through the ionosphere can be used to measure the electron density along the path.[8] Turning to the question of how much antimatter there is in the galaxy, we note that positrons and electrons cause rotations in opposite directions. But polarized light traversing the interstellar medium does suffer Faraday rotation, demonstrating that there are not comparable numbers of electrons and positrons. In fact, when these results (which in essence give the difference in the number of electrons and positrons) are combined with dispersion measures (which depend on the sum of the number of electrons and positrons), it is found that the number of positrons is negligibly small.[9]

In the case where ω_c is much greater than the other three frequencies (high-field, low-frequency approximation),

$$\theta = -d\omega_p{}^2/2cn\omega_c, \tag{6}$$

i.e., θ is now negative, and it is proportional to B^{-1} and independent of ν again and also ω. Also if $\omega_p \ll \omega$ then a zero in θ occurs[10] at a photon frequency $\omega = (\omega_c{}^2 + \nu^2)^{1/2}$, which can lead to a determination of ν. If $\nu \gg \omega$, $\omega_c \gg (\omega_p/n)$ then we get the *low-frequency Faraday rotation*

$$\begin{aligned}\theta &= -d\omega_c\omega_p{}^2/2cn\nu^2 \\ &= -2\pi d\sigma_0\mu B/c^2 n,\end{aligned} \tag{7}$$

where $\mu = e\tau/m$ is the carrier mobility and $\sigma_0 = ne^2\tau/m$ is the static conductivity. Since the latter expression for θ does not contain m or ν explicitly, one can use known values of σ_0 and the other parameters to deduce the mobility of charge carriers from a measurement of θ.

In strong magnetic fields, account must be taken of the fact that electron energies in a magnetic field are confined to discrete *Landau levels* and, in the case of interband transitions, this gives rise to oscillatory effects in the Faraday rotation, while there is evidence for a contribution also from exciton transitions. In general, there are other complications[3] which are sometimes of importance. For example, the collision frequency ν can be frequency- and magnetic-field dependent. Also, in polar semiconductors there is a contribution from optical lattice vibrations to the dielectric tensor.

In the case of thin samples, multiple reflections can play an important role with an attendant increase in the complexity of the analysis.[11,12] An example of where such multiple reflections play a role[13] is the *two-dimensional electron space-charge layer* (the motion being quantized in one direction whose effective width is negligible compared to the wavelength of the transmitted radiation), which is formed in various modern microelectronics systems, such as at the semiconductor surface in a metal-oxide-semiconductor (MOS) system. There is also a contribution to θ due to boundary effects in the transmission of radiation through different material. In the case of metals, the usual method of observing θ in transmission is not convenient except for very thin films because metals are very good reflectors in the visible and infrared regions. As an alternative, θ is measured on reflection (the *polar reflection Faraday effect*) and gives information on the electron band structure of nonferromagnetic metals.

The advent of high-intensity laser radiation has motivated the inclusion of various nonlinear terms into the laws of optics. In particular, the Faraday effect is intensity dependent, especially in a strong magnetic field.[14] A closely related phenomenon is the *inverse Faraday effect*, i.e., the magnetization of the medium by intense polarized radiation,[15] which has been suggested as the basis of a nondemolition optical quantum counting measurement.[16]

Faraday rotation has also been used as a diagnostic tool to study and measure the large magnetic fields which are produced both in controlled thermonuclear fusion plasma and in laser-produced plasma,[17] as well as being one of the first phenomena to be studied by the megagauss magnetic fields which are being increasingly produced in many laboratories.[18]

All of the effects discussed so far depend on the dielectric tensor and arise from the interaction of the charge carriers with the electric field of the electromagnetic wave and, in addition, the spatial dependence of the electric field is generally neglected (electric dipole approximation). However, for magnetic materials the Faraday rotation depends on the magnetic permeability tensor. In ferromagnetic metals very large rotations occur which are proportional to the net magnetization and not to the external magnetic field.[19,20] Thus the rotation per cm in a magnetic field of 10^4 gauss is of the order of 2 degrees in quartz, 10^2 degrees in aluminum and 1.3×10^5 degrees in iron. The large value of the latter rotation arises from a spin-orbit interaction: the magnetic moment of an electron, due to its spin, interacts with the magnetic field which arises by virtue of its motion through the electric field created by the nuclei and all the other electrons in the absence of radiation. This phenomenon is often called the *ferromagnetic Faraday effect* and refers to the transmitted beam, whereas effects associated with reflection from a ferromagnetic material are called *polar Kerr magnetooptic effects*. In a certain sense the spin-orbit interaction can be looked on as the effect of a large internal magnetic field acting on the electrons. Also, the role of the external magnetic field is peripheral in that it serves only to magnetize the sample in a certain direction. It should also be mentioned that there is also a contribution from spin-orbit effects in nonferromagnetic material, albeit small compared to the situation for ferromagnetics.

Absorption in the metallic ferromagnets is very large except in the case of very thin films. On the other hand, ferrimagnetic substances are particularly good magnetooptical materials because they combine the low absorption of a good insulator with high permeability. For example, yttrium iron garnet (YIG) is transparent in the optical region and also gives rise to a large Faraday rotation which makes it an excellent material for the observation of magnetic domains. In fact, measurements of θ can be used to measure several macroscopic magnetic properties of thin rare earth garnet films which are used for magnetic bubble devices.[21] Ferrimagnetic materials are used extensively in microwave technology,[22] their importance stemming from the fact that they can be used to make Faraday isolators which permits a signal to be transmitted with low attenuation in one direction but causes the reflected signal to be highly attenuated. Thus, for example, this permits the decoupling of an oscillator from a measuring system. Similar devices have also been used in laser systems.[23] At higher frequencies it turns out that antiferromagnetic materials perform better.

FEEDBACK

The concept of feedback lies at the heart of modern systems theory and control engineering. The term itself seems to have been used for the first time in a technical sense in 1920,[1] and refers to the return or feedback of system output signals to the inputs in order to improve or change the behavior of the system. A very simple example is the control of a heating system by using a bimetallic strip (Fig. 1). The system output is heat, the input the voltage across the heating element. When the desired temperature (the *set-point*) is reached the heat causes the bimetallic strip to deform sufficiently to switch off the heating element. As the temperature falls back below the set-point the strip returns to its original shape, contact is reestablished, and the heater switches on again. A second illustrative example may be found in the flyball governor (attributable to Sir James Watt) and used to control steam engines (Fig. 2). As more steam is fed to the engine the shaft

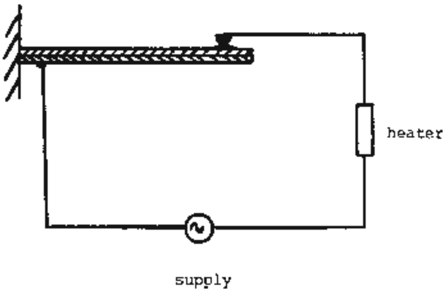

FIG. 1. Simple bimetallic strip heating control.

accelerates and the centrifugal forces generated are used to reduce the amount of steam made available, notice here the importance of *negative* feedback—as the output exceeds the set-point the input signal is decreased and vice-versa. If the governor had been incorrectly installed so that the steam supply increased with increasing velocity (*positive* feedback) the resulting instability would have destroyed the steam source or engine or both. The governor acts as a regulator. If the load is increased the speed of the shaft will initially decrease but with negative feedback the governor will then increase the steam supply pressure to restore the speed close to its nominal value. This illustrates one of the most important uses of feedback, namely to reduce the sensitivity of the controlled variable to disturbances made to the system. Even earlier examples of such regulation are mechanical clocks and lift tenters designed to regulate the grinding of corn. A detailed discussion of the mechanisms used in centrifugal governors and of the early history (up to 1930) of control engineering may be found in Ref. 1.

The true birth of feedback control in the analytical as well as the practical sense can perhaps be pinpointed to the publication of Nyquist's seminal paper of 1932,[2] which arose from an attack on the problem of feedback amplifier stability. The three succeeding decades saw the emergence of what is now considered the classical theory of control as a coherent discipline which held and continues to hold a pivotal position in a world of increasing technical complexity and automation. The classical results, including the stability criteria and design techniques of Nyquist, Bode, and Nichols, are concerned primarily with linear systems having a single control input and a single output. The interested reader can do no better than consult Refs. 3, 4, or 5 or any other of the excellent introductory textbooks available on the subject. The historical perspective has been discussed by Macfarlane.[6]

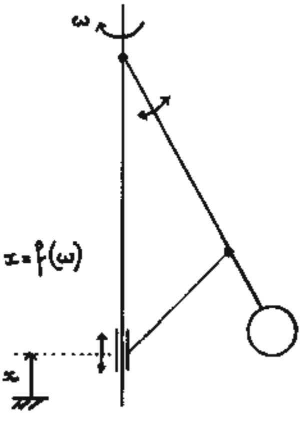

FIG. 2. Simple governor.

From the early 1960s system complexity increased exponentially and various problems arose which were not amenable to the classical methods of feedback design. Many practical systems have not one, but many inputs and outputs, and these exhibit varying degrees of interaction with a signal to one input causing responses on several outputs. For example, the adjustment of the wing flaps of an aeroplane will cause a change in the direction of flight, but will also cause the aircraft to bank, and a change in the set-point of one of the propulsion units of a jet foil will cause changes in the roll, pitch, and yaw motions of the vessel. Implementation of classical single-loop controllers on such systems frequently leads to stability problems traceable to this interaction, and hence Rosenbrock, Macfarlane, and others[7,8] produced extensions of the classical techniques to allow the design of *multi-input*, *multi-output* (MIMO) *feedback systems*. Unlike the earlier methods these are in no sense "pencil and paper" techniques; they usually require the use of computer graphics terminals and extensive, interactive, computer-aided design programs. They resemble earlier work, however, in that they present information concerning system dynamics in a graphical form easily interpreted by the practiced engineer.

Most analysis and design techniques require that the system to be controlled be linear, and that a linear controller be used. However, many practical systems are highly nonlinear, and the design of a nonlinear controller, such as the bimetallic strip in the heating control, can lead to a particularly elegant solution to a control problem. Analysis and design of *nonlinear feedback systems* can be difficult. However, the stability theorems of Liapunov[9] have provided a basis for the development of techniques such as the cricle criteria[8] which allow analysis and design of a restricted set of nonlinear feedback systems using traditional frequency domain techniques for both single-input-single-output and multivariable systems. Although closed loop stability can be guaranteed by such methods, design tends to be conservative, and in practice there has been some success in the application of approximate methods such as the describing function[10] whereby a nonlinear element is replaced by a set of equivalent linear elements for a set of specified input signal amplitudes.

Another area of increasing importance is that of *adaptive* or "*self tuning*" *feedback*. This has been an identifiable topic in the literature of control engineering for at least the last two decades, although the majority of practical applications are of relatively recent date. Adaptive techniques have been mainly concerned with classically structured feedback systems, the word *adaptive* signifying that the controller "learns" about the controlled process while at the same time controlling its behavior. It is thus expected that control will improve with the passage of time and further that the control will be robust in the presence of minor variations in the parameters of the controlled process and its environment. In crude terms the controller may be described as one which "learns from its own mistakes" and may thus be regarded as having some degree of intelligence. To date the majority of applications have been in nonlinear, stochastic systems. A good overview of both theory and application may be found in Ref. 11.

The work described above is concerned with the design of feedback systems; the hardware used to implement the controllers clearly varies from application to application, but it is of interest to note that virtually every area has been affected by the availability of inexpensive microprocessors. The availability of such computers as control elements allows much greater flexibility in the design of controllers. The use of a digital controller however causes additional delays around the feedback loop because of finite sampling rates, computation times, and digital-to-analog conversion times. Designs are generally undertaken either directly on the discrete systems model[12] or via a design of a controller for a continuous system.[13] Sampling rate, wordlength, and computer algorithm need to be carefully chosen for successful design.

Currently one of the most exciting applications of feedback is in the rapidly growing area of *robotics*. One method of increasing the industrial applicability of robotic devices is to give them the capability of sensing their environment via simple vision and touch systems. The robot gripper is frequently a useful location for such sensors. Signals from the sensor are processed to extract the relevant information, which is then passed to the robot control system, which in turn uses it to determine an optimal control strategy and thus obtain a degree of closed loop feedback.[14]

The impetus to understand and design feedback systems has come from all branches of engineering, in particular electronic and mechanical engineering. However, the concept of feedback has much wider scope than this. In particular, biological systems have very successfully used feedback for millions of years. Attempts have also been made to model ecological and economic systems in order to gain further understanding of these complex feedback systems and to be able to apply appropriate control to modify their behavior.

FERMI-DIRAC STATISTICS AND FERMIONS

Solid metals are good conductors of heat and electricity because about one electron per atom is free to migrate through the volume of the conductor. These electrons were once thought to behave like gas molecules which obey Maxwell-Boltzmann statistics in which the number of particles at higher energies falls off exponentially according to a relation of the form

$$n_{E,T} = \frac{1}{e^{E/kT}}$$

where E is the energy, k the Boltzmann Constant and T the absolute temperature. This electron gas theory was qualitatively useful in explaining many metallic properties, but it was never quantitatively successful. One notable failure was its prediction that electrons should contribute to the specific heats of metals.

Bohr had shown that the electron in hydrogen is not free to assume any energy, but is restricted to certain permitted energies called quantum states or energy levels. When this quantum view of atomic electron structure was extended to more complex atoms, it was found that electrons obey the Pauli exclusion principle—only two electrons in any one atom having oppositely directed spin can occupy the same energy state. Thus in an atom with many electrons, no more than two can have the lowest permitted energy, no more than two may have the next higher permitted energy, etc. An unexcited atom with all its electrons in their lowest possible energy states includes many electrons whose energy is well above the energy of the lowest two. The old electron gas theory of metals recognized that the inner electrons associated with each atom were quantized but assumed that the electrons that were not bound to particular atoms were entirely free to migrate through the metal with no *a priori* restrictions on their energy. Fermi-Dirac statistics describes the behavior of the electron gas under the assumption that *all* electrons within the conductor have their energies quantized and obey the Pauli principle. This new viewpoint leads to a distribution of electron energies according to a relation of the form

$$n_{E,T} = \frac{1}{e^{(E-E_i)/kT} + 1}$$

where the new symbol, E_i, is a critical energy characteristic of the metal more fully described below. If the metal is at high temperature, this function approaches the Maxwell-Boltzmann distribution. We can see this by noting that if $T \to \infty$, the exponent of e approaches zero regardless of E. Thus, in both cases, the number of electrons of each energy tends to become uniform. The high-temperature electrons have so many states available to them that quantum restrictions make little difference. If we let the temperature approach absolute zero, the difference between these distributions becomes extreme. If T is very small, the Maxwell-Boltzmann distribution is strongly dependent on E with most particles having low E and few having high E. Indeed for $T = 0$, the number of particles with $E \neq 0$ becomes zero—in a Maxwell-Boltzmann gas all particles come to rest at absolute zero. A Fermi-Dirac gas behaves very differently at absolute zero. The exponent of e is plus or minus infinity depending upon whether E is greater or less than E_i. The exponential term is either infinity or zero. The denominator is either infinity or one. All energy states below E_i are filled whereas all those above E_i are empty. Thus, consistent with the assumptions, at absolute zero the electrons do not crowd into one state of zero energy but are uniformly distributed among those states which are below the critical energy E_i called the Fermi energy or the Fermi level. Fermi energies depend on the kind of metals but they are of the order of several electron volts. Thus, even at absolute zero, some electrons have energies which would be typical of a Maxwell-Boltzmann electron gas only if that gas were at several thousand degrees.

The contrast may be dramatized by the following analogy. If grains of sand are spilled on an open floor, they will spread out so they are only one deep and each has zero potential energy. If the grains are poured into a drinking straw, the straw will fill to a certain height and some grains will have considerable potential energy.

Heating a metal from absolute zero to room temperature adds only .025 eV to the average energy of its particles. Since the electrons already have a *much* greater average energy, heating a metal has but a slight effect on the energy distribution of the electrons. This accounts for the fact that electrons make a negligible contribution to the specific heats of metals, and it also explains why metals must be glowing hot before electrons acquire enough additional energy to escape from the metal surface as in the filaments of radio tubes. Since the quantum view of electrons in a metal provides both a qualitative and quantitative picture of many metallic properties, we know metallic electrons are quantized Fermi particles rather than unquantized Maxwell particles. The application of Fermi-Dirac statistics to semi-conductors accounts for their special properties as demonstrated by transistors.

From the standpoint of wave mechanics, all particles which are confined in any way are quantized. Those whose spin is integral have symmetric wave functions and do not obey the Pauli principle. If they are so numerous that they must be treated statistically, they are called *bosons* and are described by Bose-Einstein statistics. Photons are the most common bosons. Those particles whose spins are odd multiples of $\frac{1}{2}$ have antisymmetric wave functions and obey the Pauli principle. They are called *fermions* and obey Fermi-Dirac statistics. Although electrons are the most common example, protons, neutrons, and μ-mesons are all fermions with spin $\frac{1}{2}$. At high temperatures, the quantum nature of both bosons and fermions becomes insignificant and both obey the classical statistics of Maxwell-Boltzmann. The technique of deriving these distributions is called statistical mechanics.

To convey the over-all method of STATISTICAL MECHANICS, we note that it is a probability theory in which the basic technique is to compute the number of possible ways in which a system can arrange itself subject to restrictions as to the number and total energy of the particles. These ways are all assumed equally likely. (There are 52 factorial, 52!, different arrangements which might result from the shuffling of a deck of playing cards. Each is equally likely.) Then, depending on the nature of the particles, bosons or fermions, the number of distinguishable ways is computed. (In the game of bridge, there are many fewer deals $52!/(13!)^4$, than there are shuffles because the order in which a player receives his cards does not change his "hand.") The probability of any particular distinguishable distribution is proportional to the number of ways in which it can be achieved. (If we flip a coin five times, there are $2^5 = 32$ orders in which the coin can fall. Of these, there are ten ways to get two heads and only one way to get five heads. We therefore find getting two heads ten times more probable than getting five heads.) The actual expected distribution is the one which can be achieved in the largest number of ways.

FERMI SURFACE

The Fermi surface of a metal, semi-metal, or semiconductor is that surface of constant energy in momentum space which separates the energy states which are filled with free or quasi-free electrons from those which are unfilled. [Momentum space is defined in terms of three orthogonal axes, the components of the momentum vector, p_x, p_y, and p_z (or alternatively, the components of the wave vector, k_x, k_y, and k_z: $\mathbf{p} = \hbar\mathbf{k}$, where $\hbar$ = Planck's constant divided by 2π). The components of momentum of an electron at a given instant of time may be thought of as the coordinates of a point in momentum space which then moves about as various forces act on the electron.] The Fermi surface exists simply because the electrons obey Fermi-Dirac statistics.

Consider first an elementary model of a metal consisting of a lattice of fixed positive ions immersed in a sea of conduction electrons which are free to move through the lattice. Every direction of electron motion is equally probable. Since the electrons fill the available quantized energy states starting with the lowest, a three-dimensional picture in momentum coordinates will show a spherical distribution of electron momenta and, hence, will yield a spherical Fermi surface. In this free electron model, no account has been taken of the interaction between the fixed positive ions and the electrons; indeed the only restriction on the movement or "freedom" of the electrons is the physical confines of the metal itself.

A short derivation starting with the Schrödinger equation shows that the total energy of an electron (and thus also its kinetic energy) is given by

$$E = \hbar^2 k^2/2m = p^2/2m$$

where m is the mass of the electron. A plot of E against k is then a parabola, as shown in Fig. 1(a). The Cartesian components of those values of k which are possible solutions to the Schrödinger equation are $k_i = 2\pi n_i/L$, where the n_i's are integers and L is a physical dimension of the metal. Since for each energy value so defined there are actually two states (one for an electron with spin up, one with spin down), it can be shown that the density of energy states available to the electrons is

$$g(E) = \frac{(2m)^{3/2}}{2\pi^2\hbar^3} E^{1/2}$$

where $g(E)\,dE$ is the number of states in the energy range E to $E + dE$. Then $n(E)$, the number of electrons per unit volume occupying energy states in this energy range, is

$$n(E)\,dE = g(E)f(E)\,dE$$

where $f(E) = \{\exp\,[(E - E_f)/bT] + 1\}^{-1}$, a function characteristic of particles which obey Fermi-Dirac statistics. In this expression, T is the absolute temperature, b is Boltzmann's constant, and E_f is a parameter depending on the number of electrons involved and indeed turns out to be the Fermi energy. E_f can be evaluated by integrating $n(E)\,dE$ from $E = 0$ to $E = \infty$ and recognizing that the integral is equal to N, the total number of electrons per unit volume. The result (at $T = 0$ K) is

$$E_f = \frac{\pi^2\hbar^2}{2m}\left(\frac{3N}{\pi}\right)^{2/3}$$

At $T = 0$ K, for $E < E_f$, $f(E) = 1$, while for $E > E_f$, $f(E) = 0$. Physically this means that the probability of a state below the Fermi level

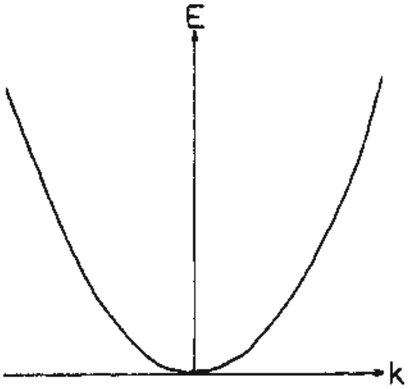

FIG. 1. (a) Energy plotted against wave number for the free electron model. (b) Energy plotted against wave number for the "quasi-free" electron model, showing energy discontinuities at Brillouin zone boundaries.

being occupied is one; whereas for states with $E > E_f$ the occupancy probability drops abruptly to zero. For temperatures greater than absolute zero, the occupancy probability drops smoothly from 1 to 0 in a range of energy of width approximately equal to bT. This shell of partially filled states gives rise to the following definition: The Fermi level is the energy level at which the probability of a state being filled is just equal to one half.

A numerical evaluation of the Fermi energy for a simple metal having one or two conduction electrons per atom yields a value of approximately 10^{-11} erg, or a few electron volts. The equivalent temperature, E_f/b, is several tens of thousands of degrees Kelvin. Thus, except in extraordinary circumstances, when dealing with metals, $bT \ll E_f$; i.e., the energy range of partially filled states is small, and the Fermi surface is well defined by the statement above. It must, however, be noted that this is not necessarily true for semiconductors where the number of free electrons per unit volume may be very much smaller.

The foregoing treatment gives a qualitative insight into the physics of metals and, under some circumstances, semi-metals and semiconductors. A more detailed analysis requires that the effects of the ions in the lattice be recognized. This can be accomplished by introducing the periodic potential due to the lattice through which the electrons must move. Then the electrons are no longer "free," but, depending on the strength and character of the potentials and the approximations used in solving the Schrödinger equation, act as "quasi-free" particles. Another approach is the "tight-binding approximation"; occasionally a combination of the two approaches is used. In any case, introduction of lattice effects changes the characteristics of the model; the total energy and kinetic energy of an electron are no longer equivalent. The periodic lattice can be described conveniently in terms of Brillouin zones, each of which is large enough (in momentum space) to accommodate two electrons per atom. The Brillouin zone boundaries appear to the electrons as Bragg reflection planes or energy discontinuities, resulting in an energy versus wave number plot as shown in Fig. 1(b).

For many metals, the "nearly free" electron description corresponds quite closely to the physical situation. The Fermi surface remains nearly spherical in shape. However, it may now be intersected by several Brillouin zone boundaries which break the surface into a number of separate sheets. It becomes useful to describe the Fermi surface in terms not only of zones or sheets filled with electrons, but also of zones or sheets of holes, that is, momentum space volumes which are empty of electrons. A conceptually simple method of constructing these successive sheets, often also referred to as "first zone," "second zone," etc., was demonstrated by Harrison.[1] An example of such a construction is shown in Fig. 2. This construction works quite well, for example, for aluminum which has three valence electrons per atom. Experiments, and indeed more elegant theoretical calculations, show that the fourth zone is totally unoccupied and that the third zone monster is not multiple-connected in the manner shown. The recipe for constructing these figures, some of which may even be pleasing to art connoisseurs, cannot be developed in the limited space of this article but will be found in the references.[1,2]

The intense research effort of the last 15 years on the Fermi surfaces of metals and semimetals originated, to a great extent, with Pippard's ingenious deductions, based on anomalous skin-effect experiments, concerning the Fermi surface of copper.[3] Prior to Pippard's

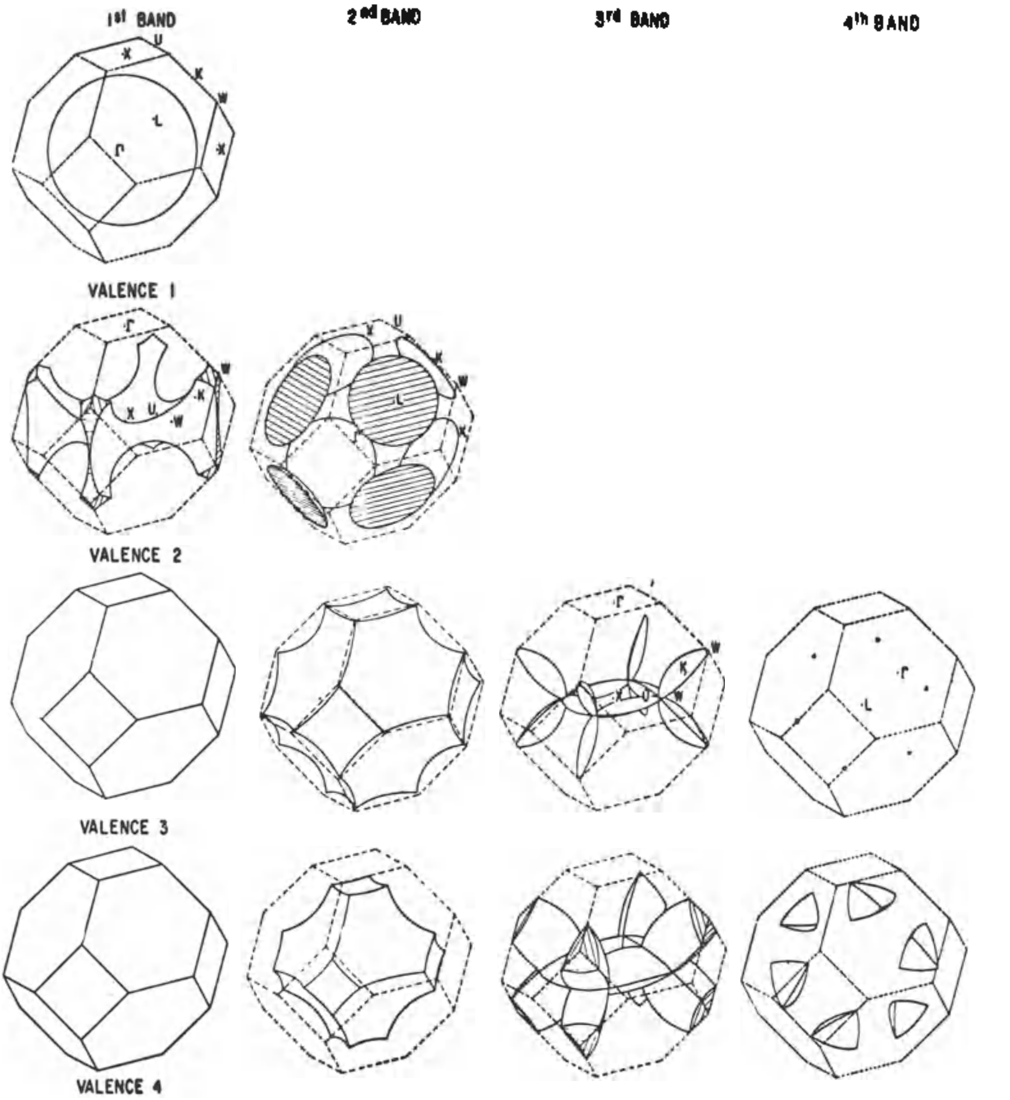

FIG. 2. Fermi surfaces in several zones or bands, for face-centered cubic metals having various numbers of "quasi-free" electrons per atom, as constructed by Harrison.[1]

work, it was taken for granted that in copper, with one quasi-free electron per atom, the first Brillouin zone would be only half filled and, hence, would have a nearly spherical Fermi surface. His work suggested that a series of eight necks pull out and touch the Brillouin zone boundaries in the [111] crystallographic directions. This shape has now been confirmed and precisely mapped, not only for copper but also for silver and gold.

A variety of experimental techniques has been developed, capable of yielding both overlapping and complementary information concerning Fermi surfaces of metals. Some of these techniques are described briefly:

(1) The DE HAAS-VAN ALPHEN EFFECT[4] is an oscillatory behavior of the magnetic susceptibility (or more generally, oscillatory behavior of any electronic property) due to the quantization of magnetic flux through an electron orbit in units of hc/e (where h = Planck's constant, c = speed of light, and e = electron charge). Measurements of the periods of the oscillations can be directly related to extremal cross-sectional areas of the Fermi surface.

(2) Cyclotron resonance[5] refers to oscillations in the magnetic field dependence of high-frequency surface impedance arising when the electron's cyclotron frequency is an integral multiple of the rf frequency. The periods of

these oscillations measure dA/dE, the rate of change of cross-sectional area with energy at extremal cross sections.

(3) Magnetoresistance[6] refers to extra resistance in a metal in the presence of a magnetic field. This magnetoresistance may be changed by changing the direction of the magnetic field and/or its magnitude. This direction and field dependence gives information about Fermi surface topology, particularly regions of contact with Brillouin zone boundaries.

(4) The magnetoacoustic effect[7] refers to oscillations in the magnetic field dependence of ultrasonic attenuation. The oscillations occur when dimensions of cyclotron orbits of electrons in extremal states on the Fermi surface are equal to integral multiples of the ultrasonic wavelength so that measurements of these oscillations give extremal linear dimensions of the Fermi surface.

(5) The anomalous skin effect[3] occurs when the electron mean free path is long compared to the rf skin depth. In this circumstance, electrons moving nearly parallel to the sample surface will dominate the conductivity. A measurement of surface impedance then gives an integral of the radius of curvature over that part of the Fermi surface containing the effective electrons.

(6) Positron annihilation in metals[8] gives directly the number of electron states in various cross sections of the Fermi surface. Because a positron impinging upon a metal is quickly thermalized, when it annihilates with an electron the resulting gamma rays must carry off the annihilated electron's momentum. Thus gamma ray angular correlation measurements can be related to the distribution of electron momenta.

(7) The Gantmakher effect[9] (or radio frequency size effect) occurs in thin samples when a magnetic field parallel to the sample surface is adjusted so that extremal electron orbits just fit in the sample thickness. RF energy can then be transported across the thickness of the sample by the electrons. Observation of these Gantmakher resonances, like the magnetoacoustic resonances, gives extremal linear dimensions of the Fermi surface.

These techniques have been used primarily to measure extremal properties of the Fermi surface geometry. Considerable effort has also been applied to the measurement of nonextremal properties[10,11] which can do much to elucidate Fermi surface geometry. The precision and applicability of each of these techniques is dependent on the material under investigation. Among pertinent factors are the number of quasi-free electrons per atom, crystallographic structure, magnetic properties, purity, and practicality of sample preparation.

The fundamental interest in the measurement and calculation of Fermi surface properties derives from their central role in understanding metallic behavior. Because the Pauli exclusion principle prevents more than one electron from occupying a given quantum state, the electrons in most of the filled states below the Fermi energy are "frozen," that is, they cannot be excited to a higher energy state by an external electric or magnetic field because the higher states are already occupied. Only the relatively small number of electrons within about bT of the Fermi energy can respond to external influences, and these "Fermi surface" electrons determine all the basic metallic properties, e.g., electrical conductivity, magnetic susceptibility, heat capacity, catalytic activity, thermoelectric effects, etc. Thus the experimental characterization and theoretical understanding of Fermi surface properties is one of the major activities in solid state physics.

Extensive application of the experimental techniques described above has resulted in a great deal of Fermi surface information about a large number of metals.[12] Nearly all the elemental metals (except those with severe sample preparation problems) have been investigated,[13] and many are extremely well characterized.[14] The complicated Fermi surface geometries that occur in the transition metals can be conveniently described by any of several parametrization schemes, the most successful of which is based on the Koringa-Kohn-Rostoker (KKR) method of energy band calculation.[15] This technique allows even the most intricate Fermi surfaces to be accurately described by a small number of physically meaningful parameters (usually seven or less), so that the anisotropy of various fundamental quantities over the Fermi surface can be studied and correlated in a simple way. These parametrization schemes have been used in detailed studies of the variation over the Fermi surface of the electronic Fermi velocity,[15] scattering lifetime due to impurities and defects,[16] the electron-phonon interaction,[17] and superconducting energy gap.

Paralleling this experimental work has been a great deal of theoretical effort devoted to first-principles calculation of energy bands and Fermi surface properties.[18,19] Like the experimental work, theoretical treatments of the Fermi surfaces of elements have been highly developed,[20] to the extent that agreement with experiment is usually within 10% and often much better.

Increasingly, both theory and experiment are turning away from the elements to alloys[21,22] and intermetallic compounds,[23] where a much greater range of unusual metallic behavior is to be found. Of particular interest is the behavior arising from various many-body effects: superconductivity from the electron-phonon interaction, spin fluctuations and itinerant magnetism from exchange interactions, and electron localization and local moment formation from electron correlation effects. Experimentally these many-body effects reduce the Fermi velocity of electrons at the Fermi surface and can be studied through effective mass measurements in the de Haas-van Alphen effect[23] and cyclotron resonance. The theoretical description of these many-body effects is less well developed, but is receiving increasing attention.[24] Understanding these many-body effects and their influence on Fermi surface properties and metallic behavior is likely to be a major theme of both theory and experiment in the coming years.

FERRIMAGNETISM

Snoek's publication (1946) of his wartime work on ferrites established the existence of new ceramic magnetic materials capable of combining the resistivity of a good insulator (10^{12} ohm-cm) with high permeability. (see MAGNETISM.) In 1948, Néel introduced the term ferrimagnetism to describe the novel magnetic properties of these materials. A simple ferrite is composed of two interpenetrating FERROMAGNETIC sublattices with magnetizations $M_a(T)$ and $M_b(T)$ which decrease with increasing temperature and vanish at the Curie point, T_c. In a ferromagnetic material, the resulting saturation magnetization, M, would be $M_a + M_b$; however, in a ferrite, strong antiferromagnetic interaction between sublattices results in antiparallel alignment, and $M = M_a - M_b$. In general $M_a(T) \neq M_b(T)$, and the material behaves in most respects like a ferromagnet, exhibiting domains, a hysteresis loop, and saturation of the magnetization at relatively low applied magnetic fields. Practical values for saturation magnetization and Curie temperature range from 250 to 5000 oersteds and from 100 to 600°C.

Ferrimagnetic materials have spinel, garnet, and hexagonal structures. A typical spinel ferrite is $NiFe_2O_4$. Other ferrites may be obtained by substituting magnetic (Co, Ni, Mn) or nonmagnetic (Al, Zn, Cu) ions for some of the Ni or Fe ions, e.g., $Ni_{1-y}Co_yAl_xFe_{2-x}O_4$, where x and y may be varied to modify M and T_c. Yttrium iron garnet (YIG), $Y_3Fe_5O_{12}$, is the classical ferrimagnetic garnet which combines very low magnetic loss with high resistivity. Substitution of magnetic RARE EARTH ions (Gd, Yb, Ho, etc.) for Y and of nonmagnetic ions (Ga, Al) for some of the Fe ions leads to many different ferrite compositions with a wide range of M and magnetic loss. The rare earth ions form a third magnetic sublattice with attendant magnetization M_c antiparallel to the resultant magnetization $M_{a,b}$ of the two Fe sublattices. Since M_c and $M_{a,b}$ exhibit different variations with temperature, the net magnetization may vanish twice, at T_c and at an intermediate temperature called the compensation point, T_{comp}, where $M_c = M_{a,b}$.

A typical hexagonal ferrite is $BaFe_{12}O_{19}$. Again, other magnetic ions such as Mn, Co, and Ni may be introduced to produce wide variations in M and T_c. Hexagonal ferrites are characterized by large anisotropy fields with an axis of symmetry which may be either a direction of hard (planar ferrites) or easy (uniaxial ferrites) magnetization.

To distinguish among major fields of applications, ferrites can be separated into five groups: soft, square-loop, hard, microwave, and single-crystal ferrites.

Soft ferrites have a slender, S-shaped hysteresis loop with low remanence and low coercive force permitting easy magnetization and demagnetization with little magnetic loss. Mn-Zn and Ni-Zn ferrites with spinel structure exhibit these properties and permit adjustment of M, and permeability, μ_i, over a wide range of values through variations in composition. Ni ferrite has $\mu_i = 15$ and $M = 3000$ G, whereas Ni-Zn ferrite may have as much as $M = 5000$ G combined with a permeability of several thousand. Mn-Zn ferrites have values of $\mu_i = 500$ to 5000 depending on composition. These ferrites are uniquely suited to low-loss inductor and transformer cores for radio, television, and carrier telephony.

Square-loop ferrites are materials exhibiting an almost rectangular hysteresis loop with two distinct states of remanence and with a coercive force of a few Oe. All practical square-loop ferrites have a spinel structure. The Mg-Mn (Zn) system has retained its preeminent position in computer memory applications two decades after its discovery in 1951. More recently, Li-Ni ferrites and more complex systems containing Li, Mn, and Al have become competitive in applications requiring stability and fast switching over a wide range of temperatures.

Hard ferrites are characterized by hexagonal structure, a hysteresis loop enclosing a large area, and a coercive force of several thousand Oe. These ferrites can store a significant amount of magnetic energy, and have found widespread application as permanent magnets in hi-fi loudspeakers, small motors, generators, measuring instruments, etc.

Microwave ferrites have garnet, spinel, or hexagonal crystal structure, and very low electric and magnetic loss factors. In general, the required M increases with the frequency, f, of application. Substituted and pure garnets, Mg-Mn-Al ferrites and Mg-Mn ferrites are used at the lower part of the microwave spectrum where $M = 200$ to 3000 G is adequate. In the millimeterwave region, $f = 30$ to 100 GHz, one uses Ni-Zn ferrites ($M = 5000$ G) and hexagonal ferrites of various compositions.

All microwave ferrite devices such as isolators, circulators, switches, phase shifters, limiters, parametric amplifiers, and harmonic generators are based on interactions of rf signals with the ferrite magnetization. Aligning M with an external biasing magnetic field, H_{dc}, and applying a microwave signal in an orthogonal direction leads to strong interaction and gyromagnetic resonance. On a microscopic scale, this is explained as application of a torque to the unpaired ELECTRON SPINS of the magnetic ions which causes them to precess at the rf frequency much like so many spinning tops. The precessional motion has a microwave RESONANCE frequency f_r dependent upon H_{dc} and the gyromagnetic splitting factor g_{eff}. In ferrimagnets with spinel structure, g_{eff} is related to the g-factors of the sublattices as follows:

$$g_{eff} = M/[(M_a/g_a) - (M_b/g_b)]$$

On a macroscopic scale, this interaction modifies the rf magnetic field in a manner which is described by introducing an antisymmetric permeability tensor $[\mu]$ whose complex components depend on M, H_{dc}, and frequency. When the frequency approaches f_r, one observes a resonance absorption line whose width, ΔH, is determined by the magnetic loss of the material. Values for ΔH cover a range from <1 oersted for single-crystal YIG to >1000 oersteds for some polycrystalline Ni-ferrites. The interaction of rf fields and electron spins becomes a maximum if the rf field is circularly polarized in the same sense as the precessional motion of the spins. Circular polarization in the opposite direction produces almost no interaction and no gyromagnetic resonance. This permits design of nonreciprocal ferrite devices. At high levels of microwave power, nonlinear coupling between microwave signal and precessional spin motion causes the parametric excitation of higher order modes of spin motion (magnetostatic modes and spin waves). This effect has been exploited in limiters and parametric amplifiers.

Single-crystal ferrites of practical importance are rare-earth garnets grown in a flux of molten lead oxide. Some of these are optically transparent permitting direct observation of magnetic domains. Interaction of infrared and visible light with the electron spins is called the magneto-optic effect. It permits electronic modulation of a beam of light which propagates through a single-crystal garnet. Devices of this type are of great potential interest in the rapidly developing laser technology.

Magnetic Bubbles Single-crystal, rare-earth garnet sheets have been grown on a substrate with a preferred direction of magnetization perpendicular to the plate. In these plates, tiny round magnetic domains called *bubbles* can be formed by an applied magnetic field. These bubbles can be propagated, erased, and manipulated to perform binary functions in computers including logic, memory, counting, and switching.

Bubbles are cylindrical magnetic domains whose magnetization is reverse to that in the remainder of the thin magnetic layer in which they are present. If the magnetic layer is a garnet then the process of bubble formation can be observed with a polarizing microscope as an external *bias* field applied perpendicular to the surface is slowly increased until bubbles develop from isolated island strip domains. This process is illustrated in Fig. 1. These single domain configurations will only occur if the magnetic material has a uniaxial anisotropy with the easy axis of magnetization perpendicular to the surface.

An external bias field is a necessary condition to support isolated bubble domains with the allowable ranging of the bias field approximately one-tenth the saturation magnetic moment, about 50 Oe for the typical garnet film supporting 2-μm-diameter bubbles. The upper limit of the bias field is set by bubble collapse, the lower limit by a distortion instability in the bubble shape leading to the conversion of a bubble into a long meandering strip domain. This instability occurs at the domain strip width at which the total energy is independent of the strip length. These rules are applicable for materials in which the uniaxial anisotropy field H_K is much greater than $4\pi M_s$ (M_s is the saturation magnetization in gauss). The ratio $H_K/4\pi M_s$ is defined as the material q and is, in fact, a measure of the "stiffness" of the magnetization. Experience has shown that for most useful bubble materials $q > 3$.

A material length $l = \sigma_W/4\pi M_s^2$ characterizes materials for the bubble domain size they support. Here l is in centimeters and σ_W is the domain wall energy in ergs/cm^2. The optimum magnetic film thickness $h = 4l$ results in the smallest stable domain diameter $d = \pi l$ at a bias field $H_A = (0.3)\ 4\pi M_s$.

The interplay of the material parameters σ_W and M_s in determining bubble stability is shown in Fig. 2 and 3. Note that the bias field acting directly on the bubble domain in the classical sense and the energy of domain wall both act to reduce the size of a bubble and are opposed by the stray magnetostatic fields which arise from the surface magnetic charges and which attempt to increase the bubble size. The expression for the stray field H_D shown in Fig. 2 is an approximation. Since the total energy ξ_T for the bubble has a minimum with $\partial\xi_T/\partial r = 0$ and $\partial^2\xi_T/\partial r^2 > 0$ the bubble is statically stable.

For a film of thickness $h = 4l$ the nominal bubble diameter d, i.e., the diameter when the bias field is set in the middle of the stable range,

FIG. 1. The garnet epitaxial film is grown on a nonmagnetic substrate. The serpentine nature of the magnetic domains in garnet films arises from a preferred "easy" axis of magnetization perpendicular to the film surface. With no external magnetic field, the magnetic domains are arranged such that the sample is magnetically neutral, half pointing up and half pointing down. As a small external magnetic field is applied, the domains, whose polarity is opposite to that of the field, shrink. If the external magnetic field is further increased, the stripes shrink into cylinders—the bubbles. The bubbles are free to move throughout the film and can be viewed as tiny magnets afloat in a magnetic field sea of the opposite polarity.

FIG. 2. The fields effective on the domain wall of the bubble domain which combined maintain static stability are indicated. The bias field H_A acts to diminish the volume of the bubble by exerting a direct force on the domain wall directed radially inward. An effective domain wall field results from a reaction by the domain wall energy density σ_W to reduce the wall area to zero. The magnetostatic (stray) field H_D operates to equalize the overall magnetic surface charge by an increase in the bubble volume. By resolving (a) into (b) and (c) the r-dependent part of the field is seen to be that of a cylindrical dipole magnet.

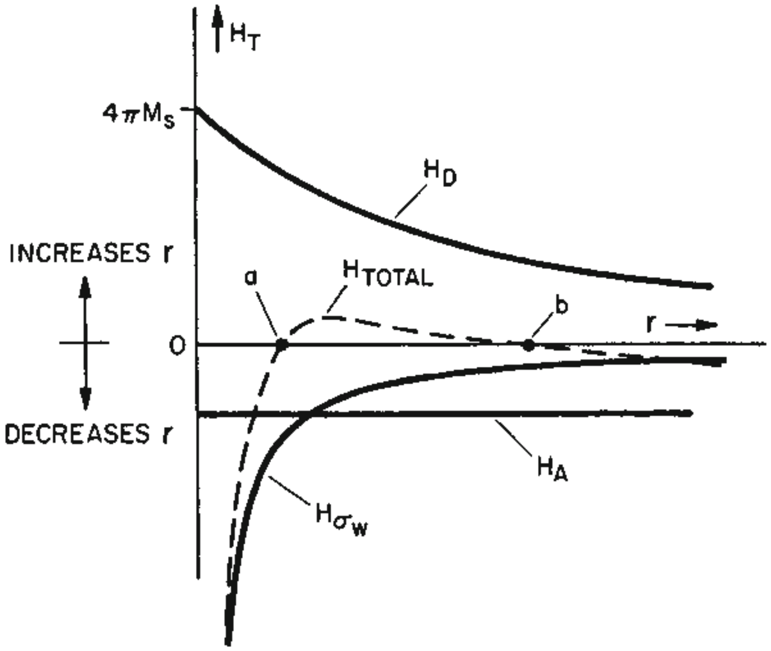

FIG. 3. There are two values of the bubble radius for which H_T, the sum of the fields illustrated in Fig. 2, is zero. Condition *a* is radially unstable and *b* is stable, a conclusion that can be reasoned from this figure.

is predicted by theory to be *8l*. To store the greatest amount of information in a given area is equivalent to packing the greatest number of bubbles into that area, thus the highest bit density will be realized in a material which supports the smallest-diameter bubbles.

Bubble propagation circuits such as T-bar, chevron, etc., provide a traveling local perturbation of the bias field. A bubble will move in a small magnetic bias field gradient $\partial H_z/\partial x$ at a velocity $v_x = \mu_W(2r\partial H_z/\partial x - 8H_c/\pi)/2$ where μ_W is the planar wall mobility in cm/s - Oe, H_c is the domain wall coercivity in oersted, and r is the bubble radius. At higher values of the applied field gradient, often reached in device operation, the velocity reaches a maximum value v_p which in turn limits the maximum data rate of a bubble device. A theoretical expression for this limiting velocity is $v_p = 24\gamma A/h\sqrt{k_u}$ where γ is the gyromagnetic ratio, A the exchange constant, K_u the uniaxial anisotropy constant ($H_K = 2K_u/M_s$), and h the magnetic film thickness. For most bubble film compositions in which the bubble thickness equals the bubble diameter, v_p is in the range 2000–3000 cm/s.

It was an unexpected discovery that bubbles with differing static and dynamic properties can exist in the same garnet film. Different domain wall states give rise to these unusual properties. The simplest bubble wall structure is a *Bloch wall*. In a Bloch wall the magnetization rotates in a plane parallel to the wall as we move radially across the wall of the bubble. Rotation within the wall can be either clockwise (cw) or counterclockwise (ccw). In a hard bubble the domain wall is divided into cw and ccw Bloch segments linked to one another by Néel segments. In a Néel wall the magnetization rotates cw or ccw in a plane perpendicular to the wall. Néel and Bloch segments, really twists in the bubble wall, repel each other through the exchange energy which operates to keep "adjacent" spins parallel. Thus the static properties of hard bubbles differ from those of normal bubbles. Examples of wall configurations are shown in Fig. 4; bubbles (a) and (b) have normal static properties. Bubble (c) is the only bubble that moves parallel to a field gradient, i.e., "normal" in the dynamic sense.

Three techniques can be used to suppress hard bubbles. They are multilayer garnet films, ion implantation, and a very thin (~300 Å) Permalloy film directly on the garnet layer. Ion implantation is normally used. Figure 5 illustrates the effect of a hydrogen ion implant into the outer 0.5 μm surface of a nominally 6-μm-thick $(YGdTm)_3(GaFe)_5O_{12}$ garnet film on suppressing hard bubbles. The material parameters of $(YLuSm)_3(CaGeFe)_5O_{12}$ garnet films are less sensitive to temperature variation and are used exclusively in devices with bubble diameters 3 μm or less. Garnet films can be tailored to support 0.5-μm bubbles, which im-

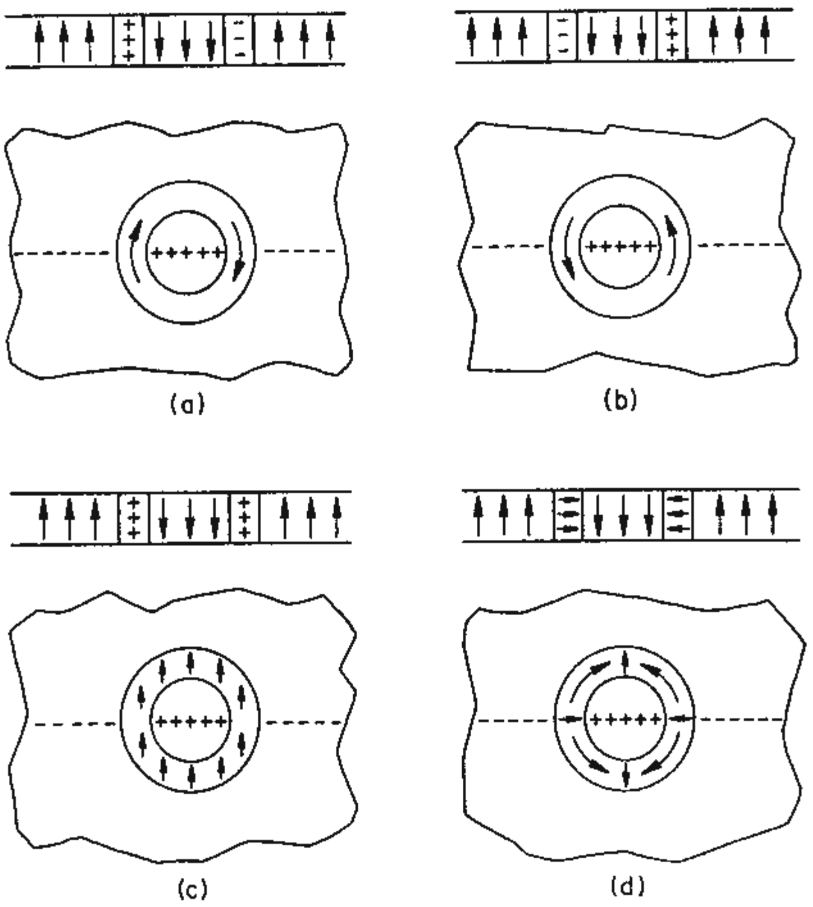

FIG. 4. (a) A simple Bloch wall. (b) a ccw sense for the Bloch wall. (c) A wall structure partially (a) and (b). (d) A more complex example of wall structure.

plies that a storage density of 2×10^7 bits/cm^2 can be realized with the garnet material system. Garnet films are grown epitaxially on polished (111) wafers of $Gd_3Ga_5O_{12}$.

Bubble operations used in chip designs are propagation, generation, detection, transfer, replication, annihilation, and swap. It is beyond the scope of this section to discuss all of these in detail; however, we will dwell on the most basic operation, that of propagation. Conductor propagation was the first method used to move bubbles but was replaced by feed access which features inductive power field to produce bubble motion via patterned permalloy features.

Field access propagation by T-Bar permalloy features is illustrated in Fig. 6. The Permalloy pattern is generally not in direct contact with the bubble supporting garnet material to guard against local spontaneous domain nucleation. Bubbles move to the right with a cw rotation of the in-plane field and to the left with a ccw rotation. The drive field should be imagined as a constant amplitude rotating field in the plane of the figure whereas the bias field and the easy axis are normal to this plane. It can be seen that the bubble moves from a feature to the like feature one period away as the drive field rotates by 360°.

Propagation elements can be combined with bubble generators, detectors, etc. to build functional chips. Many chip organizations are possible. For example, Fig. 7 illustrates a 70 kbit "endless loop" shift-register architecture.

Bubble memory chips are packaged in an assembly of two mutually orthogonal wire-wound solenoids which are driven to provide a rotating in-plane drive field, and a permanent magnet which provides the bias field necessary to maintain stable bubbles. Because the field of the permanent magnet tracks the temperature variation of the bias field, the temperature range of satisfactory operation is wide. Data retention is completely nonvolatile.

Magnetic bubbles bridge the capacity-data

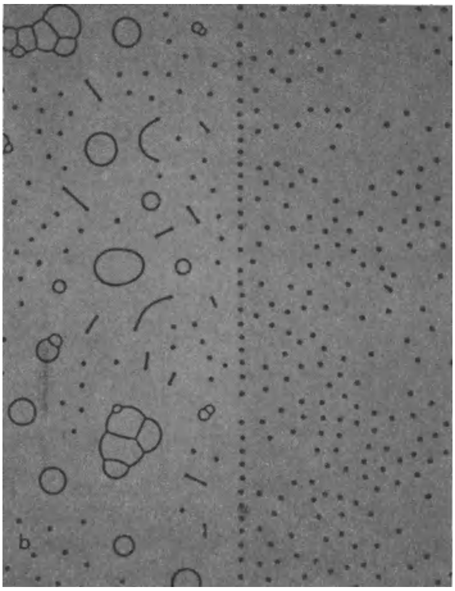

FIG. 5. The effectiveness of a hydrogen ion implant in suppressing hard bubbles is evident in this photograph. Only normal bubbles are found in the implanted area to the right, while a diverse collection of hard bubbles and strips are found to the left.

FIG. 7. Example of a 70-kbit bubble chip, approximate size 5 mm by 6 mm, processed at the Reading Division of Western Electric Research Department.

retrieval time gap left vacant by magnetic core and semiconductor devices on one side and the electromechanical magnetic tape and disk on the other. Improvements in bubble materials, circuit processing, and device design have advanced bubble technology to where it is used in applications requiring 10^6–10^8 bits and retrieval times less than 0.005 s. Bubble chips with 10 million storage cells are currently under development. Magnetic bubbles utilize remanent magnetization to provide data storage. How-

FERROICITY, FERROELECTRICITY, AND FERROELASTICITY

Originally the concept *ferroic* was a unification and generalization of *ferromagnetic*, *ferroelectric*, and *ferroelastic*, but here only nonmagnetic crystals are considered.

When a given phase (phase I) has a structure that can be regarded as a slight distortion of another real or imaginary structure (structure II), it is called a *ferroic phase*. (*Distortion*, unlike *modification*, implies lowering in symmetry.) If structure II cannot be regarded as a slight distortion of any other structure, it is called the *prototype* of phase I. If there really exists a phase whose structure is an equisymmetric slight modification of the prototype, it is called the *prototypic phase*. The interatomic distances in the prototypic phase, like those in every phase, vary continuously with temperature (and pressure, etc.), while those in the prototype are fixed. The prototype is the zero point for all the order parameters, all the lattice vibration coordinates, and all the components of electric polarization vector and mechanical strain tensor. If we agree that the prototype is the same as the prototypic phase at a certain temperature T_p, then the prototypic phase at any other temperature is not the zero point. For example, let the point group of the prototype be $4mm$; the z component of spontaneous polarization vector and the (x, x) and (z, z) components of spontaneous strain tensor of the prototypic phase are zero at T_p and nonzero at any other temperature. In some cases, no prototypic phase exists really (owing to melting, dehydration, or the like); still it is possible to imagine the prototype.

The term "a ferroic phase" is often abbreviated to "a ferroic," and "a prototypic phase" to "a prototypic," omitting "phase."

If one phase is a slight distortion of a second phase, and this phase II is a slight distortion of a third phase, and this phase III cannot be regarded as a slight distortion of any structure, then phase III, not phase II, is recognized as the prototypic of phase I. Both phase I and phase II are ferroics derived from phase III. Phase III is the common prototypic of phases I and II. No phase can be both ferroic and prototypic. The relationship between ferroic and prototpyic phases is not simply the relationship between lower- and higher-symmetry phases.

The structure of a ferroic can be conceived to result from modulating the prototype in a wave. Let α denote the quotient ($\geqq 1$) of the wavelength by the unit-cell length of the prototype. According to whether α is integral or deviates slightly from an integer, the ferroic is said to be *commensurate* or *incommensurate*. (The deviation from an integer is not due to thermal expansion.) Only if it is commensurate is the ferroic three-dimensionally periodic (as the prototype is). We will consider below only commensurate ferroics.

As the *cell multiplicity* of a ferroic we refer to the quotient (integral) of the number of molecules in the primitive unit cell of the ferroic by that of the prototype. If the customary unit cell of the ferroic or prototype is not primitive, it needs to be rendered into a primitive unit cell.

A ferroic has a definite number of *situations*. Situation is a kind of state. The structure of the ferroic can be specified by assigning to every atom a displacement vector from its position in the prototype. When the ferroic is in a situation, the displacement vectors of all the atoms are uniquely determinate. The displacement vectors in one situation are not all equal to the displacement vectors in another situation. The latter displacement vectors (or the latter situation) can be obtained by performing a certain operation of the space group of the prototype upon the former displacement vectors (or the former situation). The mentioned operation is not uniquely determinate; there are many operations each changing the former situation to the latter. By performing every operation of the space group of the prototype upon one situation, all situations can be obtained. The number of situations is finite. Regardless of the situation the ferroic is in, it has the same free energy.

Different situations are regarded as the same *oriate* (short for *ori*entational st*ate*) if they can be changed to each other by pure translations. The number of situations belonging to one oriate equals the number of situations belonging to any other oriate. This number equals the cell multiplicity. The number of all situations of the ferroic, therefore, equals the product of the number of oriates and the cell multiplicity. Furthermore, the number of oriates equals the quotient of the order of the point group of the prototype by that of the ferroic.

Figure 1 shows a model ferroic. Points A, B, · · · , F have $z = c_0/2$. Their images across the xy plane as a mirror are A′, B′, · · · , F′. Points A, B, C, D, A′, B′, C′, D′ are the vertices of a primitive unit cell of the prototype. (Thus c_0 is a lattice constant of the prototype.) *White* atoms lie at the vertices. The unit cell, moreover, constains two *black* atoms which lie at $z = \pm d/2$ $(0 < d < c_0/2)$. The ferroic results from the displacement of every black atom by the drawn vector which is perpendicular to the z axis. (For simplicity it is assumed that no white

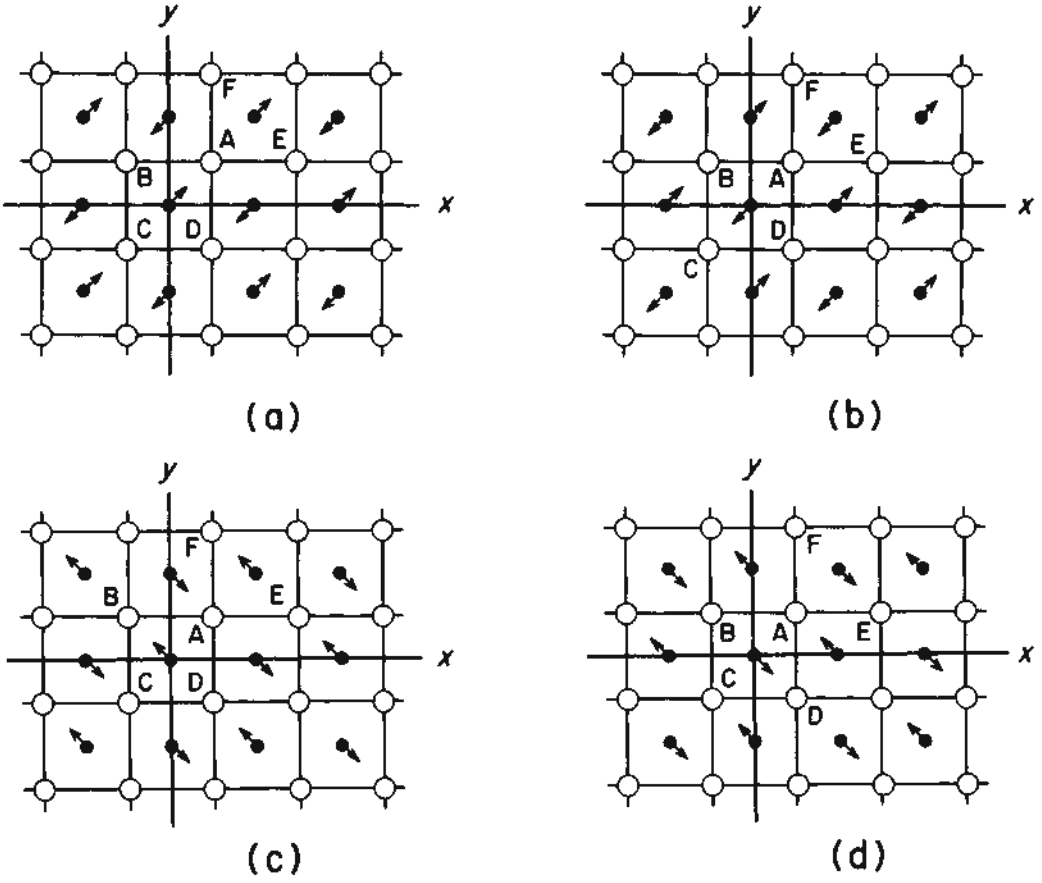

FIG. 1. A model ferroic; (a) situation $\mathcal{S}_1$, oriate $\mathcal{O}_1$; (b) situation $\mathcal{S}_2$, oriate $\mathcal{O}_1$; (c) situation $\mathcal{S}_3$, oriate $\mathcal{O}_2$; (d) situation $\mathcal{S}_4$, oriate $\mathcal{O}_2$.

atom is displaced.) Obviously, B, D, E, F, B′, D′, E′, F′ are the vertices of a primitive unit cell of the ferroic. Hence the cell multiplicity is 2. The ferroic has, in all, four situations which are represented by $\mathcal{S}_1, \mathcal{S}_2, \mathcal{S}_3, \mathcal{S}_4$. The translation along the x axis by length a_0 (= $\overline{AB}$), obviously, changes $\mathcal{S}_1$ to $\mathcal{S}_2$, and $\mathcal{S}_3$ to $\mathcal{S}_4$. Thus $\mathcal{S}_1$ and $\mathcal{S}_2$ are regarded as the same oriate, $\mathcal{O}_1$; $\mathcal{S}_3$ and $_4$ as the same oriate, $\mathcal{O}_2$. Obviously, no pure translation changes $\mathcal{S}_1$ to $\mathcal{S}_3$ (the $\pi/2$ rotation about the z axis does so). Thus $\mathcal{S}_1$ and $\mathcal{S}_3$ are regarded as different oriates. In other words, $\mathcal{O}_1$ differs from $\mathcal{O}_2$. The number of situations 4, equals the product of the number of oriates, 2, and the cell multiplicity, 2.

A specimen of a ferroic often consists of several *domains* (or *terrains*); each domain (or terrain), as a whole, is in one oriate (or situation), and the oriates (or situations) of any two adjacent domains (or terrains) are different. Domain corresponds to oriate, and terrain to situation. But the number of domains (or terrains) in the specimen has no connection with the number of oriates (or situations) of the ferroic; the former can be any integer between 1 and ∞. Each domain comprises a number of terrains; this number may be any integer between 1 and ∞, having no connection with the number of situations per oriate, i.e., the cell multiplicity.

When at least two of the oriates of a ferroic are unequal with respect to (the direction of) the spontaneous polarization vector, the ferroic is said to be *ferroelectric* and those two oriates are said to be *ferroelectrically related.* (Two oriates that are equal with respect to the spontaneous polarization vector are said to be *ferroelectrically unrelated.*) According to whether all the oriates, or not all but some, are ferroelectrically related, the ferroic is said to be *fully* or *partially* (or a full or partial) *ferroelectric.* Analogously, when at least two of the oriates of a ferroic are unequal with respect to the spontaneous strain tensor, the ferroic is said to be *ferroelastic* and those two oriates are said to be *ferroelastically related.* According to whether all the oriates, or not all but some, are ferroelasticity related, the ferroic is said to be *fully* or *partially* (or a full or partial) *ferroelastic.* The oriates of a partial ferroelectric (or ferroelastic) can be divided into subsets such that any two oriates belonging to the same subset are ferroelectrically (or ferroelastically) unrelated and any two oriates belonging to different subsets are related. The number of oriates in one subset equals that in another subset. Hence this number is a divisor of N, the number of all oriates of the ferroic. It indicates the *degree of partiality.* In particular, if it is 1 the ferroic is fully ferroelectric (or ferroelastic); if N, not ferroelectric (or ferroelastic). Any ferroic with a prime N, especially with $N = 3$, is neither partially ferroelectric nor partially ferroelastic.

Since the spontaneous polarization vector and spontaneous strain sensor are invariant under every translation, any two situations belonging to the same oriate are ferroelectrically and ferroelastically unrelated.

A specimen of a full ferroelectric (or ferroelastic) can easily be changed from a multidomain state to a unidomain state, and from a unidomain state to another unidomain state, by the application of an electric field (or a mechanical stress). On the other hand, a specimen of a partial ferroelectric (or ferroelastic) can hardly be affected in this fashion. Even for a full ferroelectric (ferroelastic), if its cell multiplicity is greater than 1, a specimen of it can hardly be changed from a multiterrain state to a uniterrain state, and from a uniterrain state to another uniterrain state, by the application of an electric field (or a mechanical stress).

If a ferroic is both ferroelectric and ferroelastic, the ferroelectricity and ferroelasticity are not always coupled. Only when the condition is satisfied that ferroelectrically related oriates are all ferroelastically related and vice versa are the ferroelectricity and ferroelasticity completely coupled; i.e., a turning of the spontaneous polarization vector by a field is necessarily accompanied by a turning of the spontaneous strain tensor and, conversely, a turning of spontaneous strain tensor by a stress is necessarily accompanied by a turning of spontaneous polarization vector. Any ferroic that is both fully ferroelectric and fully ferroelastic satisfies the above condition.

Two oriates that can be changed to each other by a field (or stress) are not always ferroelectrically (or ferroelastically) related. If two oriates are unequal with respect to electric susceptibility tensor or elastic compliance tensor or piezoelectric modulus tensor, it is never impossible to change the oriates to each other by a field or a stress or a combination of both, respectively.

FERROMAGNETISM

Ferromagnetism is an example of cooperative phenomena in solids. It is characterized by a spontaneous macroscopic magnetization M (magnetic moment per unit volume) in the absence of an applied magnetic field at temperatures below a critical value known as the Curie temperature, T_C. This property is exhibited by the transition metals, Fe, Co, and Ni; the rare earth metals, Gd, Tb, Dy, Ho, Er, and Tm; and by a variety of alloys, compounds, and solid solutions involving the transition, rare earth, and actinide elements. Ferromagnetic Curie temperatures range from a fraction of a degree to hundreds of degrees Kelvin.

Cooperative magnetic behavior results from the exchange interaction between electrons, which is qualitatively described as follows. Electrostatic coulomb repulsion between like electric charges acts to keep two electrons apart, a separation which is also favored by the Pauli exclusion principle if the electrons have parallel spins. Thus if two electrons are farther apart when their spins are parallel than they would be if their spins were antiparallel, the parallel state will have lower mutual electrostatic energy. However, the kinetic energies increase if the electrons are separated, and consideration of this energy may lead to lower total energy for antiparallel spins. In other words, the exchange interaction is electrostatic in nature, but is modified by details of kinetic energy and the exclusion principle, and is highly dependent on the spatial distribution of the electrons. The exchange energy between two electrons, though electrostatic, is usually expressed in the mathematically equivalent form, $-2J\mathbf{s}_1 \cdot \mathbf{s}_2$, where J is the quantum mechanical exchange integral, related to the overlap of the charge distributions 1, 2; and $\mathbf{s}_1$ and $\mathbf{s}_2$ are the spin angular momentum vectors of the two electrons. The value of J is usually expressed in energy units, such as ergs, when the angular momentum vectors are assigned nondimensional values, i.e., spin quantum numbers. When J is positive, parallel spins represent a lower energy state than antiparallel spins. Since each electron has a magnetic moment proportional to its spin angular momentum, a state of parallel spins corresponds to a state of parallel magnetic moments.

The principal effect of the exchange interaction is embodied in the empirical Hund's rules, which describe the combination of electron spins in an atom to form the atomic spin. The principal interaction between magnetic atoms, i.e., between atoms with magnetic moments as a consequence of spin angular momenta, is thought to be of exchange character also, and there has been considerable success in describing magnetic properties by assuming this interaction to have the form,

$$\mathcal{H} = -\sum_{i,j} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j .$$

Here $\mathbf{S}_i$ and $\mathbf{S}_j$ are the spin angular momentum vectors of atoms i and j; the exchange integral, J_{ij}, may vary for different pairs and is usually regarded as a phenomenological parameter to be evaluated by means of experimental data. When J_{ij} is positive, parallel ordering or alignment of the atomic spins in a common direction is favored, and so there is a large spontaneous magnetization even in the absence of an applied field. For negative J_{ij}, antiparallel spins result in lower energy (see ANTIFERROMAGNETISM, FERRIMAGNETISM).

Maximum ordering obtains at the absolute zero of temperature where the randomizing effect of thermal agitation disappears. The initial decrease of the magnetization as the temperature is increased from zero is well represented by a superposition of wavelike disturbances known as spin waves. At the Curie temperature the magnetic ordering is destroyed by thermal agitation and the spontaneous magnetization is zero (Fig. 1). Above the Curie temperature a ferromagnetic material behaves paramagnetically and has a net magnetization only in the presence of an applied field (see MAGNETISM and PARAMAGNETISM).

At temperatures below T_C a sample of ferromagnetic material is usually divided into small regions called domains, which vary in size and shape with a typical dimension from 0.1 to 1000 μm. Within each domain the magnetization is uniform and has the maximum or saturation value, M_S, characteristic of the temperature of the material (Fig. 1), but the direction of alignment of the individual moments in each domain changes from one domain to the next. The magnetization of the sample, which is the resultant of the magnetization of all the domains, may be much less than the saturation value (of a single domain), or it may even be zero in a completely demagnetized state.

The magnetization of a sample increases when a magnetic field, H, is applied. The value of H required to saturate the magnetization may be as small as 0.01 oersted or as large as several thousand oersteds, depending on the material.

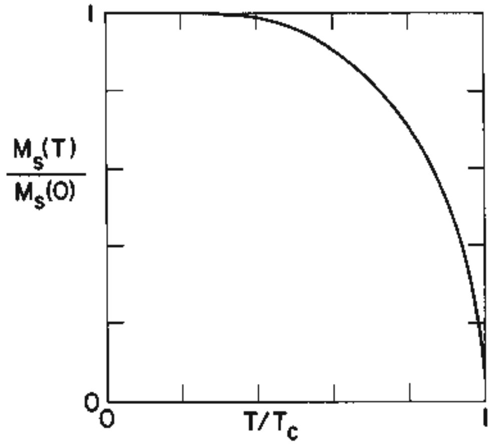

FIG. 1. Typical variation of spontaneous domain magnetization, M_S, as a function of temperature, T.

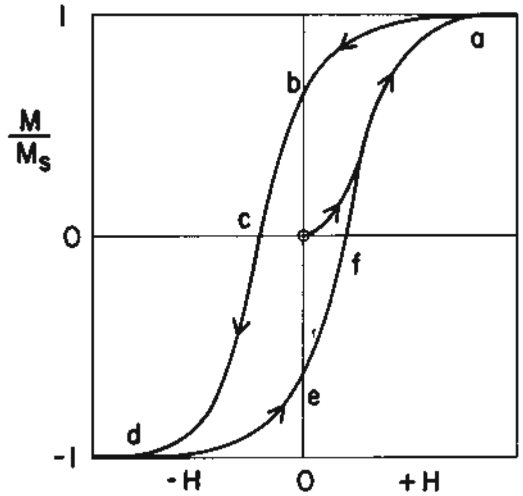

FIG. 2. Typical variation of sample magnetization, M, as a function of applied field strength, H; the magnetization curve depends on the magnetic history of the sample.

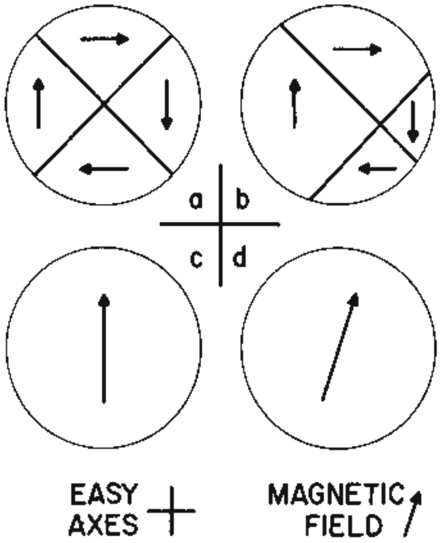

FIG. 3. Schematic representation of the change of domain structure and magnetization with applied field.

The magnetization process for a previously demagnetized material is represented by the 0-to-a portion of the magnetization curve in Fig. 2. When the applied field is subsequently removed, the magnetization exhibits the phenomenon of hysteresis, or lagging behind, tracing the path a-b and retaining a finite value, called the remanence, when the field is zero. The coercive force is the value of the field which must be applied opposite to the direction of the magnetic moment to trace the path b-c and reduce the magnetization to zero. Further increase of the field in this direction, followed by its removal, traces the path c-d-e. Repetition of the cycle then traces the curve e-f-a-b-c-d-e-, etc. Permanent magnets are characterized by a large coercive force; i.e., a large reverse field (typically thousands of oersteds) is necessary to destroy the magnetization However, in soft magnetic materials the coercive force may be less than one oersted.

Domains exist in a ferromagnetic material because their formation results in a lower total energy for the sample than it would have if the entire sample were a single domain. Total alignment of the magnetic moments is favored by the exchange forces, but these are usually short range forces acting between an atom and its neighbors. The dipole-dipole forces, although weaker, are long range and, alone, would orient the atomic moments like bar magnets, north pole to south pole, in closed chains to minimize the external field of the magnet (see DIPOLE MOMENT and MAGNETISM). One additional factor is required for the formation of domains. This factor is anisotropy, a result of the crystal structure of most solid materials. The structure of a crystal is not the same in all directions; consequently its physical properties depend on direction. It is easier to magnetize a magnetic material in some directions, called easy axes, than in other directions. When the effect of anisotropy is superimposed on the effects of exchange and dipolar coupling, the ordered atomic moments break up into segments or domains, so that in each domain the magnetization is uniform and lies along or near one of the easy axes. There is a large change in the direction of magnetization from one domain to the next, with the reorientation occurring gradually (on an atomic scale) in a narrow transition region known as the domain wall.

The initial part of the magnetization process, 0-a in Fig. 2, is represented schematically in Fig. 3. In the demagnetized state the domains are arranged to minimize the external field due to the magnetization and to give zero net moment for the sample (Fig. 3a). In low fields the domain boundaries move so that the domains with magnetization direction near the direction of the applied field grow in size while other domains are depleted (Fig. 3b). As the field strength is increased, the domain boundaries are swept out of the sample (Fig. 3c), and finally the (single) domain magnetization rotates into the direction of the applied field until saturation is reached (Fig. 3d). When the field is removed, domains re-form in varied orientation along the easy axes, but there is a preference for domains whose magnetization vectors lie in the easy directions nearest the direction in which the field was applied, and consequently the sample as a whole has a magnetic moment (remanent magnetization).

In some thin magnetic films the domains are cylindrical. Both the cylinder axis and the magnetization are perpendicular to the plane of the film, whereas in the domains shown in Fig. 3 the magnetization is in the plane of the diagram. Cylindrical domains—called bubbles because of their appearance and mobility at the surface—are caused when perpendicular anisotropy built into the film during preparation is stronger than the demagnetizing effect of the planar structure. Bubble domains are useful for data storage and control applications.

Amorphous materials have no crystalline order. They are often referred to as glasslike and have properties similar to those of liquids. Despite the total atomic disorder, the magnetic properties of amorphous alloys are sharply defined: Domain patterns are observed, including bubble domains; sharp Curie points are detected; and large permeabilities exist, almost as large as that of Permalloy.

Except when rare earth atoms are present, the exchange interactions in amorphous alloys are positive and lead to ferromagnetism. Using a variety of elements over a wide range of composition, one can obtain great flexibility of magnetic properties. When rare earth atoms are added, negative exchange interactions are induced, allowing further control of the magnetization and anisotropy energy to help stabilize domain formation and other factors affecting magnetic properties.

Ferromagnetism is also characterized by many secondary effects. Among the more important are the specific heat of the ferromagnetic state, which peaks at the Curie temperature, confirming that a phase transition has occurred; the magnetoresistance, which in metals can change the electrical resistance by as much as five percent, depending on the direction of magnetization; and the magnetostriction, which causes the sample dimensions to change during magnetization. These secondary effects give additional insight into the nature of the ferromagnetism and are useful in technical applications.

FEYNMAN DIAGRAMS

I. Introduction Feynman diagrams provide one of the most powerful methods known for finding the physical properties of systems of interacting particles, i.e., particles interacting with an external field and/or with each other. Since all physical systems—solids, liquids, gases, molecules, plasmas, atoms, nuclei, elementary particles—are composed of interacting particles, the Feynman diagram method is now used extensively in all branches of modern physics. In this article, the examples are from solid-state physics; the reader is referred to the References for examples from other branches. A very elementary account of the subject is found in Ref. 1.

The idea behind Feynman diagrams is this: In order to find the important physical properties of a system of interacting particles, it is not necessary to know the detailed behavior of the particles, but only their *average* behavior. The quantities which describe this average behavior are called "propagators" or "Green's functions," and physical properties may be calculated directly from them. For example, the *single-particle propagator* is defined thus: we put an extra particle into the system at point $\mathbf{r}_1$ at time t_1, and let it interact with the external field and with the other particles for a while (i.e., we let it "propagate" through the system). Then the single-particle propagator is the probability (or in quantum systems, the probability *amplitude*) that at later time t_2, the particle will be observed at another point, $\mathbf{r}_2$. From the single-particle propagator, we can calculate directly the energy and lifetime of certain excited states of the system, the ground state energy, etc. Similarly, there are the two-particle propagator, the no-particle propagator or "vacuum amplitude"), etc., which yield other physical properties (see Ref. 1).

Feynman diagrams give us a method of calculating propagators by means of pictures. We shall first show how this is done in a simple classical example from "liquid-state" physics, i.e., the drunken man propagator, then give a couple of illustrations from solid-state physics.

II. Classical Example: The Drunken Man Propagator A man who has had too much to drink (Fig. 1), leaves a party at point 1 and on the way to his home at point 2, he can stop off at one or more bars—Alice's Bar (A), Bardot Bar (B), Club 6 Bar (C), · · · etc. We ask for the

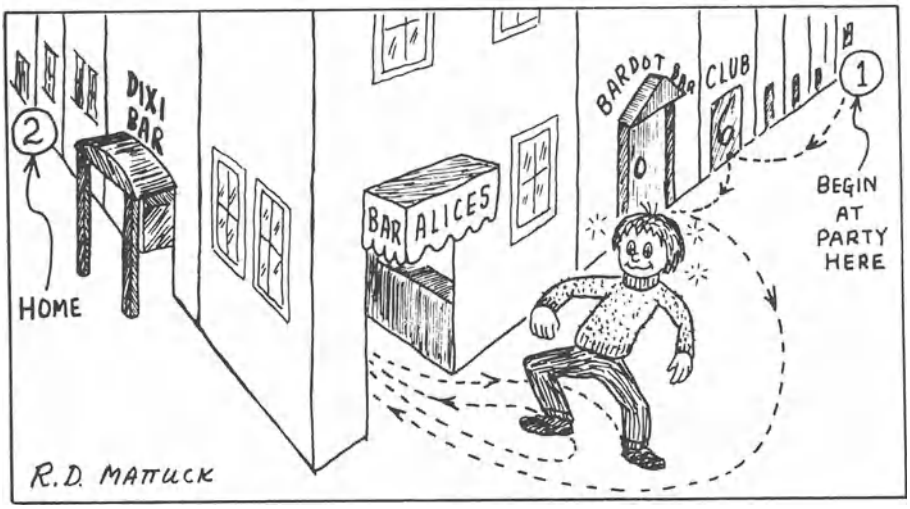

FIG. 1. Propagation of drunken man.

probability, $P(1, 2)$, that he gets home. This probability, which is just the propagator here (with time omitted for simplicity), is the sum of the probabilities for all the different ways he can propagate from 1 to 2 interacting with the various bars. Assuming, for simplicity, that the various processes involved are independent, this is just $P_0(1, 2)$ (= probability that he will go "freely" from 1 to 2, i.e., without stopping at any bar), plus $P_0(1, A) \times P(A) \times P_0(A, 2)$ (= probability he will go freely from 1 to bar A, times the probability that he stops off at A for a drink, times the probability that he then proceeds freely to 2), plus $P_0(1, B) \times P(B) \times P_0(B, 2)$ (= probability for route 1-bar B-2) plus etc. $\cdots$ plus $P_0(1, A) \times P(A) \times P_0(A, A) \times P(A) \times P_0(A, 2)$ (= probability for route 1-A-A-2) plus etc. $\cdots$. This gives us an infinite series for the propagator:

$$P(1,2) = P_0(1,2) + P_0(1,A)P(A)P_0(A,2) + P_0(1,B)P(B)P(B,2) + \cdots + P_0(1,A)P(A)P_0(A,A)P(A)P_0(A,2) + \cdots. \quad (1)$$

Now this series is a complicated thing to look at. To make it easier to read, we draw a "picture dictionary" to associate diagrams with the various probabilities as shown in Table 1. Using this dictionary, series (1) can be drawn as in Fig. 2(a). Since, by Table 1, each diagram element stands for a factor, Fig. 2(a) is completely equivalent to series (1). However, Fig. 2(a) has the great advantage that it also reveals the physical meaning of the series, giving us a "map" which helps us to keep track of all the sequences of interactions the drunken man can have in going from 1 to 2.

The series may be evaluated approximately by selecting the most important terms in it and summing them. This is called "*partial summation.*" For example, suppose the man's favorite bar is Alice's bar, so that $P(A)$ is large and all other $P(x)$'s are small. Then Fig. 2(a) becomes approximately Fig. 2(b). Assuming for simplicity that all $P_0(r, s) = c$ (a constant) we have, using Table 1:

$$\begin{aligned} P(1,2) &\approx P_0(1,2) + P_0(1,A)P(A)P_0(A,2) + \cdots \\ &= c + c^2\,P(A) + c^3\,P^2(A) + \cdots \\ &= c\,[1 + cP(A) + c^2P^2(A) + \cdots] \\ &= c/[1 - cP(A)] \quad (2) \end{aligned}$$

where we have used the fact that the expression in brackets is a geometric series. This same technique is used in the quantum case.

III. Single Electron Propagating in a Crystal The example here is just like the previous one, except that instead of a propagating drunken man interacting with various bars, we have a propagating electron interacting with various ions in a crystal. A crystal consists of a set of positively charged ions arranged so they form a regular lattice, as in Fig. 3. An electron interacts with these ions by means of the Coulomb force. The single-particle propagator here is the sum of the quantum-mechanical probability amplitudes for all the possible ways the electron can propagate from point $\mathbf{r}_1$ in the crystal, at time t_1, to point $\mathbf{r}_2$ at time t_2, interacting with the various ions on the way. These are: (1) freely, without interaction; (2) freely from $\mathbf{r}_1, t_1$ (= "1" for short) to the ion at $\mathbf{r}_A$ at time t_A, interaction with this ion, then free propagation from the ion to point 2; (3) from 1 to ion

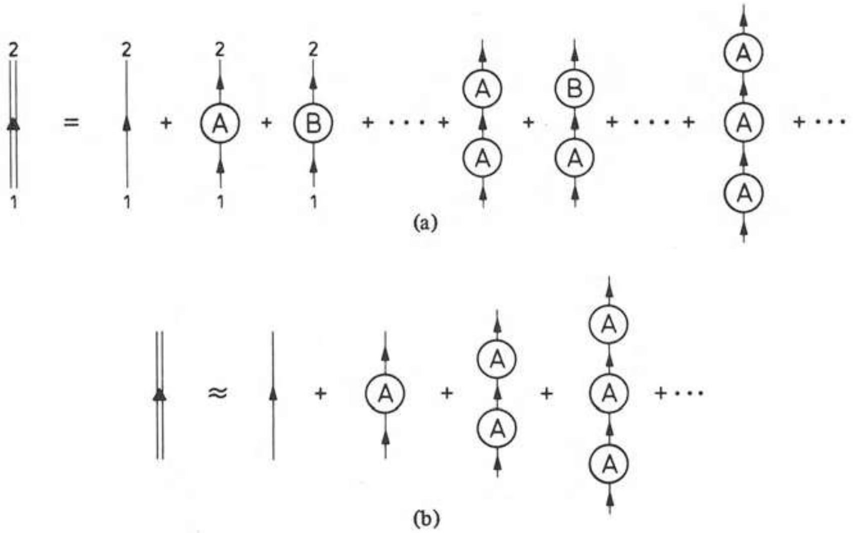

FIG. 2. (a) Feynman diagram series for drunken man propagator, or for electron propagating in crystal. (b) Approximate series ("partial sum") for drunken man propagator.

TABLE 1. FEYNMAN DIAGRAM DICTIONARY FOR DRUNKEN MAN PROPAGATOR

Word	Picture	Meaning
$P(1, 2)$		Probability of propagation from 1 to 2.
$P_0(\mathbf{r}, \mathbf{s})$		Probability of free propagation from **r** to **s**.
$P(X)$		Probability of stopping off at bar X for a drink.

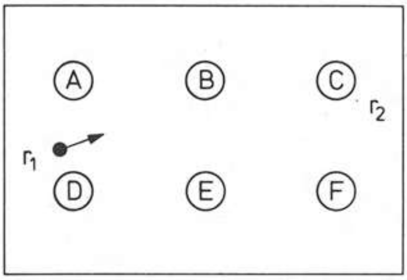

FIG. 3. Electron propagating among ions A, B, C · · · in crystal.

B, interaction at B, then from B to 2, etc. Or we could have the routes 1-A-A-2, 1-A-B-2, etc. We can now use the dictionary in Table 1 to translate this into diagrams, provided the following changes are made: change "probability" to "probability amplitude," and change the meaning of the circle with an X to "probability amplitude for an interaction with the ion at X." When this is done, the series for the propagator can be translated immediately into exactly the same diagrams as in the drunken man case! That is, Fig. 2(a) is also the propagator for an electron in a crystal, provided that

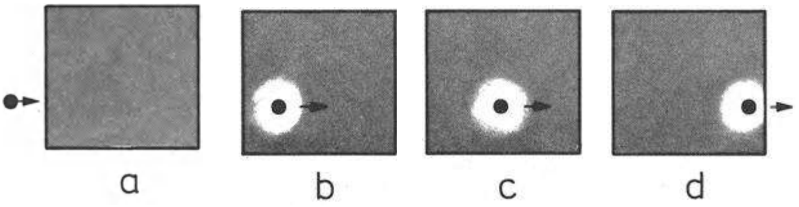

FIG. 4. Electron propagating in electron gas.

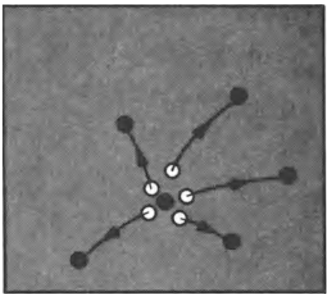

FIG. 5. "Hole" picture of empty space around electron in electron gas.

we just use a quantum dictionary to translate the lines and circles into functions. The series can be partially summed, and from the resulting propagator we obtain immediately the energy of the electron moving in the field of the ions.

IV. Electron Propagating in an Electron Gas We now look at the problem of many interacting particles, taking as an example a large number of electrons interacting with each other by means of the Coulomb force. It is assumed that there is a uniform, fixed positive charge "background" present which keeps the whole system electrically neutral. This system is called the "electron gas" and is used as a simple model for electrons in a metal. The propagation of an added electron through this system is shown in Fig. 4. Figure 4(a) shows the uniform charge distribution in the undisturbed system, with an extra electron entering from the left. In 4(b) the extra electron has entered, repels other electrons away from it (Coulomb repulsion between like charges), so we get an "empty space" near the extra electron and repelled electrons further away. The extra electron surrounded by the empty space is called the "*quasi electron*" and it propagates through the system as shown in Fig. 4(c), (d). It is convenient to view the empty space around the extra electron as composed of "holes" in the electron gas. That is, the Coulomb repulsion "lifts out" electrons from the electron gas in the immediate vicinity of the extra electron, thus creating "holes" in

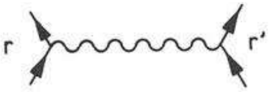

FIG. 7. Feynman diagram for interaction between two electrons.

the charge distribution of the gas, and puts these lifted-out electrons down again further away. This picture is shown in Fig. 5.

Using this picture, we can decompose the propagator into the sum of the probability amplitudes for all possible ways that the extra electron can propagate through the system interacting with the other electrons. The simplest way is free propagation without interaction. Another way is shown in the "movie" in Fig. 6. Figure 6(a) shows the extra electron entering the electron gas. In 6(b) we see the extra electron interacting with a nearby electron in the gas, creating a hole nearby and a lifted-out electron further away. The extra electron, the hole, and the lifted-out electron then propagate freely through the gas as in 6(c). In 6(d), the extra electron interacts with the lifted-out electron, causing it to fall back into the hole, thus annihilating both the lifted-out electron and the hole. Figure 6(e) shows the extra electron propagating out of the system. (It should be noted that unlike the drunken man case, the processes shown in Fig. 6 are not physical but rather "virtual" or "quasi-physical" processes, since they do not conserve energy and they may violate the Pauli exclusion principle.)

Let us represent the Coulomb interaction between an electron at point **r** and one at **r**′ by a wiggly line as in Fig. 7. Then the sequence of processes in Fig. 6 may be represented by the Feynman diagram shown in Fig. 8(a) or 8(b). Note that hole lines are drawn as electron lines with a direction opposite to the direction of increasing time. By analyzing the other possible processes which can take place, we find the series for the electron propagator shown in Fig. 9. Again, these diagrams may be evaluated by writing the appropriate factor for each free electron and hole propagator and each interaction, and carrying out a partial sum. The result-

ant expression for the propagator yields directly the energy and lifetime of the quasi electron.

For a more extensive and detailed account of Feynman diagrams, see Ref. 1.

FIBER OPTICS

As the name suggests, fiber optics deals with the transmission of light through thin strands of transparent dielectric materials such as glass or plastic. The general subject of fiber optics can be subdivided into three broad classes: fiber bundles for illumination and image transmission, fiber optic sensors, and optical fiber telecommunications. However, the physical principles involved in light transmission through optical fibers are the same in all three areas of applications.

Light Transmission Through Optical Fibers The simplest kind of optical fiber consists of an inner circular cylinder of a homogeneous dielectric material, the *core*, that is surrounded by another homogeneous dielectric material of lower refractive index, the *cladding*. Because the refractive index profile of core and cladding resembles a step, this structure is called *step-index fiber*. A light ray traveling along a straight line in the core suffers total internal reflection if it impinges on the core-cladding boundary at a sufficiently small angle. Rays traveling at angles larger than a critical angle are only partially reflected and lose all their energy after only a few repeated reflections. Thus, the fiber is able to trap light within a cone defined by the critical angle. (See Fig. 1).

More complicated optical fibers consist of a core whose refractive index is inhomogeneous, changing continuously from a relatively high value on axis to a lower value at the core-cladding interface. Rays in such a graded-index

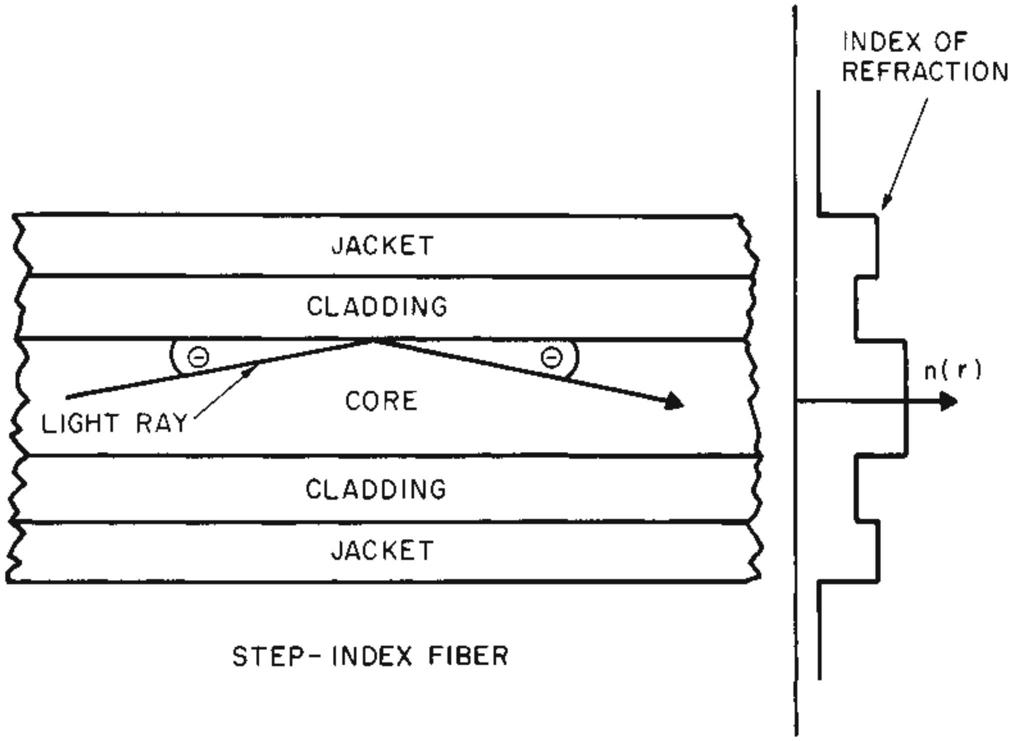

Fig. 1.

fiber travel on curved paths and remain trapped inside the core if their trajectory does not encounter the core-cladding interface (Fig. 2).

Light propagation in optical fibers can also be described in terms of wave optics. Instead of rays traveling at different angles we now speak of *modes*. A mode is defined as an electromagnetic wave that travels through a uniform fiber without changing the shape of its transverse field distribution. Depending on their core diameters and refractive index distributions, fibers can support varying numbers of modes. A fiber with a large diameter and/or large index difference can support many modes. On the other hand, it is possible to design a fiber with sufficiently small core diameter and/or small index difference so that it can support only one mode in each of two possible polarizations. Each mode can be represented by bundles of rays traveling at angles characteristic of the mode in question.

In step-index fibers, the distance and hence the travel time of light depends on the angle at which a ray propagates. Or, expressed in the language of wave optics, the travel time is different for each mode. This undesirable property of step-index fibers has the consequence that pulses, whose energy is spread over many rays traveling along different paths or on different modes, arrive at the fiber end spread out over a time interval corresponding to the difference in arrival time of the slowest and fastest ray or mode. In graded index fibers, this *intermodal dispersion* can be compensated partially. The travel time of light depends not only on its geometrical distance but also on the index of refraction of the medium. Light moves more slowly in regions with high refractive index and faster in a low-index medium. Since the light trajectory in a graded-index fiber samples high-index regions near the fiber axis and lower-index regions farther from the axis, averaging takes place. It is possible to design graded-index fibers that very nearly compensate the travel time differences along all possible rays or for all possible modes. Such optimized fibers have a refractive index distribution that is nearly (but not exactly) parabolic as a function of the radial coordinate. Even though no perfect compensation is possible, a very substantial improvement over intermodal dispersion in step-index fibers can be achieved.

Fibers that support only a single mode (*single-mode* or *monomode fibers*) do not suffer from intermodal dispersion. However, a different source of pulse spreading is operative in all fibers: *chromatic dispersion*. This means that light of slightly different wavelength propagates at slightly different velocities. Light sources used to excite optical fibers have finite spectral width. But even if the unmodulated source were strictly monochromatic, the pro-

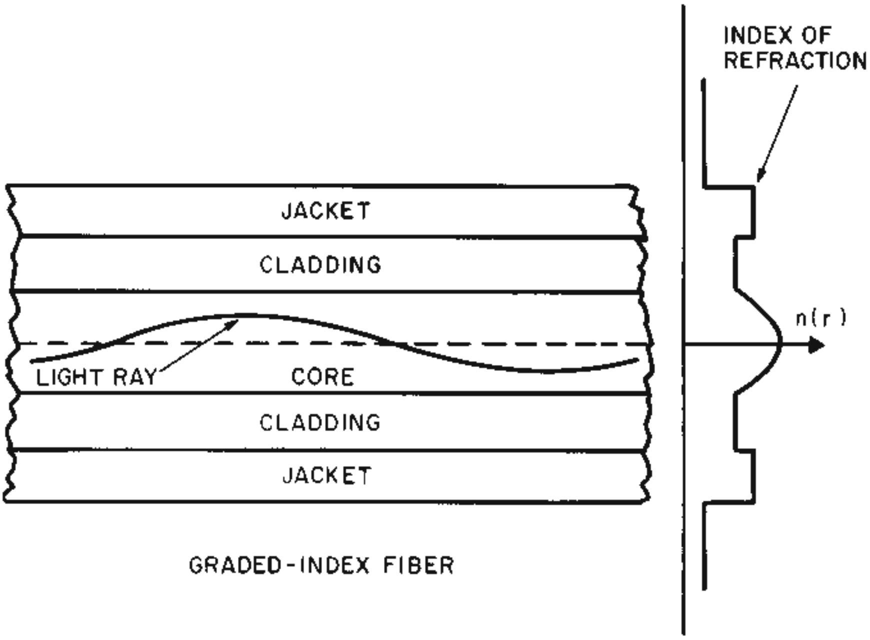

Fig. 2.

cess of modulation introduces new spectral components. Thus, chromatic dispersion is operative in all fibers. Fortunately, one of the most important materials for making optical fibers–fused silica–has the property that dispersion vanishes to first order at a wavelength near 1.3 μm. If operated at the minimum dispersion wavelength, extremely short pulses (psec) can be transmitted over long lengths (tens of km).

In addition to dispersion, the performance of an optical fiber is characterized by the power loss that a light signal suffers when traveling in it. The loss parameter depends mostly on the materials out of which the fiber is made. Fibers made of plastics have high losses and are useful only for light transmission over a few meters. Fibers made of fused silica have achieved extremely low losses indeed. The loss spectrum of fused silica has its lowest value near 1.5 μm. Losses as low as 0.2 dB/km have been measured in fused silica fibers. This means that one-half of the original input light power still arrives at the end of a fiber of 15 km length. For longer wavelengths the loss increases sharply because the light can excite vibrations of the atoms of fused silica. At shorter wavelengths the loss increases sharply because the light induces electronic transitions. In silica fibers, the window of high transparency extends roughly from 0.5 μm to 1.8 μm.

Fiber Fabrication Even though plastic fibers are cheap to fabricate, their high losses preclude their use in most telecommunications applications. For this reason we limit the discussion to a few methods for making glass fibers. A simple method consists in placing a solid glass rod of relatively higher refractive index into a glass tube of lower refractive index. The end of this rod-in-tube assembly is heated to the softening point and is pulled into a step-index fiber. The diameter of the resulting fiber depends on the diameter of the starting tube, the drawing temperature, and the drawing speed. More sophisticated methods use an arrangement of concentric crucibles filled with different molten glasses. The core and cladding glasses combine at the tips of the crucibles and are drawn into step-index fibers.

Low-loss fibers for telecommunications applications must be made of very pure materials. Contamination of the pure glass with metal ions or with water can increase the losses dramatically. In some chemical vapor deposition methods, glass is deposited on the outside of a mandrel by converting silicon tetrachloride and dopant vapors into doped silicon dioxide. In the modified chemical vapor deposition (MCVD) method a mixture of silicon tetrachloride and oxygen is passed through the inside of a heated silica tube. Added to this mixture are dopant gases such as germanium tetrachloride or phosphorus trichloride. Germanium or phosphorus increases the refractive index of fused silica, whereas the addition of boron or fluorine to silica glass decreases its refractive index. The chlorine compounds are converted to oxides and are deposited on the hot inner surface of the silica tube, where they fuse to form layers of doped silica glass. The rate of deposition is controlled by the concentration of the vapors inside the tube, by the temperature, and by the speed with which the heating torch is passed along its outside. By careful control of the ratio of silicon tetrachloride and dopant materials, desired refractive index distributions can be achieved. After the deposition step the tube is heated until it collapses to form a solid rod—the *preform*—out of which the fibers are drawn. Fibers for optical communications are protected against scratches (which weaken their strength) by a plastic jacket which is applied while the fiber is drawn.

Fiber Bundles An important application of fiber optics is the use of fiber bundles for illuminating or viewing inaccessible places such as body cavities (*endoscope*). Fiber bundles are formed by combining individual fibers. If no attention is paid to the relative position of the fibers at either end, we speak of an incoherent bundle. Fibers in incoherent bundles may have diameters between 50 to 200 μm. If the relative positions between all fibers are carefully maintained, a coherent bundle results. Incoherent bundles are cheaper to manufacture and are used for guiding light to illuminate inaccessible places. To make it coherent, the fiber bundle is first wound as a closed loop of the desired thickness and circumference. Next, the fibers of this closed-loop bundle are fused tightly to each other at one point of the circumference before they are cut at that point. Finally, the ends are polished. The fibers at both ends of the resulting linear bundle are now restrained to maintain their relative position but are free to flex in between. A coherent bundle can be used to transmit images. The image of an object is focused by lenses onto one end of the bundle. Each picture element is transmitted along one of the fibers. The resulting image can be viewed at the far end of the bundle through an eyepiece with a resolution that depends on the density and diameter of the fibers. A coherent bundle may contain from 5,000 to 50,000 fibers with diameters between 5 and 25 μm and may be several meters long. Flexible, coherent fiber bundles of sufficiently small diameter are used to view the inside of the stomach or other body cavities. Illumination is provided either by shining light through a subsection of the bundle or by a separate bundle that need not be coherent. Tapered coherent fiber bundles can be used to magnify or demagnify images. If desired, images can be scrambled by scrambling the relative positions of the fibers in the bundle.

Very short, coherent fiber bundles—*fiber optic plates*—are used for special applications. A fiber optic plate inserted into the face of a cathode ray (picture) tube can enhance image brightness by capturing more light from a fluorescent coating on its inside surface. Fiber optics plates are also used to connect successive stages in image intensifiers or infrared image converters.

An image can be transmitted through a single fiber with a parabolic refractive index profile. Short sections of such fibers act as tiny graded-index lenses. Inside a parabolic-index fiber an image focused onto one of its ends is refocused periodically along its length. The quality of the transmitted image depends on the quality of the index profile and the length of the fiber.

Fiber Sensors Because of their great length, minute changes of the refractive index along the fiber can result in sizeable phase changes of the transmitted light. The index change may be induced by many different effects such as magnetic fields, temperature, pressure, stress etc. Observation of the propagation properties of light in response to such external disturbances make fibers ideal as sensors. Pressure induced refractive index changes due to underwater sound make fibers useful as hydrophones. Their sensitivity to magnetic fields (Faraday effect) permits their use as current sensors on high voltage transmission lines; their sensitivity to stress enables their use as strain gauges.

A particularly interesting application of fiber optics is their use as rotation sensors. In principle, rotation can be sensed with any device that allows a comparison of the time of flight of light in the two opposite directions along a closed, rotating loop. Fibers have the advantage that the light path along the loop can be made very long by using fiber coils to magnify the effect. Rotation rate sensors for ships and aircraft are being developed.

Optical Fiber Telecommunications Because of their low losses, optical fibers are ideally suited as waveguides for the transmission of messages modulated on light signals. The discussion of the use of fibers as sensing elements may lead to the suspicion that optical fiber communications might be plagued by interference from electromagnetic fields, thermal changes, or sensitivity to vibrations. Fortunately, quite the opposite is true. The ability to sense changes in their environment is due to phase changes imparted by the fiber to a light signal passing through it. However, for communications applications the phase of the light field is not being sensed, so that one of the advantages of fiber communications is its insensitivity to electromagnetic interference. If fiber optics are used improperly, sensitivity to vibrations could be a problem (*modal noise*) but can be minimized by proper design of the system.

Typically, an optical fiber communications system consists of the following components: a modulated light source, the fiber waveguide, and a detector. For use with multimode fibers the light source can be either a cheap, reliable light emitting diode (LED) or a more sophisticated and expensive injection laser. Since single-mode fibers cannot be excited efficiently with an LED, a laser must be used. This is the reason why, in spite of their higher dispersion, multimode fiber systems coexist with single mode fiber systems.

Both LEDs and lasers work basically on the same principle. Electrons and holes are injected into the junction region of a semiconductor diode where they combine to emit a light photon. In an LED the photons escape from the junction as soon as they are generated. In an injection laser each photon is reflected back and forth between the mirrors of a resonant cavity and is forced to stimulate the emission of more photons. Consequently, the light of an LED is completely incoherent while the output of a good laser is highly coherent. Lasers and LEDs are pulse modulated by pulsing their electrical feed current.

With the optimum refractive index profile and operating at the wavelength of minimum chromatic dispersion (near 1.3 μm) multimode fibers can transmit pulses at rates of 100 Mbits/sec over distances of several kilometers. With single-mode fibers, pulse transmission rates of several Gbits/sec can be achieved.

Several optical fibers are usually combined into fiber cables of various constructions. Each fiber in the cable provides one independent transmission path for light pulses that themselves may carry thousands of telephone conversations or tens of television programs. Some cable designs first combine several fibers into a ribbon and then incorporate several fiber ribbons into one cable. Other designs support loosely fitting individual fibers in plastic tubes several of which are incorporated into a cable. In all cases plastic or metallic support members are included in the cables for added strength. Metallic conductors are sometimes used for the purpose of powering repeaters along the route of the cable.

Optical fibers can be spliced. In ribbon cables all fibers in one ribbon are usually spliced simultaneously. In some methods, splicing is accomplished by sliding the ends of the fibers into plastic sleeves and bonding them into place. It is also possible to heat the ends of two fibers until they join to form a fusion splice.

Optical fiber cables are used to connect local exchanges and for long distance transmission between cities, and they are being considered as submarine cables.

In applications where the length of the optical fibers does not exceed a few kilometers (for use between local exchanges for example) no repeaters are needed. But for applications between cities or for submarine cables, repeaters must be used at distances from 5 to 20 (or even more) kilometers. At each repeater the light signal is first converted to an electrical signal which is used to regenerate the pulses before they are launched into the next section of the optical communications link. Amplification and pulse regeneration of the light signal itself, even though possible in principle, it not yet contemplated for any practical fiber optic communication system.

Light detectors are semiconductor devices which absorb photons and convert them into electron-hole pairs which cause a current to flow in an external circuit. Thus, detectors and light sources complement each other in their mode of operation.

In time, optical fibers may well replace most of the metallic conductors that are now being used in the telephone plant.

FIELD EMISSION

Field emission of electrically charged particles occurs when a sufficient high electric field is applied to the surface of a conductor. Specifically, field emission of electrons from cold metals into a vacuum is a basic physical effect comparable to thermionic, photoelectric, or secondary emission. Field electron emission is also termed *cold emission* or *autoelectronic emission*. Field emission of electrons from metals at room temperature requires an electric field of an order of magnitude of 3×10^7 volts/cm; this can be obtained by applying a few thousand volts to a sharply curved cathode, which may be either a fine wire, a sharp edge, or a needle tip. From such cathodes, field emission was first observed by R. W. Wood in 1897, and technical application in high-voltage rectifiers and x-ray tubes was attempted by J. E. Lilienfeld in the early 1920s. He failed because of the inadequate vacuum techniques available at that time. The quantum mechanical theory of field emission was given by R. H. Fowler and L. W. Nordheim in 1928, which agreed with the current-voltage relationship measured by R. A. Millikan and C. C. Lauritsen, but experimental work to further verify the predictions advanced only with the possibility of controlling highly perfect emitter tips in the field emission microscope by E. W. Müller in 1937. Subsequently field emission microscopy became an established research technique for surface phenomena connected with adsorption. By operating a point emitter at a positive potential in the presence of gas, Müller discovered field ionization (1951) and developed the low-temperature field ion microscope (1956) which surpassed all other microscopic devices with its capability of showing the individual atoms as the building blocks of the crystal lattice of the metal specimen. In the last three decades, technical application of field emission has also been successful with the development of powerful flash x-ray tubes (W. P. Dyke, 1955). The extremely large current densities of up to 10^8 amperes/cm^2 make a field emission cathode very attractive for mm wave tubes, cathode ray tubes, and electron microscopes, but the sensitivity to contamination and cathode sputtering are detrimental to stability and long lifetime.

Field emission can be explained with the concepts of quantum mechanics. The conduction electrons of a metal are moving in a potential trough, from which they can escape ordinarily only by addition of thermal energy (thermionic emission), by an energy transfer from photons (photoelectric emission), or by collision with other energetic particles (secondary emission). If the barrier of the trough is narrowed by the application of an external electric field to be comparable with the wavelength of the electrons inside the metal, then a small amplitude of the electron wave will penetrate outside the barrier. Thus there is a finite probability that the electron will tunnel through the potential barrier, even if its kinetic energy is insufficient to go over it. According to the Fowler-Nordheim theory of field emission, the current density J (in amperes/cm^2) as a function of field strength F (volts/cm) and of the work function ϕ (electron-volts) is approximately given by

$$J = 1.55 \times 10^{-6} \frac{F^2}{\phi} e^{-\frac{6.85 \times 10^7 \phi^{3/2}}{F}} .$$

A more refined theory takes into account the effect of the image force on the electron, which reduces the exponent of the above equation by a factor slightly smaller than unity and which depends upon $\phi\sqrt{F}$. The field required for a given current density is thus reduced by some 10–20%. The temperature dependence of field emission is found to be very small below about 1000 K (Fig. 1). Considerable increase in emission is observed when both the temperature and the field are high. This effect is called *T-F emission*.

Field emission of positive ions can occur when an adsorbed layer is desorbed from the emitter surface by a positive electric field (*field desorption*). At a field of a few volts per angstrom, lattice atoms can also be evaporated in the form of multiply charged ions (*field evaporation*). These ion currents cannot be sustained for a long period of time, since the adsorption layer or the emitter surface will soon be consumed. Continuous field ion emission is obtained by operating the positive emitter in a gas of low pressure. Gas molecules attracted to the tip surface by polarization effect can be adsorbed on the apex of surface atoms (*field adsorption*), or can be ionized when their valence electrons tunnel into the metal when the molecules are a few angstroms above the surface (*field ionization*). Ion currents are small (less than 10^{-9} amp) because of the limited supply of the gas molecules. The fields needed for ionization are very high, about 2.2×10^8 volts/cm for hydrogen and 4.5×10^8 volts/cm for helium.

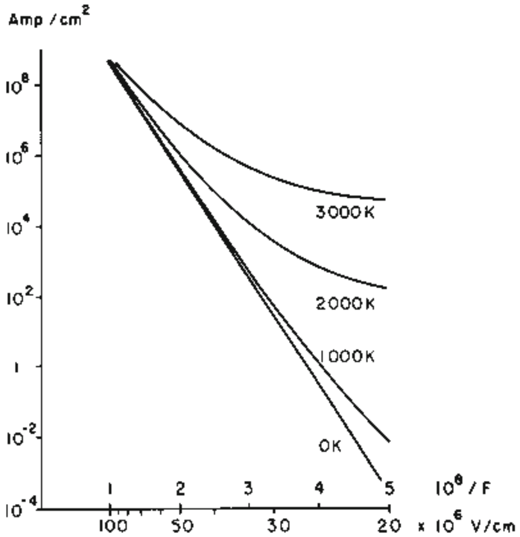

FIG. 1. Current density of field emission for a tungsten cathode plotted as a function of reciprocal field strength, for various temperatures.

Field electron emission has been successfully applied to develop a powerful flash x-ray tube (W. P. Dyke), a high resolution scanning electron microscope (A. V. Crewe), and a bright point electron source for high resolution electron lithography. Field ion emission from liquid metals is now actively pursued as a continuous high brightness point ion source with a potential application in high resolution ion lithography (R. L. Seliger). The continuous miniaturization of electronic devices makes these techniques quite attractive because of their small sizes and high brightness.

Although its technical application is not yet widespread, field emission has been a subject of intensive investigations, and the field electron and the field ion microscopes have become productive tools of basic research in the study of solid surfaces. The specimen of the field emission microscope is a needle-shaped field emitter with a hemispherical tip of a radius of some 10^{-5} to 10^{-4} cm, arranged in a vacuum tube opposite a fluorescent screen. With a few thousand volts applied, field emitted electrons move away from the tip in a radial direction, displaying on the screen an enlarged projection image of the distribution of electron emission at the emitter. The magnification of this microscope is approximately equal to the ratio of screen distance to tip radius and can exceed one million. The lateral resolution is limited to 25 Å by a random tangential velocity component of the electrons due to the Fermi distribution inside the metal and by diffraction due to the de Broglie wavelength. As even traces of adsorption layers change the work function and, thereby, the emission, the presence of such layers can be readily detected on the screen. The imaged tip cap usually represents a single crystal, so that the behavior of adsorption layers can be studied in its dependence on crystallographic orientation of the substrate. As little as 10^{-3} of a monolayer of oxygen is clearly discernible on many metals. Because of the small temperature dependence of field emission, such layers, their surface migration, adsorption and desorption rates, and the activation energies of these processes can be measured in a wide temperature range. This is done by immersing the entire microscope into a cryogenic bath and by heating the emitter to any desired temperature up to near its melting point. Most studies have been done with the high-melting metals, W, Re, Ta, Mo, Nb, Ir, Pt, Rh, Pd, V, Ni, Fe, Ti, Cu, and various alloys and with adsorption layers of H_2, N_2, O_2, CO, CH_4, and the noble gases. Detailed patterns of individual organic molecules, such as phthalocyanine or similar aromatic compounds, cannot yet be fully explained. The interpretation of thermal desorption experiments is often difficult because of the occurrence of surface migration, while the well-defined field strength obtained in field desorption experiments cannot be fully utilized because of the complex polarization conditions at the various adsorption sites.

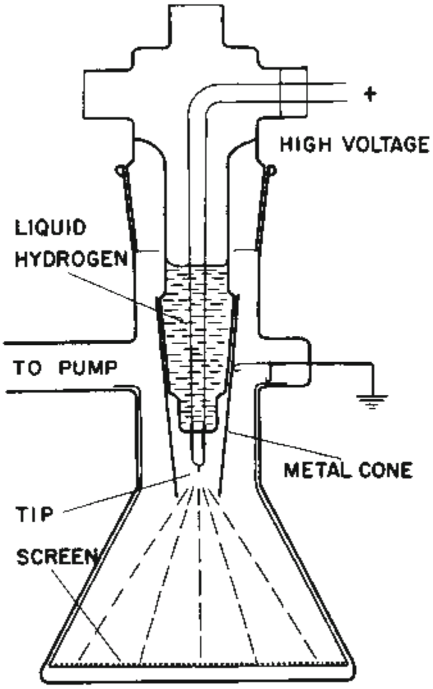

FIG. 2. Schematic diagrams of an early field ion microscope. The hemispherical cap of the tip, having a typical radius of 500 Å, is radially projected onto the fluorescent screen with the help of helium ions. Modern FIM uses a stainless steel chamber, and is equipped with a channel plate for image intensification. Otherwise, the construction is essentially the same.

The field ion microscope (Fig. 2) was developed to overcome the limited resolution of the field electron microscope. In contrast to the case of electrons, the undesirable tangential component of the motion of the imaging ions can be reduced by lowering the emitter temperature. The short de Broglie wavelength of ions is also an advantage. Usually operated with helium or neon as the imaging gas and the tip cooled down to 20 to 80 K, a spatial resolution of ~2.5 Å can be achieved. Thus most atoms on the lattice can be resolved (Fig. 3). The specimen surface developed by field evaporation at low temperature, is atomically perfect and free from contamination. Helium atoms are ionized above field adsorbed atoms, and are then accelerated toward the screen assembly. Nowadays, the screen assembly consists of a microchannel plate and a fluorescent screen. The microchannel plate converts the ion image into an electron image and amplifies the image intensity by a factor of about 100 to 1000. Each protruding surface atom is imaged by 10^3 to 10^4 helium ions/sec. The surface stays atomically clean as all impurity gases, having a lower ionization potential than helium, are ionized in the low field region in space before they can reach the tip. Image stability requires that the evaporation field of a sample be higher than the ionization field of the imaging gas. Use of helium is thus limited to refractory metals. For soft metals such as Au, Cu, Fe, Ni, Al, etc. neon, argon or hydrogen may be used with a slightly inferior resolution. Many metals yield to the mechanical field stress $F^2/8\pi$ produced by the image field, which amounts to about 1000 kg/mm^2 at the helium best image field of 4.5×10^8 volts/cm.

The field ion images usually do not tell the chemical identity of the imaged atoms. This can be done by combining the field ion microscope with a time-of-flight mass spectrometer with a single atom detection sensitivity. This new instrument (Fig. 4), the atom-probe field ion microscope, allows the observer to select one atom by tilting the tip until its image falls onto a small probe hole in the screen. By superimposing a 10-nanosecond high voltage pulse to the dc imaging voltage the selected atom is field evaporated and travels through the probe hole and the time of flight tube to reach the particle detector, which is a Chevron channel plate. The flight time can be measured either with an oscilloscope or with a set of electronic timers. From

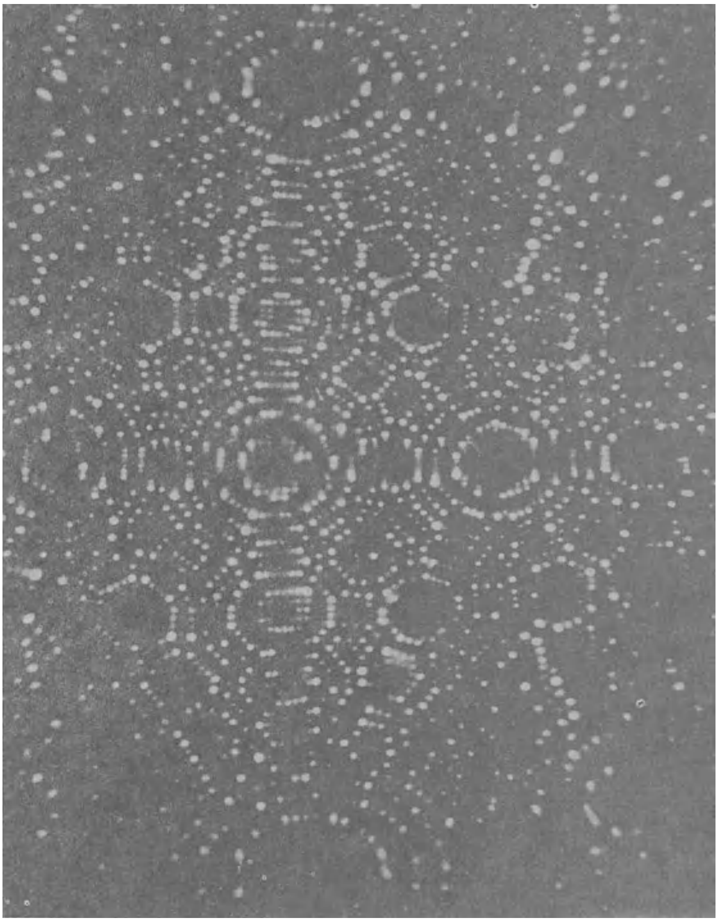

FIG. 3. Field ion micrograph of a fully ordered equiatomic platinum-cobalt alloy crystal, showing the individual atoms as single dots. Original magnification on the 5-inch screen was 1.5 million. In the image, only Pt atoms are visible.

the flight time, the mass to charge ratio and the chemical identity of the atom are identified. The energy focused time of flight atom probe is capable of separating isotopes of an element to the root of the mass lines (Fig. 5). The nanosecond pulsed field evaporation can also be done with laser pulses. High resistivity materials such as high purity silicon can only be studied with the pulsed laser atom-probe. A slightly different version of the atom-probe is the imaging atom-probe. It is essentially an ordinary FIM, but uses a screen assembly with single ion detecting sensitivity, or the Chevron channel plate. Although the mass resolution is severely limited by the short flight path, there is the advantage of finding the spatial distribution of field desorbed atoms from its desorption image. In fact by activating the chevron to detect only a certain ionic species by a time gating technique, the spatial distribution of a selected species can be displayed. A pulsed laser imaging atom-probe is shown in Fig. 6.

The atom-probe and the field ion microscope have been widely applied to study fundamental problems in metallurgy, materials science, and surface science. Single vacancies produced by quenching, cold working, or particle irradiation can be counted and localized. Interstitials resulting from impurities can be seen and their thermally activated migration to the tip surface can be measured. The structures of dislocations and the matching of the lattices along grain boundaries can be studied in atomic detail. Surface diffusion of single atoms and simple atomic clusters on atomically perfect surfaces, interaction between adsorbed atoms, and adsorbed layer superstructure formation can be studied quantitatively. The charge distribution of an adsorbed atom as manifest in the dipole moment and polarizability can be measured. The long-

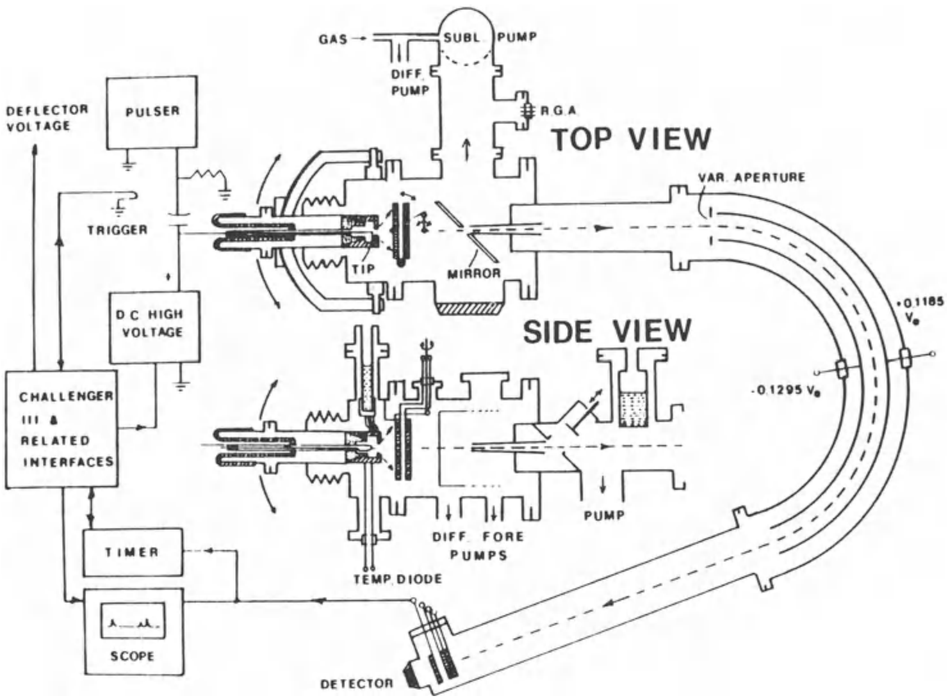

FIG. 4. The energy-focused time of flight atom-probe. The tip orientation can be adjusted with the help of an external gimbal mount and a metal bellows seal. The image can be seen through the 45° inclined mirror. By flipping the channel plate assembly away, the pulsed field evaporated atom can travel through the 163° spherical condenser plates, and be detected. The flight time is displayed in the oscilloscope, as well as recorded in an electronic timer.

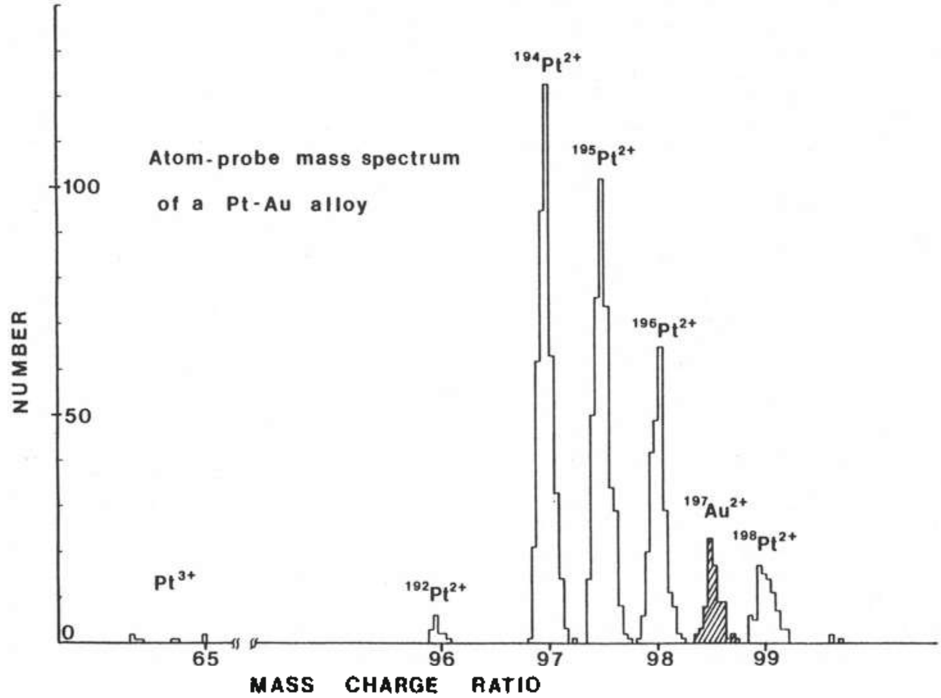

FIG. 5. An atom-probe mass spectrum of a Pt-Au alloy where all the isotopes are separated.

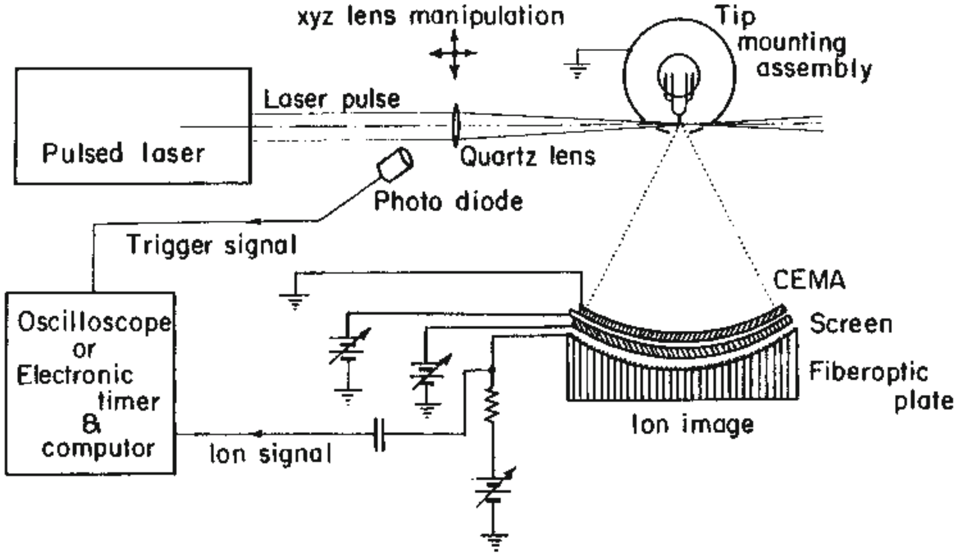

FIG. 6. A pulsed-laser imaging atom-probe. Desorption images can be displayed, and simultaneously chemical species of desorbed atoms identified from the flight times.

range and short-range order parameters in alloys can be investigated. The composition of surface layers in surface segregation of alloys can be measured with the atom-probe with true atomic layer depth resolution. The composition of precipitates, segregation of impurities to the grain boundaries, and cluster formation in alloys can be studied in the atom-probe. The atom-probe, an analytical tool of ultimate sensitivity, has also revealed the phenomena of field adsorption, thus provides new insights into the mechanism of the field ion image formation. The atom-probe has also been used to study gas adsorption, field evaporation, and exchange diffusion of surface atoms. As scientists are always interested in understanding physical phenomena through microscopic theories, atom-probe and field ion microscopy have a lot to contribute in the future.

FIELD THEORY

The description of the physical world has evolved profoundly through the ages, at times because of, at other times being the cause of, sweeping changes in our philosophical, mathematical and experimental knowledge. Greek geometry concerned itself essentially with properties of "objects as such," a triangle or a cube being studied, for example, without any thought of their spatial environment; the Ptolemaic system enhanced this view into a clockmaker's dream, where celestial bodies parade around the earth, rigidly driven in circular motions. Only with Descartes' analytical geometry did objects become "portions of space" and the properties of space itself the main object of study; with

Galileo and Newton, a correct science of dynamics was born, which permits the prevision of an amazing number of mechanical phenomena in that space from a few first principles.

Field theory studies the phenomena of the physical world as due to interactions which propagate through space; the "geometrical emptiness," which is the space of mathematics, becomes the medium into and through which actions take place or, even more drastically, a structure which is itself determined by the properties of matter, as in general relativity (which will not be discussed in this article).

Suppose two bodies interact in space, e.g., the sun and the earth with Newton's law, or two electric charges with Coulomb's law. Two pictures of this situation are equally possible and correct. One is that this interaction cannot be conceived if *both* bodies are not there and that we should study primarily its effects without looking for a detailed mechanism for its propagation from one body to the other; this is the description of "action at a distance", in which *forces* are the main concepts and space is a vacuum into which bodies follow trajectories determined by the forces acting upon them. The other picture consists of imagining that each body, whether alone or not, modifies the structure of the space which surrounds it, geometrically or because in each point of that space there is now potentially a force, which becomes active if another body occupies that point, but should be conceived as existing there in any case; the main objective here is to study how these "fields of force" are created in space by material objects and how they propagate; this is the point of view of "action with contact," which finds its full development in field theory.

Mathematically, a field is characterized by assigning to each point of space a quantity which is *intrinsically* associated with it; a temperature, for instance, or a velocity, or a tensor or a spinor of arbitrary rank. "Intrinsic" means that if we change our frame of observation, this quantity does *not* change; supposing, e.g., that our field is that of the velocities at a given instant of all the points of a moving fluid, if we rotate our coordinate system we shall observe different values for the components of those velocities, just because we, not the velocities, have changed position. It is therefore essential that, together with the specification of the field quantities, their transformation laws also be assigned under changes of the reference frame; these laws are indicated by the description of the field quantity as a "scalar" (which does not change), a "vector" (which changes with the same law as the coordinates), a "tensor," etc.; the complete specification of all such possible laws is a standard chapter of group theory.

Physically, we have to account for the creation or the existence of the field, by describing the field quantities as generated by "sources," such as positive or negative charges for the electromagnetic field, or the sources and sinks of hydrodynamics. Moreover, we have to describe in which way the values of the field quantities change when the point at which they are considered, or the time, is changed. In the absence of discontinuities, for instance in vacuum, one expects these values to differ by infinitesimal amounts if the corresponding points are infinitesimally close, in some way which is typical of the field considered; in other words, that the rates of change of the field quantities with respect to the space coordinates and time be connected by relations which specify both how these changes can occur compatibly with the geometrical properties of space, and how they are related to the sources. Group theory determines all the possible forms which are permissible for these relations, which take the name of *field equations*; each field theory is characterized by a special set of field equations, which are clearly *partial differential equations*.

RELATIVITY and QUANTUM THEORY have played a great rôle in the development of field theory; we shall briefly discuss, later, their influence both in the explanation of new physical phenomena and in the mathematical formulation of the theory.

Field theory has taken an entirely new shape with the so-called second quantization, which has led to several modern developments, of which some embody faithfully the concepts outlined thus far and others instead represent new views in natural philosophy; this is still a matter of controversy at present, and it is yet unpredictable whether a reasonably lasting description of nature will come out of such attempts or whether a new drastic turn in human thought will be necessary before we can hope to understand the fundamental laws of physics. Be that as it may, the ideas and the computational techniques of field theory have proved already of invaluable help in the description of many phenomena, from particle physics to superconductivity.

It is convenient to examine first the theories in which the field quantities are ordinary functions of space and time points, regardless of whether they have a direct physical meaning (as with the velocities of hydrodynamics and the electromagnetic forces) or not (as with the wave function which obeys a Schrödinger equation). This comprises of course most of classical and modern physics; mathematics permits again, however, a tremendous conceptual simplification. In the study of continuous media or fields one is, most often, interested in one of the following classes of phenomena:

(1) Phenomena which consist of the propagation of some action; the medium itself is not transported from one place to another; typical is the propagation of waves, whether they be seismic, fluid or electromagnetic;

(2) Phenomena in which there is transport or diffusion of a quantity in a medium: of heat in

a wall, of solute in a solvent, of neutrons in a pile;

(3) Equilibrium phenomena: deformations of strained elastic bodies, electro- or magnetostatic fields as determined by charges and boundaries.

Each class is ruled by essentially one type of equation. Let $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$ denote the Laplace operator; $\phi = \phi(x, y, z, t)$ the field quantity; F some function of x, y, z, t, ϕ and, at most, of the first-order derivatives of ϕ; v a velocity; and D a diffusion constant. The corresponding equations can be brought into the standard forms:

$$\Delta\phi - \frac{1}{v^2}\frac{\partial^2\phi}{\partial t^2} = F \text{ (hyperbolic partial differential equation)} \quad (1)$$

$$\Delta\phi - \frac{1}{D}\frac{\partial\phi}{\partial t} = F \text{ (parabolic partial differential equation)} \quad (2)$$

$$\Delta\phi = F \text{ (elliptic partial differential equation)} \quad (3)$$

If the field quantity has more than one component, one may deduce for each of its components an equation which is essentially of the same type, although it may be difficult or impossible to obtain an independent equation for each component.

This classification of physical phenomena according to the type of equation to which their study can be reduced is of the greatest importance: Eqs. (1), (2) and (3) are called in fact "the equations of mathematical physics"; more specifically, Eq. (1) is also called the wave equation, Eq. (2) the heat equation, and Eq. (3) the Laplace or potential equation. The study of their mathematical properties gives complete information on all the physical phenomena which they describe.

The equations of quantum mechanics can also be brought, at least formally, into the form of Eq. (1) or (2); the intervention of complex quantities modifies the situation somewhat, in a way which we cannot discuss here.

Electromagnetic phenomena fall typically into the category of Eq. (1): each of the components of the electric field $\mathbf{E} \equiv (E_x, E_y, E_z)$ and of the magnetic field $\mathbf{H} \equiv (H_x, H_y, H_z)$ satisfies, in vacuum, Eq. (1), with $F = 0$; the connections between **E** and **H** are given by the Maxwell equations, which characterize completely the theory, and lead in vacuum to the result just mentioned. When **E** or **H** does not vary with time, Eq. (1) reduces to Eq. (3), thus yielding electro- or magnetostatics.

The electromagnetic field, i.e., the vectors **E** and **H**, generated by a distribution of moving charges or currents confined within a limited volume has a part which becomes dominant at a large distance from that volume, because it decreases only with the inverse of that distance (instead of the inverse-square law of static fields); this part constitutes the *radiation* field, which is responsible for the transmission of energy and signals (the radiated energy is, of course, supplied by the mechanism which drives the generating charges or currents). This is easy to understand: the energy radiated through a large sphere around the source is proportional to the area of the sphere times the square of E; it vanishes therefore with increasing radius for all but the radiative component, for which it stays constant: energy is actually removed from the source and radiated away to all distances. The study of radiation is a most important part of the theory, both macroscopically (telecommunications, radar) and microscopically (atoms, nuclei, elementary particles).

Relativity and quantum mechanics have extended and modified profoundly the classical picture presented so far. The very concepts of space and time change with special relativity: events which are simultaneous for an observer are not such when seen by another observer in uniform motion with respect to the first, because time and space are mixed together by the Lorentz transformations which relate the reference frames associated with the two observers. As a consequence, the laws of nature can retain their universal validity only if they are formulated in the same form by any such observer, i.e., if their form is not altered by a Lorentz transformation—technically speaking, if they are "Lorentz covariant." This requirement becomes a stringent dogma; it suffices to determine, with the help of group theory, the possible equations for any conceivable relativistic field theory; it is of invaluable help, when computations are made, in checking or correcting them.

The nonrelativistic Schrödinger equation for the wave function of a particle is, but for the appearance of complex quantities, of the type (2) described before: this is not acceptable in a relativistic world, because time and space are not treated alike. One needs either an equation which contains only second-order derivatives, or one with only first-order derivatives; for a free particle, this leads either to the Klein-Gordon equation, which is of type (1), or to the Dirac equation, which contains linearly only the first-order derivatives of the wave function, but has a mathematical structure which necessarily assigns special physical properties to the particles described by it. It was one of the greatest triumphs theoretical physics ever witnessed, to discover that such properties are actually displayed by all particles which obey the Dirac equation: spin, and the existence for each Dirac particle of a corresponding *antiparticle*, i.e., a particle having the opposite mechanical and electrical properties. (See article on ANTIPARTICLES.)

The requirement of relativistic covariance has thus led to fundamental physical discoveries; for each particle obeying the Dirac equation, the corresponding antiparticle has been experimentally found in nature; electron and positron, proton and antiproton, neutron and antineutron, etc. What is more, the theory predicts that a particle-antiparticle pair can be created in a collision phenomenon, if sufficient energy is available, or can annihilate itself, giving away its energy in the form of electromagnetic radiation or other particles.

The classical theory allowed only for the electromagnetic radiation emitted by moving charges or currents; the creation or absorption of particles in collision phenomena, as well as the creation or annihilation of pairs, were outside its scope and possibilities. A new formulation of the theory was needed, which could account consistently for all such phenomena, handling situations in which particles can be created and destroyed in any numbers. The formalism devised for this purpose is that of quantum field theory.

The basic idea is to describe each type of particle by means of a field which is not any more an ordinary numerical function of space and time, but an "operator," i.e., a quantity which changes the number of particles existing in any given state of the system. If the field operator is known, one can then evaluate the probability of a given state (so many particles, with determined energies and momenta) changing into an equally determined, different state. If the particles do not interact among themselves or with other particles, no change is possible; if there is interaction, the field operator has a structure which can cause such transitions. The field equations appear to be essentially the same as those of the classical Maxwell, Klein-Gordon, Dirac theories, etc.; their structure is however fundamentally different, because they now must be equivalent to infinite sets of ordinary equations, which couple states with different and ever-increasing numbers of particles.

Fields which are associated with particles obeying Bose-Einstein statistics (of which any number can be found in any given state) have radically different mathematical properties from fields associated with particles obeying Fermi-Dirac statistics (of which at most one can be found in any given state); examples of the first are photons (the massless neutral quanta of the electromagnetic field), pions (massive particles, with or without electric charge, which are believed to be responsible for nuclear forces), etc.; examples of the second are electrons and positrons, protons and antiprotons, etc.

The passage from numerical fields to operator fields is called "second quantization"; quantum field theory deals with operator fields.

Striking successes have been met with this approach. From a quantitative point of view, they are confined mostly to electrodynamics, where very small deviations from the values predicted by the non-quantized theory, which were observed in the measurement of the magnetic moment of the electron and in the so-called Lamb shift, were accounted for with amazing accuracy by quantum field theory. Qualitatively, the new conceptual framework has proved extremely useful in understanding elementary phenomena, especially with the help of the diagrams devised by R. P. Feynman, which give a simple intuitive picture of collision and radiation processes involving elementary particles. Very little has been achieved quantitatively, though, for theories other than electrodynamics, because of the tremendous mathematical difficulties which arise as soon as the simplest approximation techniques are not applicable because the interaction is too strong; nevertheless, these ideas have proved greatly helpful in many ways, in combination with general principles of symmetry, Lorentz invariance and causality.

A beautiful consequence of this conception, which assumes that particles are the quanta of a field (as photons were recognized by Einstein to be the quanta of the electromagnetic field) was the discovery of H. Yukawa, that whenever such quanta have a mass different from zero, the force they create between two bodies which interact by exchanging such quanta with each other must be an exponentially decreasing function of distance; this force can become of a coulombian type only if the mass of the quanta vanishes. Thus, the Coulomb force can be explained as due to the exchange of photons among electric charges, the nuclear forces (which have typically short ranges) as due to the exchange of massive particles among nucleons. Exchanges of this nature are not observable in the laboratory, because this runs against Heisenberg's indeterminancy principle; if enough energy is supplied, however, such quanta can actually break loose and do appear as the particles created in collision processes.

The mathematical difficulties encountered in quantum field theory are many, and there is as yet lack of agreement as to the best way to circumvent some of them. Besides mathematical complexity, which prevents all but the simplest calculations, there are many unsolved problems of mathematical rigor and apparent inconsistencies which can be removed only by delicate analyses. Typical of the latter is the fact that unsophisticated calculations give infinite values for masses and charges of interacting particles, and a painstaking analysis is required to retrieve from them the significant physical values; this is the so-called renormalization procedure, which copes with infinities which partly are already present in the classical theory (such as the infinite electromagnetic contribution to the mass of a point-like charged particle, when computed from Maxwell's equations) and partly originate from the new formalism (which permits, for instance, pair creation).

It is not yet certain whether such difficulties are due to the lack of adequate mathematical techniques or are the expression of a fundamental inadequacy of the theory to describe ultimate laws of nature. For this reason, while, on the one hand, the attention of some theoreticians has been directed to perfecting the mathematical foundations of quantum field theory (giving rise to axiomatic field theory and to more rigorous methods of obtaining and studying the quantum field equations, etc.), on the other hand, most physicists have been trying new avenues, such as the S-matrix theory, dispersion relations, the so-called Regge poles, etc.; these approaches have certainly led to very useful results, but they leave altogether at least as many doubts as hopes.

Whatever may be the future prospects of field theory as the correct means for describing the fundamental laws of nature, its tremendous usefulness in providing a conceptual framework, in inspiring new ideas, and in suggesting computational techniques has been overwhelmingly demonstrated in the last decades. It has now found a new, very fertile ground of application in the study of systems containing a very large number of particles, where it has already provided a reasonably good quantitative understanding of superconductivity and superfluidity, and promises many other results of interest in the study of solids and liquids.

FISSION*

Nuclear fission is the breakup of a heavy nucleus, such as that of uranium, into two medium-weight nuclei, with the release of a considerable quantity of energy. Also produced are a few neutrons, some gamma rays, and a number of beta-particles (electrons) from the radioactive decay of the two fragments. Fission occurs spontaneously in some cases, or may be induced by bombardment of the fissionable material with neutrons, protons, or other particles.

Discovery of Fission Although fission was not discovered until 1939, it had been realized, ever since Einstein published his theory of relativity in 1905, that there was a theoretical possibility of releasing tremendous energy from matter.

Fission is now known to have been first produced by Enrico Fermi and his co-workers in 1934, when they irradiated many elements, including uranium, with the newly discovered neutrons. They found a number of different β-activities to be produced from uranium, but believed that these were due to neutron capture. Later radiochemical work indicated that some of the new activities were from elements chemically similar to the much lighter elements Ba, La, etc.

Fission remained unrecognized until O. Hahn and F. Strassmann, German radiochemists, showed by very careful work that these products were not merely chemically similar to lighter elements, but *were* lighter elements. They published their startling results in the January 6, 1939 issue of *Naturwissenschaften*. On January 16, Lise Meitner and O. Frisch sent in to *Nature* (from Stockholm and Copenhagen) a paper in which they named the new process "fission," predicted that the fragments should have large kinetic energies, and explained the process in terms of a liquid-drop model. On the same date, Frisch sent in to *Nature* another paper in which he reported that he had observed the large electrical pulses from fission fragments in an ionization chamber.

Niels Bohr in the meantime had taken the news of the discovery of fission, and the prediction of large energies, to a conference on physics in Washington, D.C. During the conference physicists in a number of laboratories independently verified the tremendous kinetic energies of fission fragments, unaware as yet of Frisch's results.

During the months following the discovery of fission, there was feverish activity in laboratories around the world. It was soon discovered that neutrons were being produced by fission, and that almost all of the fission of U was taking place in the relatively rare isotope, ^{235}U. In that same year (1939), Bohr and Wheeler published their theory of fission, based on the liquid-drop model, which is still basic to modern fission theory.

Development of Atomic Energy On the date of publication of the Bohr-Wheeler paper, September 1, 1939, Germany invaded Poland, the Second World War was underway, and fission suddenly had a new importance. It was realized by many that a chain reaction was possible for fission, with the neutrons from each fission producing more fissions, resulting in the release of very large amounts of energy.

The fission process results in the conversion of 0.09 per cent of the mass of the original nucleus into kinetic energy. This amounts to about 200 MeV per fission, or 3.20×10^{-11} joules. The fission of 1 kilogram of ^{235}U thus releases a total energy equal to 8.21×10^{13} joules, or 2.28×10^{7} kilowatt-hours. This is roughly equal to the daily output of a large hydroelectric power plant such as Hoover Dam, and very much greater than the energy released in chemical reactions. One kg of ^{235}U is equivalent in energy release to the burning of 3.45×10^{6} kg of coal (C) by 9.20×10^{6} kg of oxygen. This chemical process releases 7.2×10^{-11} of the mass as heat energy, more than 10 million times smaller than for fission.

The fission of 1 kg of ^{235}U is also equivalent

*Work performed under the auspices of the U.S. Dept. of Energy.

in energy released to the detonation of 19.6 × 10^6 kg (19.6 kilotons) of high explosive. A kiloton, 1000 metric tons, is conventionally taken to be equivalent to 10^{12} calories, or 4.186 × 10^{12} joules; a megaton is 1000 times larger.

Thus it was known to many people in 1939 that it might well be possible to produce the destructive effect of many thousands of tons of high explosive with a single bomb containing a relatively small amount of fissionable material. It seemed probable that Germany would press ahead with this development. Aware of this danger, scientists in the rest of the world largely ceased publishing fission results by 1940.

Work on fission was continued quietly at an increasing rate. In June 1942, the Manhattan Project (under U.S. Army direction) was set underway in the United States, with the objective of producing nuclear weapons, if possible. The first chain reaction was produced on December 2, 1942, under the direction of Enrico Fermi, who had arrived from Fascist Italy in January 1939. Fermi and his co-workers had piled up blocks of ordinary uranium and extra-pure graphite (carbon) to produce a nuclear reactor, under Stagg Field Stadium of the University of Chicago. The carbon was used to slow down fission neutrons and thus increase the likelihood of fission. Cadmium rods inserted in the reactor (at that time called a "pile") were used to control the chain reaction by capturing a certain fraction of the neutrons.

Thus, by December 1942, a fission chain reaction had been achieved. In the following years, research vital to the Manhattan Project was carried on at many laboratories. In order to produce the fissionable material for nuclear weapons, two tremendous industrial plants were set up beginning in 1943, at Oak Ridge, Tennessee, and Hanford, Washington.

The Oak Ridge plant was for the purpose of separating the more fissionable isotope, ^{235}U, from the much more common isotope, ^{238}U, which accounted for 99.3 per cent of the mass of ordinary uranium metal. The most successful separation process, which is still in use at Oak Ridge, was that of gaseous diffusion. Uranium in the form of a gas, uranium hexafluoride, is passed through a long series of porous barriers. The lighter isotope ^{235}U can diffuse more readily than ^{238}U, and the result of the process is enriched uranium, the ^{235}U content having been increased from 1 part in 140 to around 95 per cent.

The Hanford plant consists of giant nuclear reactors to produce a new element, plutonium, from ordinary uranium by neutron capture. It was thought, and eventually proved, that plutonium should be fissionable by slow neutrons in the same way as ^{235}U. Capture of a neutron by ^{238}U produces the heavier isotope ^{239}U, which then decays by beta-emission to the new element ^{239}Np (neptunium), and then by another beta-decay to ^{239}Pu.

The work of designing and building nuclear weapons was carried out at a laboratory set up at Los Alamos, New Mexico. This laboratory, under the direction of J. Robert Oppenheimer, began its work in early 1943. Before the end of the war, a good fraction of the world's most eminent nuclear physicists had come to work at Los Alamos, including Bohr, Fermi, Frisch, and many British scientists.

One of their most basic problems was to find a way to assemble the fissionable components of a weapon rapidly enough to produce a powerful chain reaction, lasting less than one μsec. The individual masses of enriched uranium or plutonium had to be of such a size and shape as not to be capable of a chain reaction; i.e., they had to be of less than critical mass. If these pieces were not assembled at sufficient speed, the result would be only a minor explosion, or perhaps the melting of the device. Two approaches were tried. One involved firing one piece of fissionable material at another in a short "gun." The other was the implosion method, in which the fissionable material is assembled into a highly compressed mass by the explosion of a surrounding spherical shell of high explosive.

Both methods of achieving a nuclear explosion were ultimately successful, but it was not known whether either method would work until July 16, 1945, when the first "atomic bomb," a plutonium implosion device, was set off in a desert area near Alamogordo, New Mexico. On August 6 a uranium gun weapon was exploded over Hiroshima, Japan, and on August 9 a second plutonium implosion warhead was detonated over Nagasaki. Each weapon had a yield equivalent to about 20 kilotons of high explosive and caused tremendous destruction. On August 10 the Japanese first offered to surrender, and accepted Allied terms on August 15; the mobilization of the massive United States invasion force was called off. Germany, which had surrendered on April 8, 1945, was found to have made little progress toward nuclear weapons during the war.

Following the end of the war, the work on nuclear weapons and nuclear power in the United States were placed under the newly created (1946) Atomic Energy Commission. Similar agencies have since been set up in many countries. On August 29, 1949, the U.S.S.R. detonated its first nuclear device. During the next several years, enormous production plants for ^{235}U were built at Paducah, Kentucky, and Portsmouth, Ohio, as well as facilities for producing ^{239}Pu and hydrogen isotopes on the Savannah River in South Carolina. On November 1, 1952, the Los Alamos National Laboratory exploded the first thermonuclear device (hydrogen bomb), with a yield equivalent to many megatons of high explosive. Such a weapon uses nuclear fission to trigger nuclear fusion, in which light elements (such as the various isotopes of hydrogen) are combined at exceedingly high temperature to give heavier nuclei, with considerable release of energy. On August 12, 1953, the USSR set off its first thermonuclear weapon. In the years since then, Great Britain, France, China, and India have all developed their own nuclear weapons.

Nuclear reactors and nuclear power have been developed extensively since the war, in many countries. Nuclear-powered submarines, aircraft carriers, and other vessels have revolutionized naval strategy. Nuclear-propelled rockets (the "Rover" program at Los Alamos) have been developed for space exploration. The possible use of nuclear explosives for earth-moving, increasing gas-well yield, and other engineering purposes has been an extensive project ("Plowshare") of the Lawrence Livermore National Laboratory, as well as of Los Alamos. Nuclear power plants already account for a significant fraction of electrical power production.

Chain Reactions The basic feature which makes both nuclear reactors and nuclear weapons possible is the "chain reaction," in which each fission produces another fission, or several, by means of the several neutrons emitted from fission. If there is not enough fissionable material, or it is not arranged compactly enough, no chain reaction will be possible. The fission neutrons emitted in such a situation will have too great a chance of escaping from the fissionable material, or of being absorbed in non-fissionable material, to continue the chain of fissions should one fission occur.

There is thus a "critical mass," or minimum amount of fissionable material, necessary for a chain reaction in any given arrangement. For a spherical mass of metal in air, the critical mass of highly enriched (94 per cent) ^{235}U, for instance, is 52 kg; the critical mass for ^{233}U or ^{239}Pu metal is lower, about 16 kg. It is the capture of neutrons by ^{238}U which leads to a higher critical mass in the first case. The critical mass can be lowered by mixing fissionable material with graphite or other material as a "moderator" to slow down the neutrons, or by surrounding the fissionable material with a reflector to scatter neutrons back.

The smallest critical masses are achieved by water (or heavy water) solutions of fissionable material, since H and D are most effective in slowing down neutrons. The "Water-Boiler" thermal reactor at Los Alamos operated ordinarily with about 1100 grams of enriched uranium in water solution, and achieved criticality with less than 600 grams.

The energy of the neutrons producing most of the fissions in a reactor determines whether it is called "fast," "intermediate," or "thermal." Fast reactors use neutrons only slightly slowed down from the 2-MeV average energy with which they are emitted. Thermal reactors use neutrons slowed down, by collision with moderator atoms, almost to the velocities corresponding to thermal motion at the temperature of the reactor. At 294 K, about room temperature, the most probable velocity is 2200 meters/sec., which corresponds to a neutron energy of 0.0253 eV. Intermediate reactors use partially slowed down neutrons, with less than 100-keV energy.

In order for a chain reaction to continue, it is necessary that each fission produce, on the average, at least one more fission. The average number of fissions produced by the neutrons from one fission is called k, the criticality factor or multiplication constant. If k is less than 1.0 (the critical value), a chain reaction, even if begun with many fissions, will soon die out.

A reactor must have $k = 1.0$ during normal, steady, operation, and must have k greater than 1.0 during the start-up operation. These changes in criticality factor can be brought about by introducing or removing from the reactor control rods made of neutron-absorbing elements, such as cadmium or boron.

This regulation of reactor power is made much easier by the phenomenon of delayed neutrons, which are emitted from some fission products for a few seconds after the fission. In the case of thermal-neutron fission of ^{235}U, 0.7 per cent of the neutrons produced (0.017 out of 2.43 neutrons per fission) are delayed in this way. Only if k were increased above 1.007 in this case could the reactor power increase rapidly, since each fission would then, on the average, produce one more fission promptly. Reactors are of course designed to avoid this "prompt critical" condition, since this can lead to overheating and destruction of the reactor. In any case, reactors cannot possibly achieve the high values of the criticality factor needed for a true nuclear explosion.

A "breeder" reactor is one which produces as much nuclear fuel as it consumes, such as by using the capture of neutrons in ^{238}U to produce thermally fissionable ^{239}Pu. It is of course necessary to reprocess the fuel elements to recover the ^{239}Pu. Breeder reactors are now being developed for more efficient power production. It is of interest that the uranium contained in coal, which is discarded with the fly ash and flue gases, could produce more power than the coal if efficiently used.

The Fission Process The fission of a nucleus can be understood on the basis of the liquid-drop model, which was first discussed by Meitner and Frisch and later greatly extended by Bohr and Wheeler. This model explains many features of fission, but others are still not fully understood, and the complete theory of fission is still awaited.

On the basis of this model, the nucleus is assumed to be similar to a uniformly charged drop of incompressible liquid. It will then be normally spherical, kept in this shape of minimum energy by the effect of surface tension. However, the individual parts of the positive charge, actually protons, tend to repel each other and to lessen the effective surface tension. It has been calculated that the two effects will cancel each other out for a value of Z^2/A equal to about 45 (Z is the atomic number or the number of protons; A is the mass number or total number of nucleons in the nucleus). The ratio of Z^2/A to this critical value is called the fissionability parameter x.

For a fissionability parameter equal to 1.0, the nucleus should have no effective surface tension and no stability against distortion, so that it should promptly elongate to a point where the coulomb (electrostatic) forces can blow it apart. Such a nucleus would have no "fission barrier" and could not exist long. Known nuclides have lower values of the fissionability parameter; for ^{235}U the value of x is about 0.8. For such nuclei, it takes 5 or 6 MeV of energy to deform the nucleus to the point where coulomb forces can cause fission. However, such a fission barrier may be overcome by the capture of a neutron, which adds an excitation energy of 5 or 6 MeV.

For the even-Z, odd-N nuclides ^{233}U, ^{235}U, and ^{239}Pu (N is the number of neutrons in the nucleus), fission can be induced by the capture of even a low-energy neutron. Even-even target nuclides require more energy, so that ^{238}U is very unlikely to fission upon capture of a thermal neutron, but needs about 1 MeV additional neutron energy to overcome the fission barrier. Even-even *compound* nuclei (i.e., after neutron capture) are evidently more likely to undergo fission. Even-even nuclei are also much more likely to undergo spontaneous fission, in which an occasional nucleus manages to overcome the fission barrier without any added energy. Fission may also be induced by gamma rays of energy equal to the fission barrier or by energetic particles of many kinds such as protons or alpha particles.

The probability that particles passing through a target of fissionable material will induce fission is measured by the fission cross section. The "cross section" is the effective area of a nucleus for a given process. For a thin target of thickness l cm having n nuclei per cubic centimeter, each with fission cross section σ_f cm^2, the probability that a particle passing through the target will induce a fission is $nl\sigma_f$.

Figure 1 shows the fission cross section for 11 fissionable nuclei, as a function of the energy (in MeV) of the neutron inducing fission. For those nuclides (^{233}U, ^{235}U, ^{239}Pu) which lead to even-even compound nuclei, the cross sections are very high for low-energy neutrons; these are "fissile" nuclides. For the other target nuclides, the fission cross section is extremely small until the neutrons have energy in excess of a threshold energy. All the cross sections may be seen to increase noticeably at about 7 MeV. This increase is due to the added possibility of fission following low-energy neutron emission, which becomes energetically possible here.

The energy released when fission takes place amounts to about 200 MeV. This is the difference in mass between a heavy fissionable nucleus and the two medium-weight nuclei, plus neutrons, into which it breaks up. This energy release of 200 MeV amounts to 21.3 per cent of the mass of a single proton or neutron. Most

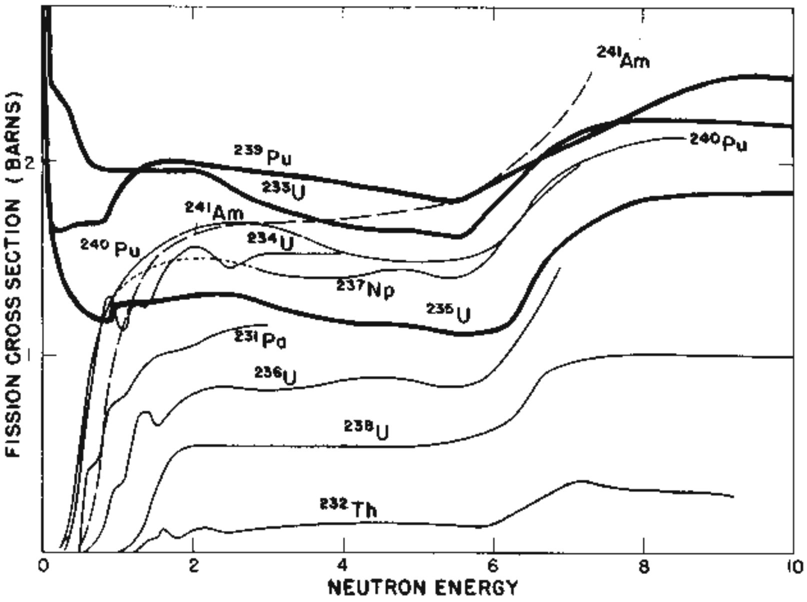

FIG. 1. Dependence of fission cross section (a "barn" is 10^{-24} cm^2) on inducing neutron energy (in MeV) for 11 different fissionable nuclei (reprinted with permission from R. L. Henkel, "Fission by Fast Neutrons," in J. B. Marion and J. L. Fowler, Eds., "Fast Neutron Physics, Part II," New York, Interscience Publishers, 1963).

of the energy appears in the form of kinetic energy of the two fission fragments, which are sent flying apart with an average total of 167 MeV in the case of thermal fission of ^{235}U.

The two fragments share the kinetic energy in the inverse ratio of their masses, since they have equal and opposite momenta. The mass division is usually asymmetrical, as may be seen in Fig. 2. The probability that neutron fission of ^{235}U will produce two given fragments of nearly equal mass (symmetrical fission) is about 600 times lower than that of the most probable case of asymmetrical division into light and heavy fragments. The initial fragments (before neutron emission) in this case have masses averaging 96 and 140 mass units. The lighter fragment has on the average about 99 MeV of kinetic energy, and the heavy fragment about 68 MeV. These energies correspond to initial velocities of 1.4 and 1.0×10^9 cm/sec, or 4.7 and 3.2 per cent of the speed of light, respectively. The total fragment energy is reasonably well approximated by $0.121\ Z^2/A^{1/3}$ MeV.

Such fragment energies are due to the Coulomb interaction between the two fragments, and would be expected on the basis of any fission theory. The asymmetrical mass division, however, would not be predicted by liquid-drop theory and is evidently due to nuclear shell effects. The liquid-drop model would, in its simplest form, predict primarily symmetrical fission, which is rarely observed.

The fragments, as we have seen, carry away most of the 200-MeV energy release in the form of kinetic energy. The rest of the energy is released in the form of neutron energy, gamma rays, and beta decay. The prompt neutrons, which are emitted within 10^{-14} sec. following fission, will be discussed below. The fission fragments are strong sources of prompt gamma rays, emitting about 8 within a microsecond or less following fission. The gamma rays have a broad spectrum of energies, up to as much as 7 MeV, but they average about 1 MeV apiece, so that the total energy emitted in prompt gamma rays is about 8 MeV. This is more than simple theories would predict.

Immediately after the emission of neutrons and prompt gamma rays, the fragments (now called "fission products") begin the process of beta decay, which ultimately accounts for perhaps 22 MeV of fission energy release. The fission products have neutron-to-proton ratios which are nearly the same as that of the heavy nucleus from which they were formed (about 1.55). This is too many neutrons for stability in the fission-product mass region, where non-radioactive nuclei have neutron-proton ratios in the range 1.3 to 1.4. Since there is thus energy to be released by changing neutrons to protons, the result is a long sequence of beta decays averaging 3 or 4 for each fission product. Each beta decay results in the emission of a negative electron, a neutrino, and usually gamma rays, and an increase of the charge of the nucleus by one unit. The neutrinos ultimately carry away about 10 MeV of the energy released, and for all practical purposes this energy is not detectable and is never seen again. The fission products are intensely radioactive immediately after fission, as the beta decays having the shortest half-life are completed, and gradually become less radioactive with the passage of time.

For a small fraction of the fission products it is energetically possible for a neutron to be emitted at some stage in the chain of beta decays. These delayed neutrons, amounting on the average to 0.017 per thermal-neutron fission of ^{235}U, are very useful in stabilizing the operation of nuclear reactors, as mentioned above. Because they are emitted immediately following beta decays, they appear to follow the same radioactive decay curves as some of the beta decays, and have varying half-lives, of the order of seconds.

In rarer cases—about one fission out of 400—an alpha particle (^{4}He) is emitted during the fission process, in addition to the two fragments. This process is usually called ternary fission, as distinguished from the usual binary fission. Because of the high energy (averaging 15 MeV) and direction (roughly perpendicular to fragment motion) of the alpha particle, it is probably formed at the same time as the two heavier fragments, and between them. In still rarer cases, other light charged particles such as nuclei of tritium (^{3}H) or of ^{6}He are seen. There seems even to be evidence that, in perhaps one fission out of 100 000, three fragments of roughly equal mass are formed.

In the vast majority of fissions, however, two fragments and several neutrons are the result. For low-energy fission it is clear that most, or perhaps all, of the neutrons are emitted by the fragments. The average number of neutrons per fission ($\bar{\nu}$) ranges from 2.0 to 4.0 for various nuclides. Fission at high energies, such as that induced by 100-MeV alpha particles, produces many more neutrons, most of which are emitted before fission.

In the typical case of thermal-neutron fission of ^{235}U, $\bar{\nu}$ is 2.43, including delayed neutrons. For individual fissions the number ν can vary from zero to 5 or 6, the standard deviation from the average being ±1.10. The prompt neutrons in this case have an average energy of 1.94 MeV. The neutron energy spectrum in this and other cases is well described by a Maxwellian distribution,

$$N(E) = (2/\sqrt{\pi T^3})\sqrt{E}e^{-E/T}$$

in which $N(E)$ is the number of neutrons per unit energy E, and T is a parameter equal to two-thirds of the average energy $\overline{E}$. Such a spectrum is predicted from nuclear temperature theory.

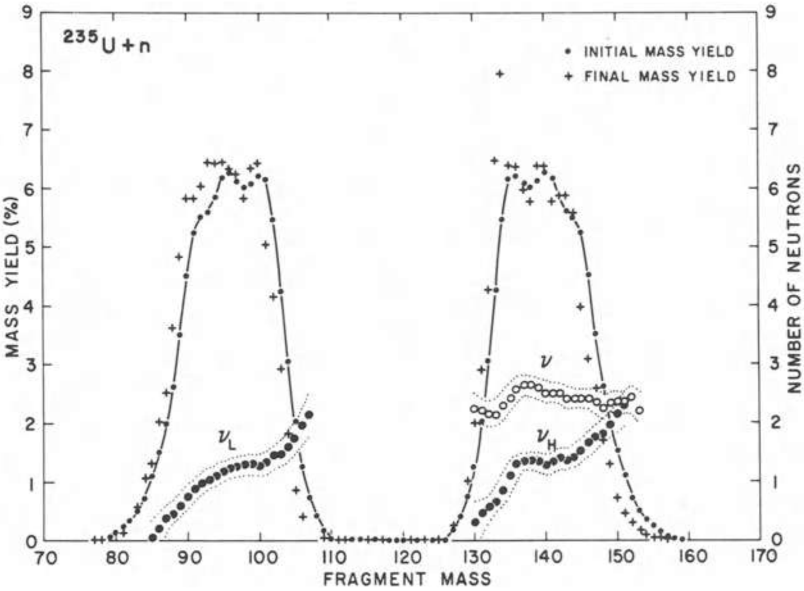

FIG. 2. Dependence of neutron yield on initial fragment mass for thermal-neutron fission of ^{235}U. Average numbers of neutrons emitted by light and heavy fragments are given the symbols ν_L and ν_H; the total from both fragments is ν. Standard deviations are indicated by dotted lines. Also shown are the initial and final mass yields [reprinted from J. Terrell, *Phys. Rev.*, **127**, 880–904 (1962)].

Of the roughly 2-MeV average energy per neutron, about 0.75 MeV is contributed by the motion of the emitting fragments. There is evidence that the average neutron energy increases with increasing number of neutrons. This would be expected from considerations of nuclear temperature, which lead to the relation $\overline{E} = 0.75 + 0.65\sqrt{\overline{\nu} + 1}$, in MeV, in agreement with experimental data.

The total kinetic energy carried away by the typical 2 or 3 neutrons per fission is thus about 5 MeV, of which 2 MeV is taken from fragment energy. The fragments after neutron emission thus have a total energy reduced (in the case of ^{235}U) from 167 to 165 MeV, and lower mass numbers.

The final fragment masses may be determined by radiochemical data on fission products. The final mass yields for ^{235}U are shown in Fig. 2, as crosses. The initial mass yields may be determined from simultaneous measurement of the velocities of the two fragments and are also shown in the Figure. The differences between initial and final mass yields are accounted for by emission of neutrons and may be used to determine the numbers of neutrons. The average numbers of neutrons emitted by individual fragments are shown (ν_L and ν_H) as functions of initial fragment mass; the total $\nu(= \nu_L + \nu_H)$ is also shown.

As may be seen in Fig. 2, the average number of neutrons emitted by a fission fragment depends strongly on the fragment mass; it is near zero for the lightest of the light fragments, and also for the lightest of the heavy fragments, and rises to high values elsewhere. Thus the two fragments from a fission will usually emit quite different numbers of neutrons, which implies quite different initial excitation energies. This phenomenon came as quite a surprise when it was first reported by Fraser and Milton in 1954. It has since been found to be a common and perhaps universal feature of fission.

This sawtooth dependence of neutron number on fragment mass may be understood on the basis of varying stiffness of the fragments against deformation. The fragments having "magic" numbers (closed shells) of neutrons or protons would be expected to be stiff and to be exceptionally resistant to deformation and the consequent excitation. The magic number of neutrons, $N = 50$, will occur for fragments in the vicinity of mass 82, at the lower boundary of the light fragment peak. Similarly, two closed shells ($Z = 50$ and $N = 82$) occur at the lower edge of the heavy fragment peak, near mass 130. The low neutron yields seen at these masses may be quantitatively explained on the basis of the effects of closed nuclear shells on the deformation parameters. It is hoped that this fragment-deformation theory will be able to account quantitatively for the spectrum of fragment masses, since the mass yields and neutron yields tend to vanish near the same magic numbers.

Fission isomers have been of much interest recently. These are excited states of fissionable nuclides, produced by bombardment with energetic particles or nuclei, which exist for times of the order of 10^{-2} to 10^{-9} seconds before fissioning. Such quasi-stable states, lying a few MeV above the unexcited ground states, are believed to be "shape isomers" explainable by a double-humped fission barrier, for which there is other evidence in the intermediate structure of resonances in the fission cross sections. Such a fission barrier has a second minimum, at some deformation, in the energy required to deform the nucleus from the ground state. It is thought now that all fission barriers have such a double-humped structure, first explained by V. M. Strutinsky in terms of variation of shell structure with deformation.

FLIGHT PROPULSION FUNDAMENTALS

Propulsion is the act of changing, or maintaining, the motion of a vehicle flying in air or in space. This includes deceleration for reentering the earth's atmosphere with manned spacecraft. Fundamentally, the operating principles of propulsion devices, regardless of type or class, embody the basic laws of MECHANICS, THERMODYNAMICS, CHEMISTRY, ELECTRICITY, and other sciences. In propelling a vehicle, it is necessary to accelerate a mass, commonly called the *working fluid*, in a direction opposite to flight (or thrust force). Newton's basic laws of motion, the conservation of momentum (change of momentum of the vehicle equals change of momentum of the working fluid), and the dictates of the perfect gas laws dominate the design and operation of the propulsion system, be it an aircraft engine with propeller, a turbojet engine, a solid rocket motor, a gas-turbine-driven rotor system in a helicopter, or any other propulsion device.

The advent of the "jet age" coincided with World War II and a wide variety of propulsion devices have been studied and developed since then. Table 1 lists the major types of propulsion devices and indicates their status. Note the three energy sources listed. In time, additional energy forms may prove feasible such as the laser beam, electromagnetic waves and proton or other particle beams transmitted to a flying receiver.

Fundamental Relations Assume an ideal engine inside of which the fluid receives energy and is heated and accelerated as shown schematically in Fig. 1. The acceleration of a mass flow of air or fluid $\dot{m}_a$ from an initial velocity v_0 (which equals the forward flight velocity of of the vehicle) to the jet velocity at the exit v_e will result in a net thrust F, which is equal to the mass flow rate multiplied by the velocity increment. Additional terms are added to this momentum relation in order to correct for the additional mass flow rate of the fuel or propellant ($\dot{m}_p$) (the fuel is carried in the vehicle) and for any difference in static pressure of the jet exit of the engine (p_e) and the atmospheric or ambient pressure p_0.

$$F = \dot{m}_a(v_e - v_0) + \dot{m}_p v_e + A_e(p_e - p_0)$$

The last term in this equation is called the pressure thrust; it is positive if $p_e > p_0$ (which occurs when there is incomplete expansion of the gases in the engine exit nozzle) or negative if $p_e < p_0$ (which occurs when there is overexpansion in the engine exit nozzle). For a rocket engine, the air mass flow $m_a = 0$, and the thrust is equal to the last two terms of the equation only. In the case of a propeller engine, there are really two different air flows, and the first term in the above equation is split into two separate terms: one flow which crosses the plane of the propeller and is accelerated by the propeller blades and a second smaller airflow which goes through the engine to furnish oxygen for combustion.

Consider a winged vehicle in equilibrium rectilinear flight in a two-dimensional (fixed plane) trajectory; assume all control forces, lateral forces and turning moments to be zero and the flight direction to be the same as the thrust direction. In the direction of the flight, the instantaneous vehicle mass m_v times the vehicle acceleration dv/dt has to equal the sum of all the forces, namely a component of the thrust F, the aerodynamic drag D, and a component of the gravitational attraction or the weight $m_v g$. The angles are as defined in Fig. 2.

TABLE 1. TYPES/STATUS OF FLIGHT PROPULSION DEVICES (ELECTRIC PROPULSION EXCLUDED)

Propulsion Device	Energy Source* Chemical	Nuclear	Solar	Working Fluid
Piston engine/propeller	D/P			Surrounding air
Turbojet	D/P	TFD		Surrounding air

Air turborocket	TFD			Stored + surrounding air
Solar heated rocket			TFD	Stored propellant
Photon rocket		TFND		Photon ejection (no stored propellant)
Solar sail			TFD	Photon absorption (no stored propellant)

*D/P: developed and/or considered practical; TFD: technical feasibility has been demonstrated, but development is incomplete; TFND; technical feasibility has not been demonstrated as yet.

$$m_v dv/dt = F - D - m_v g \sin\theta \qquad (2)$$

The vehicle mass m_v multiplied by the acceleration in a direction perpendicular to the flight path ($v\, d\theta/dt$) must equal the sum of all forces perpendicular to the flight direction; here, the lift force L must be considered.

$$m_v v \frac{d\theta}{dt} = L - m_v g \cos\theta \qquad (3)$$

The solution to these two equations results in the determination of a two-dimensional trajectory, maximum flight velocity, range, and other flight performance parameters. The actual solution is three-dimensional, and must usually be a numerical integration since m_v decreases with time, L and D vary with speed and altitude, and the direction of thrust is not the same as the flight direction; also, both the flight angle and the angle of attack are usually changing. For the case of a linear, simplified horizontal equilibrium flight, $\theta = 0$, $dv/dt = 0$, and thus Eq. (2) reduces to $F = D$. The vehicle mass m_v consists of the vehicle dry mass or final vehicle mass after expenditure of all propellant $(m_v)_f$ plus the propellant or fuel mass m_p. For steady fuel flow, $m_p = \dot{m}_p t$. For the case of gravity-free flight in a vacuum (true space environment), Eq. (1) can be rewritten for a rocket:

$$\frac{dv}{dt} = \frac{F}{m_v} = \frac{\dot{m}_p v_e}{(m_v)_f + \dot{m}_p t}$$

Integration gives

$$v_v = -v_e \ln \frac{m_v - m_p}{m_v} = v_e \ln \frac{(m_v)_i}{(m_v)_f}$$

Thus the maximum velocity attained by a rocket-space vehicle operating in a gravitationless vacuum is equal to the product of the average effective rocket exhaust velocity v_e and a logarithmic function of the initial vehicle mass $(m_v)_i = (m_v)_f + m_p$ (fully fueled vehicle) at start of the engine operation, divided by the

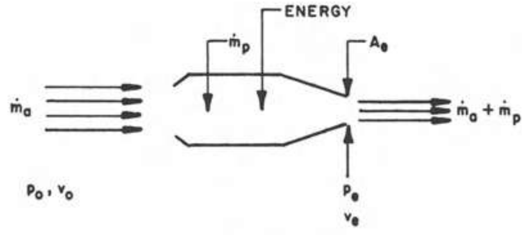

FIG. 1. Simple engine.

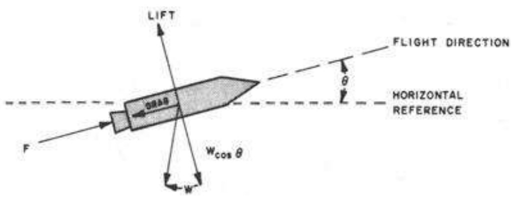

FIG. 2. Simple free body diagram of flying vehicle.

final vehicle mass (with all the fuel expanded) $(m_V)_f$ at the end of engine operation. This velocity v_V will be large when v_e is large, i.e., high energy is available from the propellant or the engine and when $(m_V)_i$ is small, i.e., whei the dry mass of the vehicle (dry engine mass tanks, payload, or structure) is small and no unnecessary mass is designed into the vehicle. This means that m_P is large and the initial vehicle mass $(m_V)_i$ consists largely of propellant.

Two important measures of engine performance are *specific fuel consumption*, *sfc*, (for airbreathing engines) and *specific impulse* I_s (for rocket engines); one is the reciprocal of the other. Specific fuel consumption for turbojets, turbofans, and ramjets is expressed as pounds of fuel per hour per pound of thrust, and as pounds of fuel per hour per shaft horsepower for piston engines and turboprop engines. Specific impulse is usually expressed in seconds, a short designation for units of thrust (force) per units of propellant mass flow per second. Both of these parameters are an indication of engine design quality, the higher the I_s the better, and conversely for sfc.

By definition, specific impulse per second is:

$$I_s = \frac{F}{\dot{w}} = \frac{F}{\dot{m}g} \text{ (kg force/kg mass per second)}$$

with $\dot{w}$ being propellant flow rate per second. For a given I_s, the nozzle expansion ratio should be stated such as 1000 → 14.7 (sea-level specific impulse at 1000 psi chamber pressure), or 1000 → 0.2, indicating expansion at high altitude or space flight.

Some of the most significant types of engines are described briefly in the remainder of this section.

Rocket Engines These engines use both a fuel and oxidizing propellant and both are stored within the flying vehicle, making it independent from its surrounding fluid. Thus a rocket can operate in space, air, or under water. The supersonic nozzle jet exit velocity v_e of a rocket using ideal gas laws can be derived to be

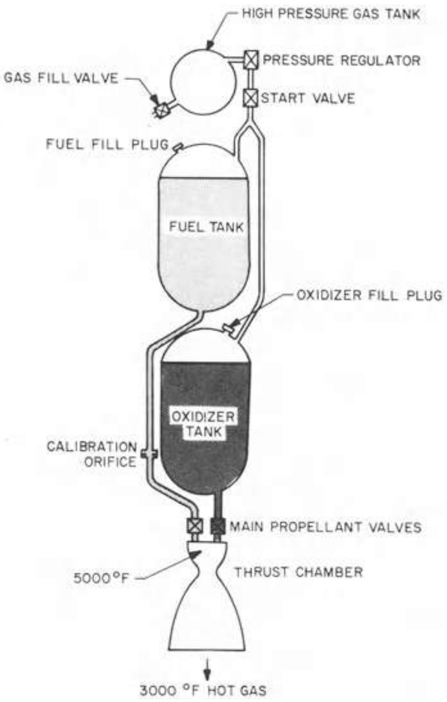

FIG. 3. Simplified schematic diagram of liquid propellant rocket engine with pressurized gas feed system and uncooled thrust chamber (reproduced by permission from McGraw-Hill Encyclopedia of Science and Technology, Vol. II, New York, McGraw-Hill Book Co.)

TABLE 2. TYPICAL DATA FOR VARIOUS ROCKET ENGINES

Type	Typical Range of Thrusts (lbs)	Typical Range of Duration	Application
High thrust liquid propellant rocket	1 000 000 to 4 000 000 for each engine with several engines in a cluster	1 to 5 min	Booster and sustainer stages of large missiles and space vehicles
Large solid propellant rocket	100 000 to 3 000 000	1 to 3 min	Long range missiles, space boosters
Prepackaged storable liquid propellant	100 to 100 000	1 to 60 sec	Small missiles, lunar landing and takeoff missiles, lunar landing and takeoff
Jet assisted takeoff (solid propellant)	200 to 10 000	5 to 30 sec	Assist takeoff of airplanes
Space vehicle attitude control	1 to 150	0.01 to 10 sec/cycle; accumulate up to an hour	Control position, angle and orientation of spacecraft

$$v_e = \sqrt{\frac{2gkR}{(k-1)}\frac{T}{M}\left[1-\left(\frac{p_e}{p_c}\right)^{(k-1)/k}\right]}$$

where

v_e = nozzle exit velocity
g = gravitational constant
k = ratio of specific heats of gas
R = universal gas constant
M = molecular weight of hot gas
T = absolute combustion temperature
p_e = nozzle exit gas pressure
p_c = combustion chamber pressure.

The exhaust velocity (or the specific impulse which is $I_s = v_e/g$) increases as the molecular weight M is decreased or as the combustion temperature T is increased. Because of the pressure ratio effect, there is actually a slight (10 to 20 per cent) increase in specific impulse as the altitude is increased (lower ambient pressure) or as chamber pressure is increased. Values of v_e or I_s calculated for a given propellant and engine from thermochemical and thermodynamic data are usually very close to actual performance (usually within 5 to 10 per cent), because rocket combustion efficiencies are high and nozzle losses are usually low. Schematic diagrams of several liquid and solid propellant systems are shown in Figs. 3 to 6, and some important applications are shown in Table 2.

In *liquid propellant rocket engines* the propellants are fed under pressure from tanks in

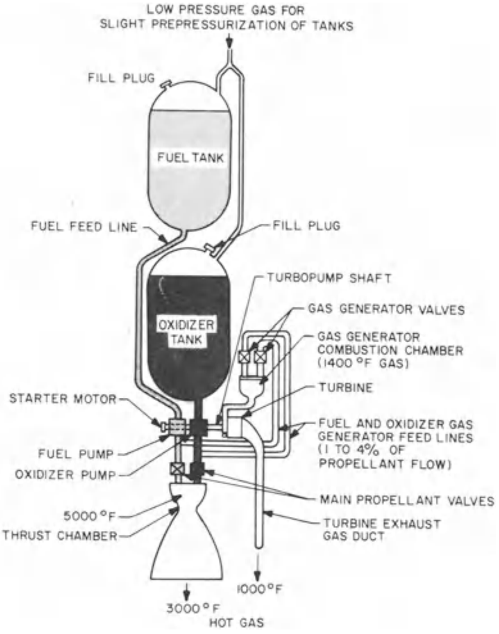

FIG. 4. Simplified schematic diagram of liquid propellant rocket engine with turbopump feed system and regeneratively cooled thrust chamber (reproduced by permission from McGraw-Hill Encyclopedia of Science and Technology, Vol. II, New York, McGraw-Hill Book Co.)

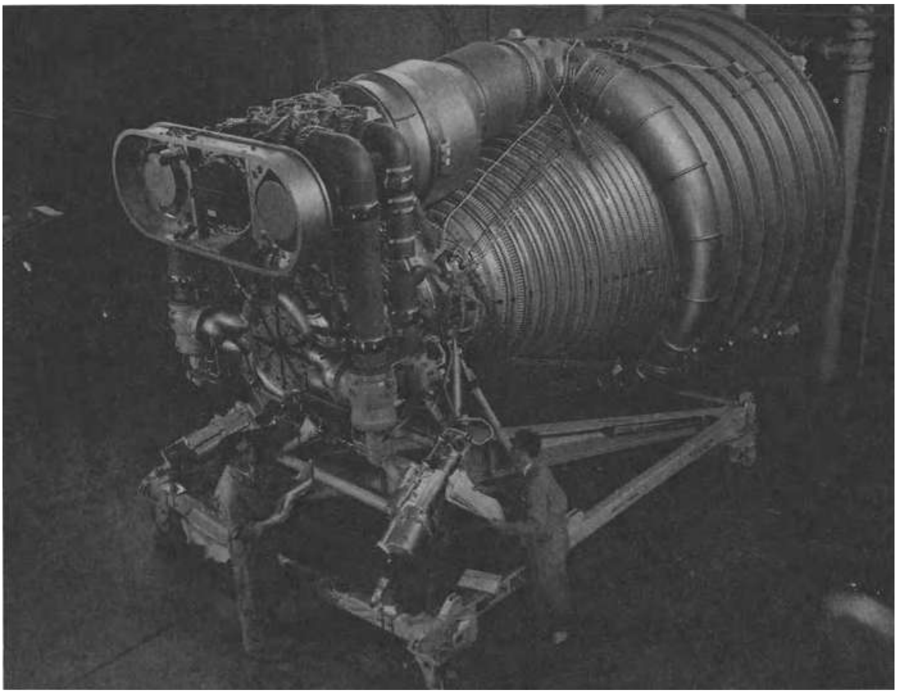

FIG. 5. F-1 rocket engine used in booster stage of advanced Saturn space vehicle. (Courtesy of Rocketdyne, A Division of North American Aviation, Inc.)

the vehicle into a thrust chamber where they are injected, mixed, and burned at high pressures and very high temperatures to form the gaseous reaction products, which in turn, are accelerated in a nozzle and ejected at high velocities. The feed system for transferring the propellants into the thrust chamber includes valves and controls.

The principal components of a *thrust chamber* (Figs. 3 and 4) are the *nozzle*, the *chamber*, and the *injector*. An injector introduces and meters the flow of the liquid propellants and also atomizes and mixes them in the correct proportions in such a manner that they can be readily vaporized and burned. In the combustion chamber, the burning of the liquid propellant takes place at high pressure, usually between 5 and 150 atmospheres.

The *gas pressure feed system* (Fig. 3) offers one of the simplest and most common means of transferring propellants by displacing them with a high-pressure gas which is fed into the tanks under a regulated pressure. In a *turbopump feed system*, the propellant is pressurized by means of pumps driven by one or more turbines (Fig. 4) which derive their power from the expansion of hot gases. A separate gas generator ordinarily produces these gases in the required quantities and at a temperature which will not hurt the turbine buckets (1200 to 2000°F).

Liquid Propellants. A *bipropellant rocket* unit has two separate propellants, a fuel and an oxidizer (such as liquid hydrogen and liquid oxygen), which are not mixed until they come in contact with each other in the combustion chamber. Most liquid propellant rockets have been of this bipropellant type. A *monopropellant* contains oxidizing agent and combustible matter in a single substance. It can be a mixture of compounds, such as hydrogen peroxide with liquid alcohol, or it may be a homogeneous chemical agent, such as hydrazine. Typical values of liquid and solid propellant characteristics are given in Table 3.

Solid Propellants. In a *solid propellant rocket engine* all the propellant is contained within the combustion chamber. The hardware includes, in addition to the combustion chamber nozzle, an igniter and provisions for mounting the rocket (Fig. 6). Solid propellants themselves usually have a plastic, cakelike appearance (specific gravity is approximately 1.6) and burn at high pressure (10 to 150 atmospheres) on their exposed surfaces to form hot exhaust gases which are ejected through the nozzle. The physical mass or body of the propellant is called the *grain*.

Processed (including curing) propellants fall into three general types: (1) double-base; (2) composite; and (3) composite double-base.

A double-base propellant forms a homogeneous cured propellant, usually a nitrocellulose-type of gunpowder dissolved in nitroglycerin, plus minor percentages of additives. Both the major ingredients are explosives, and both contribute to the functions of fuel, oxidizer, and binder.

A composite propellant forms a heterogeneous propellant grain with the oxidizer crystals and a powdered fuel (usually aluminum), held together in a matrix of synthetic rubber (or appropriate plastic) binder, such as polybutadiene. Normally, composite propellants are less hazardous to manufacture and handle than double-base propellants.

Composite double-base propellants are a combination of the double-base and composite propellants, usually comprising a crystalline oxidizer (ammonium perchlorate) and powdered aluminum fuel, held together in a matrix of nitrocellulose-nitroglycerin. The hazards of processing and handling this type of propellant are similar to those of double-base propellants.

Representative formulations for the three basic types of propellants are given in Table 4. In actual practice, each manufacturer of a propellant has a proprietary precise formulation and processing procedure. The exact percentages of ingredients, even for a given propellant, such

as PBAN, will not only vary from one manufacturer to another, but also often varies from one motor application to the next.

Compared to liquid propellant, the solid propellant requires no pump or pressurization for the fuel tank, and hence is mechanically simpler. The combustion chamber with solid propellant is larger, especially for large rockets, and is frequently operated at higher pressure than for a liquid engine. Solid rockets are simpler, more storable, and are usually more immediately ready for use, but are generally lower in performance when compared to liquid propellant rockets.

In addition to producing a thrust force, solid and liquid propellant engines can be used also for producing auxiliary power and control torques to be applied to the vehicle. This latter is called *thrust vector control* and basically it is usually a mechanical means for altering the direction of the engine's thrust during flight.

Air-breathing Engines As shown by Figs. 7 to 10, there exists a variety of different types of air-breathing propulsion engines. The range of performance values shown in Table 5 for different types of air-breathing engines is representative and does not correspond to data for specific engines. Each engine is optimized for a specific flight operating condition of speed (Mach number) and altitude. For example the turbojet engine listed in Table 5 for a specific fuel consumption of 1 pound of thrust per pound of fuel flow per hour operating at a Mach number of $M = 0.8$, is a different engine from the one operating at $M = 3.0$ with a fuel consumption of 1.5; also it operates at different altitudes.

In an aircraft or missile engine, the atmospheric air is usually first compressed (by a mechanical rotary compressor or by a diffuser); then heated by burning with fuel; sometimes sent through a turbine (which provides the

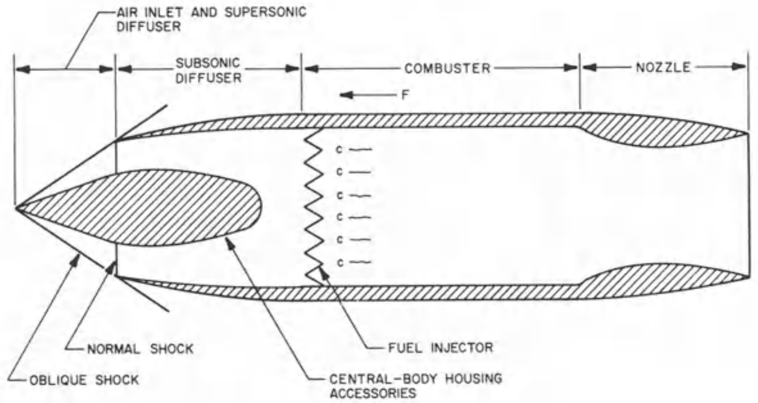

FIG. 7. Simplified schematic diagram of ram jet (reproduced by permission from H. H. Koelle, "Handbook of Astronautical Engineering," New York, McGraw-Hill Book Co., 1961).

rotary power for driving the compressor and accessories, such as electrical generators or hydraulic pumps); and then ejected at high velocities (usually supersonic) through a nozzle. The process in air-breathing engines approaches ᵃn ideal thermodynamic cycle (such as the Otto cycle for reciprocating engines or the Brayton cycle for a turbojet) which limits their maximum theoretical efficiency. The inlet duct serves to scoop up the desired air mass flow and to convert some of the kinetic energy of the flow into pressure, thus reducing the velocity. After heating the flow in a combustion chamber, the reverse process occurs adiabatically in the nozzle, where it is desired to attain a maximum exhaust velocity. The efficiency of energy conversion in the inlet duct, nozzle, combustors, compressors, and turbines is a very important factor, and becomes a predominant criterion at supersonic and hypersonic velocities, when compression is achieved usually by a series of oblique shock waves commencing at an inlet spike. To maintain good efficiency and the desired airflow, some diffusers and nozzles incorporate a variable wall contour or cross-section geometry. In general, air-breathing engines have been well developed to a high state of reliability and have given millions of hours of good service.

The available oxygen from the air limits the combustion process. For example, at constant flight speed, the thrust thus decreases with altitude (or oxygen density) and below a combustion pressure of approximately 3 psi, combustion is not easily sustained (flameout limit). Available high-temperature materials will set an upper limit to the maximum combustion temperature at approximately 1700 to 2400°F. At high speeds and high altitude, the ram-compression of the air causes its temperature to rise substantially, so that the amount of energy that can be added by combustion (without damaging turbine materials) is thus limited; also, special cooling provisions are required.

Engine Type	Flight Speed (mph)	Altitude (feet)	Cruise Specific Fuel Consumption or Specific Thrust	Thrust to Weight or Power to Wt. Ratio	Typical Applications
Piston engine with propeller	0–400 mph	0–35 000	0.37 to 0.52 lb/hp–hr	1.0 to 2.0	Transport aircraft Small airplanes Helicopters Target drones
Turbojet	0–2000	0–100 000	0.8 lb/lb–hr at M = 0.8 1.5 lb/lb–hr at M = 3.0	0.8 to 5.0 (depending on afterburner)	Bomber Fighter Missiles Transport aircraft Target drones
Turbofan	0–600	0–40,000	0.5 lb/lb–hr at M = 0.1 0.65 lb/lb–hr at M = 0.9	3.5 to 5.5	Transport aircraft
Turboprop	0–450	0–35 000	0.8 lb/hp–hr at M = 0.6 0.25 lb/hp–hr at M = 0	2.0	Fast transport aircraft Small airplanes Helicopters
Ramjet	1200 to 4200	0–120 000	1.5 lb/lb–hr at M = 2 2.0 lb/lb–hr at M = 6	up to 20.0	Anti-aircraft missiles

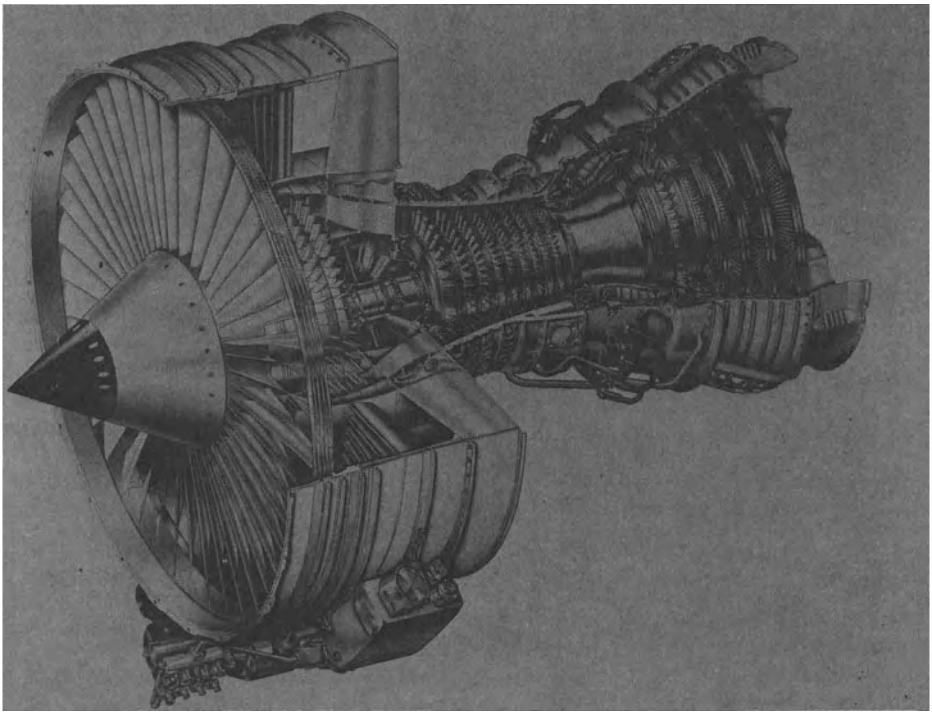

FIG. 10. Sectional photo of CFU56-2 turbofan engine (Courtesy of General Electric Company).

The simplest air-breathing engine is a *ramjet* (Fig. 7). It does not produce static thrust (at zero flight speed, such as during takeoff) and thus needs a rocket engine or some other engine to bring it to its minimum operating speed.

The *piston engine with a propeller* was the very first engine to fly. It is the most economic engine for subsonic flight speed and is now used mostly in small airplanes. The hot gases do work against a piston (not a turbine), which in turn requires a crank mechanism to convert the reciprocating piston motion into shaft rotation. The use of a variable pitch propeller and superchargers for precompression of the inlet air further increases the economy.

The *turbojet* (Figs. 8 and 9) can be designed for a variety of speeds, altitudes and thrust ranges. It often includes special design features such as afterburners and water injection to increase the thrust.

The turbofan (Fig. 10) followed the turbojet in development and utilizes the same design principles. It is widely used in cargo and passenger airplanes. Its advantages over a turbojet include reduced fuel consumption, higher thrust to weight ratio and reduced noise—but it is limited to subsonic flight speeds.

The *fuel* used is usually a narrow-cut petroleum refinery hydrocarbon product, having the approximate formula of $CH_{1.95}$.

Photon Propulsion. Solar sail engines rely on the reflection of photons from the sun (radiation pressure at the distance of the earth from the sun is about 5×10^{-7} kg/m^2). Although this force is limited by being directed only "away" from the sun, solar "sailing" can provide low thrusts, and attitude control, turning a spaceship completely around in a few hours. No working fluid is carried in the vehicle.

For the vehicle to carry its own light source, a photon rocket engine of adequate thrust would necessitate energies and techniques far beyond present capabilities.

FLUID DYNAMICS

Fluid dynamics is study of the motion of matter in the gas, liquid, plastic, or plasma state. When restricted to flow of incompressible (i.e., constant density) fluids, it is called *hydrodynamics*; when dealing with electrically conducting fluids with magnetic fields present, it is called *magneto-fluid-dynamics*; when dealing with practical problems of air flow past airplane wings, through ventilating equipment, etc., it is called *aerodynamics*; when dealing with nonlinear materials such as wax and polymers, it is called *rheology*.

Fundamentally, two approaches to describing the motion of fluids are taken. The first, and most common, is continuum or field dynamics, the physical elements of which were stated in modern form by Stevin (about 1590), Torricelli and Pascal (1647), D. Bernoulli (1738), Euler (1755), and Stokes (1845). Clarification of the complex mathematical nature of the correct physical equations describing the deformation and flow of matter has involved and continues to involve the most astute mathematicians.

The second approach is kinetic theory and nonequilibrium statistical mechanics. In this approach, matter is not thought of as a continuum or field, but as consisting of discrete molecules moving in empty space (gas) or bound to one another by forces (condensed matter–liquids and solids). In either case, the molecules are in continuous motion, either colliding with other molecules or vibrating about a "home position." This approach, discussed even in antiquity, was formulated in more modern form by D. Bernoulli (1738), Clausius (1857), Maxwell and Boltzmann (1860s) and Gibbs (1902), and continues to be developed and applied (see KINETIC THEORY).

Continuum Dynamics In continuum dynamics, fluid properties–namely, velocity components u_1, u_2, u_3, density ρ, pressure p (more generally stress), temperature T, viscosity μ, conductivity, dielectric constant, electric field, electric current density, etc.–are assumed to be meaningful functions of three spatial variables x_1, x_2, x_3, and time t. The internal forces (pressure, stress), the velocity components, and the density are usually unknowns to be calculated, while weight, dielectric constant and some other properties are presumed given.

Measurement of these physical quantities in a moving field is important both for practical reasons and as the means for developing the working concepts of fluid dynamics. Examples of methods for measuring fluid velocity components u_i are given later in this article. For methods of measuring pressure, see FLUID STATICS.

When electromagnetic body forces are present, the situation is quite complicated, and we will in this article consider only the simpler situations where the only body force is weight. For information on situations in which electromagnetic forces exist, see MAGNETO-FLUID-MECHANICS.

In addition to internal forces (pressure, stress) and external body forces (for purposes of this article, weight), additional "fictitious" body forces appear in those cases where an accelerated frame of reference is used to describe the flow situation. Particularly common are *Coriolis* and *centrifugal* forces which arise in a frame of reference rotating relative to an inertial frame. (See CORIOLIS EFFECT, DYNAMICS.) A frame fixed to the earth has this property, but the fictitious forces can usually be ignored; the centrifugal force is combined with the gravitational force to produce the ordinary measured weight (see FLUID STATICS), and the Coriolis force is so small that it usually can be ignored. The Coriolis force is, however, extremely important in fluid dynamics of the atmosphere, which involves motion over global scales and is the basis for long range weather prediction.

A fluid is, by definition, a substance in which there are no shear stresses when *at rest*. All substances *in motion* have shear stresses acting in addition to the normal stresses. In motion, the normal stresses in a fluid are not equal in all directions, but the average of the normal stresses is employed and called *pressure* as an extension of the concept of pressure which arises in fluid statics. Many fluids, e.g., tar, waxes, oils, honey, bread dough, and many synthetic polymers, have both normal stress and shear stress components which depend on the recent deformation history as well as on the current rates of deformation (see RHEOLOGY).

The relations between the stress components and the current strain components and rate of strain components are extremely important in formulating the equations of fluid dynamics, elasticity, and rheology. The relations which exist for a particular substance determine, in fact, whether the flow of the substance is to be described within the field of fluid dynamics, elasticity, or rheology. In fluid dynamics, the stress-deformation relation is assumed to be a simple linear dependence of each stress component on the current rates-of-strain at the same point. Because the substance is also considered to be isotropic (no crystal axes), these linear relations can be shown mathematically to involve only two proportionality constants. The proportionality constants are called the *first viscosity coefficient* and the *second viscosity coefficient*; except in very unusual situations, the second viscosity coefficient is zero, so that it is common to consider the first viscosity coefficient as *the* viscosity μ. A substance which adequately follows this simple linear stress-deformation relation is called a *Newtonian substance* (see VISCOSITY).

With the linear relation between stress components and rate-of-strain components, the stress components can be expressed in terms of the pressure (i.e., the average of the normal stresses), the viscosity, and the spatial derivatives of the velocity components. Then the basic dynamical equation of continuous media–which equates the sum of all forces on an element to the element's mass times its acceleration–takes the following form, known as the *Navier-Stokes equations*:

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + g_i + \frac{\mu}{\rho}\left(\frac{\partial^2 u_i}{\partial x_j\,\partial x_j} + \frac{1}{3}\frac{\partial}{\partial x_i}\frac{\partial u_j}{\partial x_j}\right). \quad (1)$$

The Navier-Stokes equations are components of a vector equation. The index notation used for subscripts is that an index i or j may be 1, 2, or 3, representing components of vectors along axes 1, 2, or 3, respectively, and in any term where the same index occurs twice, a sum of terms with that index taking successively the values 1, 2, and 3 is implied. μ is assumed to be a known and constant value characteristic of the fluid, and g_i are components of the known weight per unit mass, nominally 9.8 N kg^{-1} downward.

The left-hand side of Eq. (1) represents the acceleration component of the parcel of fluid at the point x_1, x_2, x_3 at time t, and the right-hand side is the force per unit volume divided by the mass per unit volume.

Two additional equations are needed to determine the five unknowns u_1, u_2, u_3, p, ρ, since the three equations of motion (with subscript i taking on the values 1, 2, and 3) are insufficient.

One of these needed equations is the so-called *continuity equation*,

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_j}(\rho \mu_j) = 0. \quad (2)$$

This equation, employing the same index notation, and based on the concept that ρ represents the quantity of matter as well as the inertial mass of the fluid, essentially states that matter flowing into a fixed volume is equal to the time rate of increase of the matter in that volume. It is a kinematical statement.

The fifth equation is, in various situations, some form of thermodynamic equation of state, an example being the *adiabatic equation*,

$$\frac{p}{p_0} = \left(\frac{\rho}{\rho_0}\right)^{\gamma} \quad (3)$$

applying to an ideal gas. (γ, the ratio of heat capacities of the gas, is equal to 1.4 for air.) A variety of assumptions, usually involving the first and second laws of thermodynamics and thermodynamic equations of state of the substance, are needed in various situations.

Two further special assumptions are made in formulating situations dealt with in a large part of the fluid dynamics literature. One is the assumption that the viscosity coefficient μ is zero. The Navier-Stokes equations, then, with $\mu = 0$, are called the *Euler equations*. These equations are not really applicable to any fluid substance, but there are types of flows where important characteristics are illustrated. Such flows are said to be *ideal fluid* or *inviscid fluid* flows. The second special assumption is that the fluid is incompressible, i.e., has constant density.

These partial differential equations, even the Euler equations, are nonlinear and have no general solutions, even for the most restrictive boundary conditions. Particular solutions are carried out for various idealized flows.[1,2] Examples of particular solutions for selected geometrical boundaries are described later in this article.

Kinetic Theory and Nonequilibrium Statistical Mechanics In this approach, fluid properties are associated with averages of properties of microscopic entities. Density, for example is the average number of molecules per unit volume times the mass per molecule. While much of molecular theory in fluid dynamics aims to interpret processes already adequately described by the continuum approach, additional properties and processes are presented. The distribution of molecular velocities (i.e., how many molecules have any particular velocity), time dependent adjustments of internal molecular motions, and momentum and energy transfer processes at boundaries are examples.[3] See KINETIC THEORY and STATISTICAL MECHANICS.

Examples of Flows In Fig. 1, the special flow called Couette flow is indicated schematically. The flow is between parallel plates, lower plate at $y = 0$ at rest, upper plate at y_B

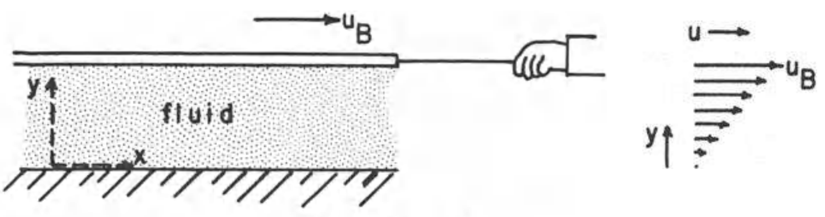

FIG. 1. Couette flow.

moving with constant speed u_B in the x direction. Stress throughout the fluid is constant, given by $P_{xy} = \mu(du/dy) = \mu(u_B/y_B)$. This is pure shear flow and experimentally is often considered to define and measure the viscosity coefficient μ assumed constant for the homogeneous fluid. The velocity profile appearing at the right in the figure shows by velocity arrows of different length at the various positions y how the velocity varies with position. Steady flow (no dependence of any quantity on time), constant pressure, constant density and laminar flow are additional assumptions for Couette flow. The flow is realized experimentally by confining the fluid in the narrow annulus between rotating concentric cylinders of nearly equal radius; the cylinders rotate at different speeds.

In Fig. 2, the special flow is in a pipe of uniform cross section, pressure is assumed to be constant across each cross section but to vary linearly with distance x along axis of pipe so $dp/dx = (p_1 - p_2)/L$. Pistons driving the flow are assumed to be infinitely far away, so that the flow velocity, parallel to pipe axis, has the same dependence upon y and z for all x. The velocity profile is parabolic in both the two-dimensional case (infinite parallel plates) and in the circular cross-section case. Mean flow velocity u_m and viscosity coefficient μ are assumed constant; the flow is assumed steady and laminar. For a circular cross-section pipe of radius a, at any distance r from the center, $u = 2u_m(1 - r^2/a^2)$, and the volume passing a cross section per second is $Q = \pi a^2 u_m = \pi a^4(p_1 - p_2)/8\mu L$. Since these formulas do not apply near pipe entrances, caution in applying them to pipes of finite length is necessary even when the flow is steady and laminar. (See later discussion of turbulent and laminar flows.)

Other examples of idealized solutions are one-dimensional flow of an ideal gas through a normal shock wave, flow of an ideal gas without viscosity through a pipe of slowly changing cross section (wind tunnel), and one-dimensional finite waves in an ideal gas. Many other solutions involve making whatever approximations and assumptions are necessary to obtain descriptions of observed flows.

When motion of the fluid consists of only small fluctuations about a state of near-rest, the continuum equations are linearized by neglecting nonlinear terms and become the equations of acoustics. See ACOUSTICS. A large variety of fluid motions are described as sound waves; when the small-motion or acoustic description can be used the *principle of superposition* is valid. This powerful principle allows addition of simple simultaneous motions to represent a more complex motion, such as the sound reaching the audience from the instruments of a symphony orchestra. The superposition principle does not apply to large-scale (nonacoustical) motions, and the subject fluid dynamics (as distinct from acoustics) treats nonlinear flows, i.e., those which cannot be described as superpositions of other flows. The description of small motions in a small region of even a nonlinear flow is useful; at each place in the flow there is a "local sound speed."

Since sound waves travel with a sound speed relative to the fluid, waves moving in a moving fluid can sometimes be carried off in a direction opposite to the direction of sound travel. The flow where such a thing happens is called *supersonic*; the flow speed is greater than the sound speed at the spot where the flow is supersonic. Supersonic flow occurs around high-speed vehicles and missles, and in pipes when high pressure gas escapes through a constriction such as a partially open valve into a region of sufficiently lower pressure.

A steady supersonic flow always must pass through a *shock front* to slow down to subsonic flow again.[1,4] A shock front is a surface of discontinuity separating fluid of high pressure, high density, and high temperature from lower pressure, density, and temperature fluid. If the shock front is in motion, it is called a *shock wave*. The component of fluid velocity perpendicular to the shock front is also discontinuous, while the other components are continuous. See SHOCK WAVES.

The continuum description of flow fails to describe nearly all actual flows because actual flows when looked at carefully are *turbulent*. Turbulent flows have violent and erratic fluctuations of velocity and pressure which are not associated with any corresponding fluctuations of the boundaries containing or driving the fluid. Turbulence is generally considered to be the manifestation of the nonlinear nature of the fundamental equations. Under certain conditions as mentioned earlier in describing Couette and Poiseuille flows, nonturbulent or *laminar* flow exists. A common example is cigarette smoke rising from a cigarette held at rest; near

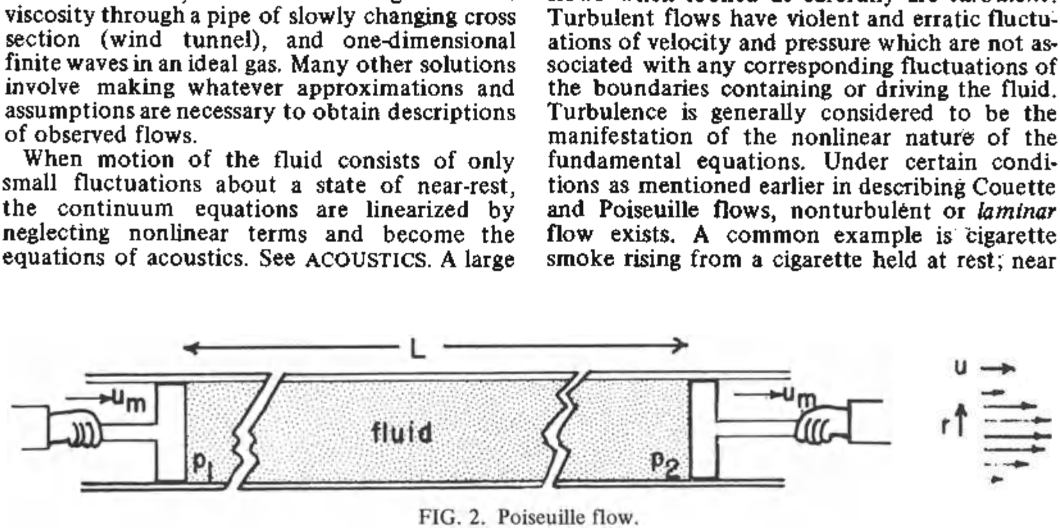

FIG. 2. Poiseuille flow.

the cigarette, the stream is smooth and straight, or laminar, and further up the flow breaks into turbulence.

Reynolds showed that Poiseuille flow in a pipe occurs when $\rho u_m a/\mu$ is smaller than 2000. The combination of variables is dimensionless and is called the *pipe Reynolds number*. Blood flow in capillaries is laminar, but water flow in household pipes is turbulent unless the flow is about that allowed by a leaky faucet or less. Other types of flow have Reynolds numbers characterizing transition from laminar to turbulent; for example a sphere falling in a fluid of viscosity μ obeys *Stokes' Law*

$$mg = 6\pi a\mu u$$

where u is the constant speed of fall, m is the sphere mass, a its radius, and g the weight per unit mass, but the law is obeyed only if the *sphere Reynolds number* $\rho ua/\mu$ is smaller than about 1.

Because of turbulence and viscosity, the very simple and useful *Bernoulli formula* is not valid; it can be derived as applying to a constant-density fluid with zero viscosity in laminar flow. However, under certain conditions, the formula applies approximately even when the flow is turbulent, predicting properties within 5 to 20 per cent of the observed values. The Bernoulli formula states

$$p + \rho gh + \tfrac{1}{2}\rho u^2 = \text{same constant in all places in the fluid}$$

where p is the fluid pressure, ρ is the fluid mass density (which must be treated as constant), u is the fluid speed, h is the vertical height above some convenient reference level, and g is the weight per unit mass.

When combined with the equation of continuity, the Bernoulli formula gives a simple description of the Venturi, used in the automobile carburetor (see Fig. 3). Continuity states $u_1A_1 = u_2A_2$ = volume crossing any cross section of the pipe per second. $u_1/u_2 = A_2/A_1$ is small so u_1 is smaller than u_2. The Bernoulli formula states $p_1 + \frac{1}{2}\rho u_1{}^2 = p_2 + \frac{1}{2}\rho u_2{}^2$, and since u_1 is smaller than u_2, p_1 is larger than p_2. The atmospheric pressure p_1 pushes the liquid up into the lower pressure region p_2.

Another common situation descrioed by the Bernoulli formula is the discharge of (constant density) fluid from a small hole. For the cylindrical bucket of water in Fig. 4, equate the sum of the quantities in the Bernoulli formula at the top surface to the sum at the hole: $p_1 + \rho gh + 0 = p_2 + 0 + \frac{1}{2}\rho u_2{}^2$. The pressure at both top and bottom is atmospheric pressure p_1; the speed at the top is approximately zero because the hole is considered to be very small. The predicted speed of the emerging water is therefore $(2gh)^{1/2}$ regardless of the size of the hole (as long as the hole is small).

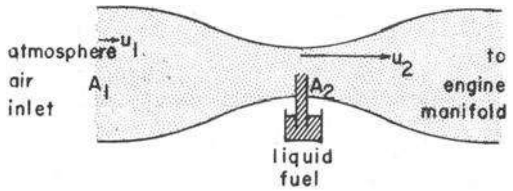

FIG. 3. Pipe flow with a constriction; carburetor employing Venturi.

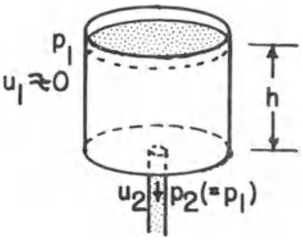

FIG. 4. Discharge through a small hole in a bucket.

A valuable instrument in the form of a probe for observing fluid speed is the Pitot tube; its operation is described by the Bernoulli formula. A glass or metal tube with an open end points into the flow, and the pressure difference Δp between the stagnant fluid in the tube and the moving fluid allows calculation of the fluid speed at the place where the tube tip is inserted by $u = (2\,\Delta p/\rho)^{1/2}$ where ρ is the fluid mass density. When observing air speed, the pressure difference Δp is easily measured by connecting the open ended tube via rubber hose to a glass U-tube water manometer. Errors as much as 50 per cent may easily occur in various practical situations, but order-of-magnitude measurements at least are usually possible.

The Pitot tube is the only *simple* instrument for measuring fluid velocity at a point. It is useful only in certain steady flows (no dependence of any quantity on time) and the degree of its accuracy is hard to determine in a given situation. *Absolute velocity measurement* is possible only by observing the velocity of tracer particles by optical methods.[5] Many other velocity measuring instruments are *calibrated*, either by comparison to tracer velocity measurements or by towing the instrument at a known speed through the fluid at rest. A tracer must be small, particularly if its density differs from that of the fluid, so that it moves exactly as the fluid surrounding it is moving. Usable tracers are liquid droplets or solid particulates in gases, and gas bubbles or solid particulates in liquids. Tracer dimensions are usually 1 to 100 micrometers, the smaller ones being required when the velocity being measured is changing spatially or temporally. Observation of the tracer is carried out either by photography with repetitive flash illumination (called *chronophotography*) or by Doppler methods.

The *laser Doppler velocimeter* has had many applications in recent years.[5] In this instrument light is scattered by tracers from two coherent laser beams which cross one another in a chosen small volume inside the moving fluid; the fluid carries micron-size tracer particles and the scattered light from them in the intersection volume is gathered by a lens on to a photomultiplier. If the direction of the velocity of the tracer is known relative to the bisector of the directions of the laser beams, the measured frequency of oscillation of the photomultiplier current gives the speed v of the tracer by means of the formula:

$$v_b = v \cos \theta = \frac{\nu_D \lambda_0}{2 \sin (\alpha/2)}$$

where θ is the angle between the bisector of the incoming laser beams and the tracer velocity $\mathbf{v}$, λ_0 is the wavelength of the light in the fluid medium, α is the angle between the incoming laser beams, and ν_D is the measured frequency of the photomultiplier signal, called the *Doppler frequency*. The quantity determined is the magnitude of one component of the velocity; the sense (sign) of the component is not measured but must be learned from other information. The electronic equipment to measure and display or record the Doppler frequency is rather elaborate, but available commercially. Fluid speed as a function of position is measured by moving the optical system mechanically about in the fluid field. The intersection volume is ordinarily small—much less than a cubic millimeter.

Measurement of fluid velocity at small scales and in small times is the most promising method for study of turbulence. The laser Doppler velocimeter can measure the speeds of successive tracer particles passing through a small measuring volume in times as close together as 1 ms, but the measurement is not very accurate. Another instrument which must be calibrated, the *hot-wire anemometer*, is used to assemble more accurate data collected in an air or water stream. The hot-wire anemometer is a probe consisting of two steel prongs supporting at their ends a tungsten wire of diameter 2-5 μm and length 1-3 mm carrying an electric current which would heat it white-hot except for the cooling produced by the fluid passing over it. Its resistance is related to its temperature, which in turn is related to the fluid velocity component perpendicular to the wire. Thus, after it is calibrated, its resistance as a function of time can be interpreted as a time record of the stream speed in which it is immersed. At larger scales than millimeters, data on the successive positions of injected dye spots or hydrogen bubbles in water are collected by cinematography using television recorders.

Measurement of other fluid variables—density, composition, and temperature—with precision, at small scales, and in rapid succession, is carried out by optical means. For example, intensity of Raman components of scattered laser light can be analyzed to determine temperature, density and even species concentration. Pressure at walls of channels or at surfaces of inserted objects is measured by "wall taps" or by miniature diaphragm or piezoelectric gages. A "wall tap" is a small hole at the point on the surface where the pressure is to be measured which connects with a pressure gage by a small channel filled with a static fluid.[5]

FLUID STATICS

The definition of a fluid—in distinction to a solid—is a substance in which there are no shear stresses when it is at rest. A fluid is an infinitely slippery material. In reality, a substance is considered a fluid if shear stresses in it vanish so rapidly when motion ceases that, for times under consideration, it may be considered shear-free. Substances like tar and glass require very long times for shear stresses to relax, in comparison with fluids like water and gasoline. The sense that everyone has of the difference between a fluid and a solid is more clearly felt than is the nature of internal forces (stress) between the parts of the substance. Shear stresses are the internal forces opposing *sliding* of one part of a substance past the neighboring parts. All real fluids *in motion* do have shear stresses (see FLUID DYNAMICS), and solids also have shear stresses which help maintain their solid shape when weight and other forces act on them (see MECHANICAL PROPERTIES OF SOLIDS).

Historically the complexity of internal forces introduced great confusion (from our modern viewpoint) into the fundamental principles of mechanics. Principles applying to fluids at rest were clarified by Torricelli and by Pascal whose experiments in 1647 settled the question of the existence of an absolute vacuum and of weight of the air. Sir Isaac Newton devoted over one quarter of the famous *Principia* to analysis of fluids (Book II, 1713); his principles are more subtle in application to fluids, and Newton's contributions to fluid mechanics are seldom quoted today. Probably Euler was the first to give, in 1755, a clear idea of the complex relation of the internal forces (stress and body forces) and the motion of fluids and solids.

The concept of pressure, and methods of measuring pressure of gases, soon led to the discovery of Boyle's law (1662), and eventually to the clarification of the concept of temperature through its measurement by the gas thermometer.

Meaning of Pressure If we consider a surface within a substance we expect that material on one side will be pulling material on the other side with a force having components both normal and tangential to that surface. In a static fluid, however, the tangential component must be zero; otherwise the material would have a shear stress and would not be called a fluid. Pascal realized that at a given place in the fluid, if a surface with a different orientation is considered, the force per unit area on it is again perpendicular to that surface and has the same magnitude as the force per unit area on the original surface. (This is not true for a solid except for very special cases of loading.) The magnitude of the force per unit area for all these orientations at the same point is called the *pressure* at that point. The strange property of a force per unit area, which is a vector, having the same value at a point for all orientations seems to give it the property of a scalar. Actually, since the property of a tensor is to relate one vector to another vector, the stress tensor for a static fluid is expressed by the negative of the pressure times the unit tensor at all points. This expresses the force per unit area as perpendicular to whatever surface is considered at the point. (In general in a solid or in a moving fluid, the force per unit area is related to the vector giving the orientation of the surface by the stress tensor. The vectors have different directions, and all six components of the stress tensor have their own dependence on spatial position.) In a static fluid, only the magnitude of the force per unit area varies from point to point, and the pressure gradient ∇p can be shown to be equal to a force per unit volume in the direction in which the pressure decreases most rapidly.

Stress components are positive when the neighboring material is *pulling*, and negative when *pushing*: tension (+) and compression (−). Pressure is, however, treated as positive when pushing, since in gases tension never occurs and in liquids tension seldom occurs.

Body Forces and the Law of Fluid Statics Stresses on a sample of matter are not the only forces acting—weight and electromagnetic forces can act also. Both these are forces per unit volume and are called *body forces*, in distinction to stresses which are *surface forces* or *contact forces.*

In a fluid the only forces acting (see, however, "surface tension," described below) are weight, electromagnetic forces, and pressure. For a volume element at rest the sum of these must be zero:

$$\rho \mathbf{g} + \mathbf{J} \times \mathbf{B} + \rho_{\text{el}} \mathbf{E} - \nabla p = 0. \qquad (1)$$

Here ρ is density (mass per unit volume), $\mathbf{g}$ is weight per unit mass, $\mathbf{J}$ is electric current per unit area perpendicular to $\mathbf{J}$, $\mathbf{B}$ is magnetic field, ρ_{el} is electric charge per unit volume, and $\mathbf{E}$ is electric field. In a dielectric liquid, ρ_{el} can include polarization charge and, in a magnetic liquid, $\mathbf{J}$ may include amperean currents representing magnetic polarization. For more information on the nature of the electromagnetic force, see MAGNETO-FLUID-MECHANICS.

Eq. (1) is the basic equation of fluid statics; it is valid at all interior points.

In all the foregoing, it is assumed that "rest" is reckoned relative to an inertial frame of reference. In a frame of reference translating or rotating relative to an inertial frame, additional "fictitious" body forces must be added to Eq. (1) (see CORIOLIS EFFECT, DYNAMICS).

An additional force called *surface tension* is evident at interfaces between liquids which do not mix (e.g., oil and water), between liquids and vapors, and between liquids and solids (see SURFACE TENSION). This force plays the role of a boundary condition that must be satisfied when Eq. (1) is integrated over an interface in a fluid statics problem. Across a curved interface, with no electric or magnetic field present, the following relation between the surface tension S, the radii of curvature R_1 and R_2, and the pressure jump $p_1 - p_2$ over the surface exists at each point on the surface:

$$p_1 - p_2 = S\left(\frac{1}{R_1} + \frac{1}{R_2}\right). \qquad (2)$$

The surface tension S has units of force per unit length in the surface, and is a joint property of the two fluids. It depends markedly on temperature and, for a liquid and its vapor, becomes zero at the critical temperature of the substance.

The surface tension still exists in a case of a plane interface (it is a force which will do work in a quasistatic deformation of the fluids), but no pressure difference exists across the plane interface. This follows from the nature of pressure as *normal* force per unit area. At a dielectric boundary, with electric or magnetic fields present, an additional contribution to the pressure discontinuity given by Eq. (2) exists. At a liquid-vapor boundary, the additional contribution is known as *electrostriction.*[1]

Equation (1) is not only the fundamental expression of the meaning of pressure; it is also the basis for the measurement of pressure. Before describing methods of pressure measurement, however, we will look at the meaning of pressure from a molecular viewpoint.

Molecular Models of Pressure[2] Pressure is nearly always used as one of the thermodynamic variables in equations of state. Our extensive knowledge of properties of substances, as compiled in thermodynamic tables, provides a wealth of data for testing molecular models of liquids and gases, as well as practical information for engineering design. The model employed in the kinetic theory of gases has been so successful that there is a tendency on the part of some to accept this molecular model's view of pressure as "real" and universally applicable. It is however restricted to gases, and models of liquids are less successful and their view of pressure is somewhat more complicated.

The kinetic theory of gases, rooted in ideas going back at least as far as Daniel Bernoulli (1738), pictures matter in gaseous form as consisting of isolated molecules flying about in a force-free vacuum and making occasional collisions with one another and with solid containing walls (see KINETIC THEORY). At a hypothetical small surface within the gas, there is nothing most of the time, but occasionally a molecule flies through the surface unimpeded. The model assumes such events to be random and uncorrelated, but to have a distribution of directions and times between occurrences. The model further assumes that the number of molecules flying through a surface per unit time and in one sense is proportional to the area considered, and that the number per unit area, per unit time, is the same for all orientations at any one position. This is the case, however, only for fluid statics—not fluid dynamics—that is, there must be no net transfer of mass through the area (no mean motion.)

If the position of the surface is at or near and parallel to one of the solid boundaries, from which the molecules are considered to rebound, the equal flux of molecules into the surface and back out is associated with an average force per unit area applied to the wall. This average force per unit area at the wall, which is equal to twice the normal component of momentum flux through the surface in one sense, is then considered to be the pressure at the wall, and the flux through a surface not at a wall for which there is likewise an equal flux in the other sense, is interpreted as the pressure within the gas. In this way, a meaning is given to "normal force per unit area" at any point within the gas, and if the density or velocity distribution of molecules varies from place to place, twice the flux of normal component of momentum in one sense through a hypothetical surface, namely the pressure, will vary from place to place as well. Since molecules actually have some size in the model, those passing through a hypothetical surface at a point may collide with other molecules before reaching a distant wall, and if the molecules with which they collide have in a certain measure the density and velocity distribution characteristic of the point, it is thought that the reverse flux of molecules may also have the local characteristics. (Again it is necessary, in making this statement, to limit ourselves to cases of no net flow of mass through the area.)

This justifies, to some extent, the application of an equation of state locally within a fluid with gradients of density, temperature, and pressure. It is apparent that only within volume elements larger than about one mean free path cubed can an equation of state have meaning in this model.

Liquid state models suppose the molecules to be in close contact with one another, as in a solid, but over a range of several molecular diameters the forces between molecules are such that long range order is not maintained as in a crystal. The picture of pressure in this model is quite similar to the picture of stress in a solid, and the absence of shear stresses in liquids at rest is actually only a qualified one in that the time for a shear deformation to relax is shorter than some time considered to be of interest. The substance is called a *glass* if the relaxation time is longer. (See LIQUID STATE.)

In statistical models of a monatomic substance such as argon, the pressure is defined[3] as a sum of two terms, one a *kinetic term* equivalent to the momentum flux of molecules through a hypothetical area in empty space as described above for the kinetic theory of gases, and a *collisional transfer of momentum term* representing the ever-present forces between adjacent pairs of molecules. The microscopic pressure tensor t_{ij} (i.e., the negative of the stress tensor) for isotropic molecules such as argon can be expressed as

$$t_{ij} = \sum_{\alpha} \left\{ \frac{p_{\alpha i} p_{\alpha j}}{m} + \frac{1}{2} \sum_{\beta} (q_{\beta j} - q_{\alpha j}) \frac{\partial U_{\alpha\beta}}{\partial q_{\alpha i}} \right\} \delta(\mathbf{q}_{\alpha} - \mathbf{x})$$

where the subscripts i and j take on the values 1, 2, 3 representing coordinate axes, and the subscripts α and β are numbers characterizing each of the molecules in the system so that the sums are over all the molecules and all pairs of molecules. The momentum components of the molecules are denoted by $p_{\alpha i}$, the mass of each by m, the separations of two molecules by $(q_{\beta j} - q_{\alpha j})$, and the forces between them by $(\partial U_{\alpha\beta}/\partial q_{\alpha i})$. The delta function $\delta(\mathbf{q}_{\alpha} - \mathbf{x})$ restricts the sum to only those molecules lying within a volume cell denoted by position $\mathbf{x}$ in space. The macroscopic pressure tensor is obtained when t_{ij} is averaged over the equilibrium statistical distribution of all coordinates $\mathbf{q}_\alpha$ and momenta $\mathbf{p}_\alpha$.

The above pressure tensor expression implies that the thermodynamic and mechanical variable pressure has the same meaning in a vapor and in a liquid; the first, kinetic term predominates in a vapor, and the second, collisional transfer of momentum term predominates in a condensed liquid, so that the expression provides a continuous pressure across a plane interface (when there is no net transfer of matter and static equilibrium prevails). Because of mathematical complications associated with the statistical mechanics of many body systems, the consequences of the model have not yet been fully worked out. The picture of pressure in the model is however clear.

Measurement of Pressure Two basic instruments are used to measure pressure, and all other pressure gages are calibrated by these.

U-Tube Manometer. Two columns of liquid partly filling a piece of glass tubing bent into a U-shape with hoses connecting to two reservoirs in which the pressure is to be measured are seen frequently in laboratories. The liquid typically has a density 10^3 times the density of the gas which is connecting the manometer to the reservoirs. The manometer equation

$$p_2 - p_1 = \rho g(z_1 - z_2) = \rho g h \qquad (3)$$

gives the pressure differences $p_2 - p_1$ between the reservoirs, where ρ is the mass density of the liquid in the manometer, g is the weight per unit mass (nominally 9.8 N kg^{-1}), and z_1 and z_2 are the vertical coordinates of the respective surfaces between liquid and gas on the two sides of the U-tube. Eq. (3) is derived by integration of Eq. (1) along a path through the liquid, under the assumptions that ρ is constant (homogeneous liquid) and that the liquid-gas surfaces are either plane or have equal curvatures.

If absolute pressure is to be measured in one reservoir, the pressure must be maintained at zero in the other, usually by a vacuum pump. When used to measure the ambient pressure in the atmosphere, the arrangement is called a *barometer*. When the pressure in some reservoir is measured ***relative to the ambient atmosphere***, one speaks of the pressure difference as the "gage pressure" of the reservoir.

For accurate measurement, the liquid must not evaporate; a "low vapor pressure" liquid such as mercury or silicone oil is commonly used.

If the vertical height of either reservoir is appreciably different from the corresponding liquid-gas surface in the manometer, a correction for the variation in pressure with height in the gas must be made. An equation similar to Eq. (3) is used, but ρ is then the gas density.

A more likely correction will be necessary due to different diameters of the glass tubing on the two sides and consequent differences in the curvatures of the meniscuses. This latter correction is minimized by using very large diameter tubing. Tubing of 1 cm radius is needed when the liquid is mercury, and accurate measurement of h by interferometry is used.

Use of the manometer is so common that pressure units stated as h and the name of the liquid employed in the manometer have become common. Table 1 lists some of the bewildering variety of pressure units found in the literature. The value of each unit is given in terms of the SI unit Pa. The table permits pressure units to be converted among each other, as well as to the standard SI unit.

Piston and Cylinder Gage. The other absolute pressure measuring instrument uses a tight-fitting piston in a precision bore cylinder. It is the basic standard for measurements above about 100 kPa and even within the range of usefulness of the U-tube manometer it is used to calibrate other gages. Also called a ***dead-weight gage*** and a ***gage tester***, it is seldom seen outside a standards laboratory because its operation requires skill, care, patience, and conditions of cleanliness.

The vertical piston supports loads of known weights, and a liquid (usually oil) or a gas (nitrogen or air) in the cylinder below the piston,

TABLE 1. PRESSURE UNITS.*

Name of Unit	Value	Name of Unit	Value
1 kgf/cm^2	98.07 kPa	1 in. Hg	3.38 kPa
1 dyne/cm^2	0.1 Pa	1 in. H_2O	249 Pa
1 bar	100 kPa	1 mm Hg (Torr)	133.3 Pa
1 atm	101.3 kPa	1 mm H_2O	9.81 Pa
0 acoustic decibel (reference level)**	10 Pa (transducers) or 20 μPa (hearing)	1 lb/ft^2	47.9 Pa
		1 lb/in^2 (psi)	6.895 kPa

*The SI unit of pressure is the *pascal* (symbol Pa); 1 Pa = 1 N m^{-2}.

**Sound pressure level, in decibels, is 20 times the logarithm to the base 10 of the ratio of the sound pressure to the reference pressure. The reference pressure should be explicitly stated; if it is not, the levels noted in the table are often used. Also, unless otherwise explicitly stated, it is understood that the sound pressure is the *rms* pressure *change*.

communicating with a gage to be calibrated, is compressed by a hand pump until the piston and loads rise a short distance. As the liquid or gas slowly leaks out through the small piston and cylinder clearance, the pressure is maintained. The *effective area* of the piston and cylinder has been determined in principle by a metrological microscope in a standards bureau. Piston and cylinder gages are obtainable from commercial manufacturers, who supply the effective area by comparing gages with gages built and maintained by national standards bureaus.

With care, pressures can be measured with errors as small as 0.01% in ranges from 100 Pa to 100 MPa (1 millibar to 1000 bars).

Other Gages. The common gages with a pointer indicating on a circular dial contain a metal chamber which deforms with the applied pressure. By combining metallurgical art with mechanical art to translate the motion of the deforming part into rotation of a needle on a dial without backlash, manufacturers have been able to supply gages with a wide variety of operating ranges, compensated for temperature change, and retaining precision on the order of 0.1% of the range.

Mechanical distortion of a thin diaphragm held rigidly at its edges is another effect widely used for pressure measurement. Sensing of diaphragm deflection by capacitatively coupling it to a fixed electrode and conversion of the capacitance change to an electrical signal has been developed to form a gage of high sensitivity and reliability. Such gages are the best way of measuring pressure in the range below 10 Pa, and are often found on vacuum systems. Their output is assumed to be a linear function of pressure, so that, with points at the ends of a straight line on a graph determined at vacuum and at 10 Pa (by means of a piston and cylinder gage) to an accuracy of 0.1%, a pressure scale in the range 0–10 Pa is defined.

Minute diaphragms formed in silicon chips by integrated circuit etching techniques are mass produced and employ deflection sensors of diffused dopant in the diaphragm itself. The sensors are electrical resistance paths which change their resistance when stretched. While quite sensitive to temperature as well as to pressure, their small size, adaptability to electrical signal generation, and cheapness make them useful in processing equipment and in other systems. Their accuracy is less than that of the other gages described.

Many other devices capable of calibration are used for pressure measurement.[4] It is apparent that pressure cannot be measured in the interior of a fluid but only at a solid surface bounding the fluid. Sometimes a probe with a pressure sensitive element is inserted into a fluid to attempt a measurement within, but there is no assurance that the pressure is not changed by inserting the probe. A "contactless" pressure measurement is impossible.

Deductions from the General Principles of Fluid Statics We have stated the elementary basis of fluid statics along with the meanings of pressure and surface tension in Eqs. (1) and (2). Some traditional wisdom now derivable from these equations preceded their statement, such as "water always runs downhill," "water seeks its own level," and "a body is buoyed up by a force equal to the weight of the displaced fluid" (Archimedes' principle). Let us derive some general conclusions from the laws of statics, namely from Eqs. (1) and (2).

Pressure Variation with Depth. We have already, in discussing the manometer, established the variation of pressure with depth in lakes and in the oceans. This is Eq. (3), valid because the density of water in the ocean varies so little with depth, and because even at the greatest depths, the distance from the center of the earth has changed by such a small fraction that g may be considered practically constant.

Hydraulic and Pneumatic Actuating Systems. Provision for application of a force or forces at distant sites by means of a fluid in tubing connected to piston-and-cylinder arrangements is very common. Movement of the control piston increases the pressure in the fluid and the increase in pressure occurs almost immediately (transmitted at the speed of sound in the fluid) everywhere in the fluid. This uniform pressure increase is sometimes called *Pascal's law* and follows from Eq. (1). The aspect of such arrangements which causes the most technical trouble is that the fluid finds the smallest holes or cracks in the containing system and leaks out. Sealing of pistons, valves and other moving parts with gaskets introduces friction, so that the computed forces are not precisely found in practice. By choosing the size (area) of the piston-and-cylinder, the magnitude of force to be delivered can be chosen. An extremely large force is achieved by this means in the *hydraulic press*, which allows forces to be "magnified," and by means of mechanical valves (in a pump) to produce significant displacements of the large force.

Surface of Water at Rest Is Horizontal. The existence of sea level on the earth, combined with the detectable curvature of the sea surface over several kilometers, follows from the absence of all body forces in Eq. (1) except weight. Weight, as represented by the common $\mathbf{g}$, is the resultant of the gravitational force in the nearly spherical earth and the local centrifugal force due to the earth's rotation. (Centrifugal force is the fictitious force introduced by describing pressure on the earth in a rotating frame of reference.) Due to the oblate shape of the earth, as well as due to the centrifugal force, $\mathbf{g}$ is not directed exactly toward the earth's center. The meaning of "vertical" is given by the direction of $\mathbf{g}$. That the surface of a liquid is perpendicular to $\mathbf{g}$, i.e., "horizontal," follows from the vector nature of Eq. (1) and the knowledge that the surface is one of constant pressure. Since **g** changes in direction as we consider various locations on the earth, the surface of constant pressure, i.e., sea level, also changes direction, giving the nearly spherical shape of the oceans' surfaces. So long as no solid body—one able to maintain shear stresses—is between water in a stream and water in the ocean, the water will move to form the static surface at atmospheric pressure which is the surface at sea level. Thus water runs down until it gets to the ocean, which is the final static equilibrium state.

Capillary Rise of Liquid. That sap rises to the top of the tree—well above sea level—is understood by Eq. (2) and the knowledge that the pressure is reduced below the atmospheric pressure by the curvature of the meniscus in the sap column.

Archimedes' Principle. That an immersed body is buoyed up by a force equal to the weight of the displaced fluid follows readily from Eq. (1), the assumption being that the only body force is weight. The pressure over the surface of the body varies with depth and is larger underneath than on top; the pressure at opposite sides is the same at the same depth, so the sideways forces pushing on the body are opposite and there is no net sideways force. Equation (1) with weight **g** as the only body force takes the form

$$\rho \mathbf{g} - \nabla p = 0, \tag{4}$$

where both terms are forces per unit volume. We divide the immersed body into many imaginary vertical prisms, one of which is shown in Fig. 1, with cross sectional area A and height h. The net upward force on the top and bottom surfaces of the prism is ∇ph times A and is, according to Eq. (4), identical to the weight of fluid in the prism of cross section A and height h, namely, $\rho g h A$. This is true for each prism and we can add the results for all the prisms, thus deriving Archimedes' principle.

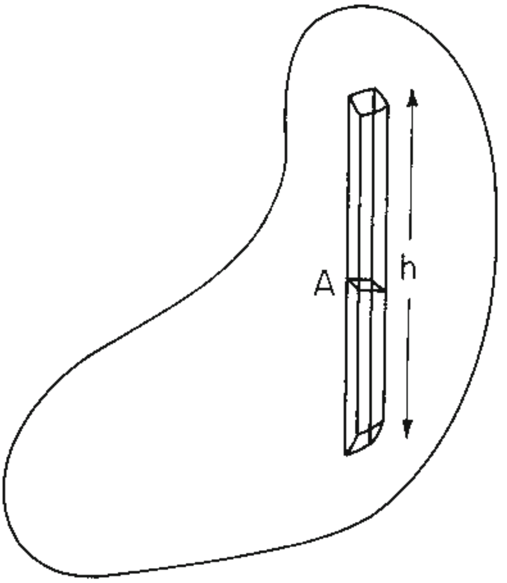

FIG. 1. Archimedes' principle.

Criterion for Unstable Atmosphere. Air is compressible, and over heights of hundreds of meters the density of the atmosphere changes appreciably. Mixing of the air at levels up to about 400 m above the ground is important in predicting whether rain will occur and whether pollutants inserted near the ground will stay there or be diluted as unstable air mixes. The criterion for stability is that the temperature T increase with height z at a rate greater than

$$\frac{dT}{dz} = -\frac{g}{C_p}, \tag{5}$$

the so-called *adiabatic lapse rate*. The heat capacity per unit mass at constant pressure, C_p, is a property of air: 1010 J kg^{-1} K^{-1}. Equation (5) is derived from the basic equation of fluid statics, with weight the only body force, namely Eq. (4), in the form*

$$\frac{dp}{dz} = -\rho g \tag{4'}$$

and the adiabatic equation of state for air

$$T = T_0 \left(\frac{p}{p_0}\right)^{(1-\gamma)/\gamma}, \tag{6}$$

where γ is the ratio of heat capacities at constant pressure and at constant volume, and is a constant equal to 1.4 for air, and T_0 and p_0 are the temperature and pressure at any reference height z_0.

If a parcel of air at height z_0 should undergo a displacement to a different height $z_0 + dz$ it may find itself surrounded by air at a different temperature and density from its own temperature and density. If it has not changed its density by the correct amount, it will not be in equilibrium and will rise or fall further (unstable), or will be pushed back to its initial height (stable). The amount its pressure has changed is given by Eq. (4′) and the amount its temperature has changed is then given by Eq. (6). The criterion for stability is

$$dT = \left(\frac{dT}{dz}\right)_0 dz = \left(\frac{dT}{dp}\right)_0 \left(\frac{dp}{dz}\right)_0 dz$$

$$= \left(\frac{dT}{dp}\right)_0 (-\rho_0 g)\, dz. \tag{7}$$

Using Eq. (6) and the ideal gas equation of state in the form

*The sense of the vector **g** is down, whereas z is positive upward.

$$\rho_0 = \frac{p_0}{C_p\left(\frac{1-\gamma}{\gamma}\right)T_0}, \tag{8}$$

Equation (5) for the adiabatic lapse rate is obtained.

FOURIER ANALYSIS

Fourier analysis is the mathematical representation of functions as linear combinations of sine, cosine, or complex exponential harmonic components. Such representations take their name from Jean Baptiste Fourier (1768–1830), French mathematician and physicist, who used them extensively in developing a mathematical theory of heat conduction. They continue to be widely used in mathematical physics and engineering, finding application in the study of such diverse subjects as diffraction, diffusion, image formation, spectroscopy, electrical networks, x-ray crystallography, and the theory of probability.

Fourier Series Let $f(x)$ be a periodic function with period L, i.e., $f(x)$ satisfies

$$f(x) = f(x - L) \tag{1}$$

for all x. For a wide class of such functions, we can represent $f(x)$ by an infinite summation of sine and cosine harmonic components

$$f(x) = a_0 + \sum_{n=1}^{\infty} a_n \cos\frac{2\pi nx}{L} + \sum_{n=1}^{\infty} b_n \sin\frac{2\pi nx}{L}, \tag{2}$$

known as the *Fourier series* representation of $f(x)$. If the left and right hand sides of Eq. (2) are multiplied by cos $2\pi mx/L$ or by sin $2\pi mx/L$, and the resulting equation is integrated with respect to x over one period L, the orthogonality of the harmonic sine and cosine components on this interval implies the following formulas for the *Fourier coefficients* a_0, a_n, b_n:

$$\begin{aligned} a_0 &= \frac{1}{L}\int_{-L/2}^{L/2} f(x)\,dx \\ a_n &= \frac{2}{L}\int_{-L/2}^{L/2} f(x)\cos\frac{2\pi nx}{L}\,dx \qquad n = 1, 2, \cdots \\ b_n &= \frac{2}{L}\int_{-L/2}^{L/2} f(x)\sin\frac{2\pi nx}{L}\,dx \qquad n = 1, 2, \cdots \end{aligned} \tag{3}$$

Other equivalent forms of the Fourier series can be obtained from Eq. (2). For example, $f(x)$ may be written

$$f(x) = a_0 + \sum_{n=1}^{\infty} C_n \cos\left(\frac{2\pi nx}{L} - \phi_n\right) \tag{4}$$

where

$$\begin{aligned} C_n &= \sqrt{a_n{}^2 + b_n{}^2} \\ \phi_n &= \tan^{-1}\frac{b_n}{a_n}. \end{aligned} \tag{5}$$

Another widely used representation is the exponential (or complex) form of the Fourier series,

$$f(x) = \sum_{n=-\infty}^{\infty} \alpha_n e^{i(2\pi nx/L)} \tag{6}$$

where

$$\alpha_n = \frac{1}{2}(a_n - ib_n) = \frac{1}{L}\int_{-L/2}^{L/2} f(x)e^{-i(2\pi nx/L)}\,dx. \tag{7}$$

For a real-valued $f(x)$, α_{+n} and α_{-n} are not independent, since $\alpha_{-n} = \alpha_{+n}{}^*$, where * indicates complex conjugate. However, when $f(x)$ is complex-valued, α_{+n} and α_{-n} are in general not related.

An important property of Fourier series, known as *Parseval's theorem*, states that the mean quadratic content of $f(x)$ (which often has the physical interpretation of average power) may be found by summing the squares of the Fourier coefficients. Thus, for the three representations used,

$$\frac{1}{L}\int_{-L/2}^{L/2} |f(x)|^2\,dx = \begin{cases} a_0{}^2 + \sum\limits_{n=1}^{\infty} \dfrac{a_n{}^2 + b_n{}^2}{2} \\ a_0{}^2 + \sum\limits_{n=1}^{\infty} \dfrac{C_n{}^2}{2} \\ \sum\limits_{n=-\infty}^{\infty} |\alpha_n|^2 \end{cases} \qquad (8)$$

No discussion of Fourier series would be complete without some mention of the conditions under which the series actually converge to the functions they are to represent. Conditions which are both necessary and sufficient are not known. However, for the series to converge to $f(x)$ at each point of continuity, it is known to be a sufficient condition that $f(x)$ have only a finite number of maxima and minima in the interval $-L/2 \leqslant x \leqslant L/2$. Under this same condition, at points of discontinuity of $f(x)$ the series converges to the arithmetic mean of the values of $f(x)$ immediately to the left and right of the discontinuity.

Fourier Integrals Just as a periodic function can be represented by the sum of harmonic components in a Fourier series, so too an aperiodic function may be represented by an integral over a continuous spectrum of complex-exponential components. In this case we write

$$f(x) = \int_{-\infty}^{\infty} F(\nu) e^{i2\pi\nu x}\, d\nu \qquad (9)$$

which is referred to as the *Fourier integral* representation of $f(x)$. Here $F(\nu)$, known as the *Fourier transform* (or Fourier spectrum) of $f(x)$, is given by

$$F(\nu) = \int_{-\infty}^{\infty} f(x) e^{-i2\pi\nu x}\, dx. \qquad (10)$$

The variable ν is generally referred to as the *frequency* variable.

Note that a simple expansion of the exponential in Eq. (10) yields $F(\nu)$ in terms of sine and cosine integrals,

$$F(\nu) = \int_{-\infty}^{\infty} f(x) \cos 2\pi\nu x\, dx - i\int_{-\infty}^{\infty} f(x) \sin 2\pi\nu x\, dx. \qquad (11)$$

If $f(x)$ is an even function of x, the sine integral vanishes, leaving $F(\nu)$ expressed as a *Fourier cosine integral*,

$$F(\nu) = 2\int_{0}^{\infty} f(x) \cos 2\pi\nu x\, dx. \qquad (12)$$

Other forms of the Fourier integral and Fourier transform are often found in the literature. For example, frequency ν is often replaced by angular frequency $\omega = 2\pi\nu$, in which case Eqs. (9) and (10) become

$$f(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} F(\omega) e^{i\omega x}\, d\omega$$

$$F(\omega) = \int_{-\infty}^{\infty} f(x) e^{-i\omega x}\, dx. \qquad (13)$$

Alternatively, the forms

$$f(x) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} F(\omega) e^{i\omega x}\, d\omega$$

$$F(\omega) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} f(x) e^{-i\omega x}\, dx \qquad (14)$$

are sometimes found. Here we shall continue to use the forms of equations (9) and (10).

As in the case of Fourier series, the Fourier integral representation will converge to $f(x)$ only for a certain class of functions. Convergence at points of continuity is assured if $f(x)$ satisfies the following set of sufficient conditions:

(i) $f(x)$ is absolutely integrable;
(ii) $f(x)$ has only a finite number of maxima and minima in any finite interval; and
(iii) $f(x)$ has no infinite discontinuities.

Under these conditions, at points of discontinuity of $f(x)$, the Fourier integral converges to the arithmetic mean of the values of $f(x)$ immediately to the left and right of the discontinuity. In general, any one of the above sufficient conditions can be slightly relaxed at the price of strengthening one or both of the additional conditions.

While the class of functions encompassed by the above conditions is wide, there do exist certain functions important in mathematical physics which are not included, such as $\sin x$, $\cos x$, and $f(x) = 1$. These may be included if the concept of the Dirac delta function, $\delta(\nu)$, is introduced, having the properties

$$\delta(\nu) = 0 \quad \nu \neq 0,$$

$$\int_{-\infty}^{\infty} \delta(\nu)\, d\nu = 1. \qquad (15)$$

Strictly speaking, $\delta(\nu)$ is not a function in the usual mathematical sense. However, it can be

TABLE 1. FOURIER TRANSFORM PAIRS

$f(x) = \exp(-\pi x^2)$	$F(\nu) = \exp(-\pi\nu^2)$
$f(x) = \begin{cases} 1 & \lvert x\rvert \leq \frac{1}{2} \\ 0 & \lvert x\rvert > \frac{1}{2} \end{cases}$	$F(\nu) = \dfrac{\sin \pi\nu}{\pi\nu}$
$f(x) = \begin{cases} 1 - \lvert x\rvert & \lvert x\rvert \leq 1 \\ 0 & \lvert x\rvert > 1 \end{cases}$	$F(\nu) = \left[\dfrac{\sin \pi\nu}{\pi\nu}\right]^2$
$f(x) = 1$	$F(\nu) = \delta(\nu)$
$f(x) = \cos \pi x$	$F(\nu) = \frac{1}{2}\,\delta(\nu - \frac{1}{2}) + \frac{1}{2}\,\delta(\nu + \frac{1}{2})$
$f(x) = \exp(i\pi x^2)$	$F(\nu) = \exp\left[-i\pi(\nu^2 - \frac{1}{4})\right]$
$f(x) = \sum\limits_{n=-\infty}^{\infty} \delta(x - n)$	$F(\nu) = \sum\limits_{m=-\infty}^{\infty} \delta(\nu - m)$

treated rigorously using the theory of distributions.

In Table 1 are presented the Fourier transforms of a number of the more important functions encountered in mathematical physics and engineering. From the basic Fourier transform pairs listed in the table, many other pairs may be derived with the help of the following Fourier transform theorems.

Linearity: If $f(x) = a\ g(x) + b\ h(x)$, then $F(\nu) = a\ G(\nu) + b\ H(\nu)$, where $G(\nu)$ and $H(\nu)$ are the Fourier transforms of $g(x)$ and $h(x)$, respectively.

Similarity: If $f(x) = g(ax)$, then $F(\nu) = (1/|a|)G(\nu/a)$.

Shift: If $f(x) = g(x - a)$, then $F(\nu) = G(\nu) \exp(-i2\pi a\nu)$.

Convolution: If $f(x) = \int_{-\infty}^{\infty} g(\xi)h(x - \xi)\,d\xi$, then $F(\nu) = G(\nu)H(\nu)$.

A relation entirely analogous to Parseval's theorem of Fourier series is *Plancherel's* theorem,

$$\int_{-\infty}^{\infty} |f(x)|^2\,dx = \int_{-\infty}^{\infty} |F(\nu)|^2\,d\nu. \quad (16)$$

In many physical applications this theorem leads to the interpretation of $|F(\nu)|^2$ as the energy spectrum of the function $f(x)$.

The Fourier integral representation (and the Fourier series representation) can be generalized to apply to functions of two or more independent variables. Most important are functions defined over a plane or over three-dimensional space. In the case of two independent variables we have

$$f(x,y) = \iint_{-\infty}^{\infty} F(\nu_X, \nu_Y) \cdot \exp\left[i2\pi(\nu_X x + \nu_Y y)\right]\,d\nu_X d\nu_Y$$

$$F(\nu_X, \nu_Y) = \iint_{-\infty}^{\infty} f(x,y) \cdot \exp\left[-i2\pi(\nu_X x + \nu_Y y)\right]\,dx dy. \quad (17)$$

For the most part, the properties of one-dimensional Fourier transforms carry over directly to the N-dimensional case. There is extra richness in the theory for the multidimensional case, however. For example, if $f(x,y)$ exhibits circular symmetry, i.e., is a function of only radius r in the plane, then Eqs. (17) can be reduced to the form of the so-called *Fourier-Bessel transform* (or Hankel transform of zero order),

$$f(r) = 2\pi \int_0^{\infty} \rho F(\rho) J_0(2\pi r\rho)\,d\rho$$

$$F(\rho) = 2\pi \int_0^{\infty} r f(r) J_0(2\pi r\rho)\,dr \quad (18)$$

where $r = (x^2 + y^2)^{1/2}$, $\rho = (\nu_X{}^2 + \nu_Y{}^2)^{1/2}$, and J_0 is a Bessel function of the first kind, zero order.

Discrete Fourier Transforms Of particular importance in the analysis of experimental data is the *discrete Fourier transform* (DFT), which is readily implemented on a digital computer. Let $f(x)$ be a function of finite duration (i.e., $f(x)$ is zero outside the range $0 < x < 2X$), and suppose that the bandwidth of $f(x)$ is limited to the approximate range $-B < \nu < B$. Let $f(x)$

be sampled with spacing $1/2B$ between samples, and define f_n to be equal to $(1/2B)f(n/2B)$. The number of such samples is $N = 4BX$. Then the DFT of the sampled data set f_n $(n = 0, 1, \ldots, N - 1)$ is defined by

$$F_m = \sum_{n=0}^{N-1} f_n \exp\left(-i2\pi \frac{mn}{N}\right), \qquad m = 0, 1, \ldots, N - 1. \tag{19}$$

The corresponding inverse discrete Fourier transform relation is

$$f_n = \frac{1}{N} \sum_{m=0}^{N-1} F_m \exp\left(i2\pi \frac{mn}{N}\right). \tag{20}$$

The relation between the resulting coefficients F_m calculated by Eq. (19) and the desired samples of the continuous Fourier transform $F(\nu)$ is relatively complex, but can be stated explicitly as

$$F_m = \sum_{k=-\infty}^{\infty} F[(m - kN)/2X].$$

In the event that there is little energy in the spectrum of $f(x)$ outside the interval $-B < \nu < B$, as supposed at the start, then to a good approximation F_m is equal to sampled values of the continuous spectrum $F(\nu)$. For indices in the range $m = 0, 1, \ldots, (N/2) - 1$, $F_m = F(m/2X)$ (these are the "positive-frequency" components of $f(x)$), while for indices in the range $m = (N/2) + 1, \ldots, N - 1$, $F_m = F((m - N)/2X)$ (these are the "negative frequency" components of $f(x)$).

The DFT can be computed very rapidly using a digital computer with the help of so-called *fast Fourier transform algorithms*. Note that a brute-force calculation of any single coefficient F_m of the DFT would require N complex multiply-and-adds, one for each term in the summation. (We refer to each complex multiply-and-add as an "operation.") Since there are N such coefficients, the total number of operations required would be N^2. When N is a power of 2, a reorganization of the order in which computations are performed allows the total number of operations to be reduced to $N \log_2 N$. The savings in computation time can be enormous for large N, and it can be said that the discovery of fast Fourier transform algorithms has made possible the widespread use of Fourier analysis in modern computational physics.

Applications The applications of Fourier analysis are so widespread throughout physics and engineering that to summarize them adequately in a brief space is nearly impossible. At best we can only outline some of the most important classes of applications, illustrating with a simple mention some of the particular branches of science that benefit from Fourier analysis in each case.

The applications of Fourier analysis can be conveniently divided into two major categories. Within the first category we find Fourier analysis used purely as an analytical tool, for the calculation and prediction of the results of experiments not yet performed, or for the explanation of experimental results already obtained. For example, in certain important cases the wave amplitude produced by a diffracting structure may be calculated using Fourier transforms, a consequence of the fact that the complete diffraction integrals may be reduced to Fourier transforms.

As a second example of this category, it might be desired to predict the image obtained when a certain object is viewed through an imaging system. The characteristics of such a system are often most easily specified in terms of its effects on spatial sine wave objects of various spatial frequencies. To predict the image obtained for a nonsinusoidal object, that object may be decomposed, by means of a Fourier integral, into sine wave (or complex exponential) components. The image is then found by synthesizing, again with a Fourier integral, the various sine wave image components, after their amplitudes and phases have been modified by the known properties of the imaging system. A similar approach is used in the analysis of linear, time-invariant electrical networks. It can also be used to calculate the diffusion of heat through a conducting plate when a known temperature distribution is impressed across one edge of the plate.

A second major category of applications utilizes Fourier analysis as an experimental tool, applied to experimental data to derive related physical information. For example, in Fourier spectroscopy the interferogram obtained from a scanned Michelson interferometer may be Fourier-analyzed to yield the spectral intensity distribution of the radiation source. In x-ray crystallography, the x-ray diffraction pattern produced by a crystal may be Fourier-analyzed to yield information about the crystal lattice structure. In radio astronomy the correlation coefficients produced when the signals collected by various elements of an array are cross-correlated may be Fourier-analyzed to yield a map of the radio brightness distribution of the sky. In all of these latter examples, Fourier analysis plays a fundamental role in transforming data which are readily collected by experiment into data which are more directly related to the physical properties of interest.

FOURIER OPTICS

Diffraction Theory The articles OPTICS, GEOMETRICAL and OPTICS, GEOMETRICAL ADVANCED are based on the approximation that light is propagated as rays. For systems whose dimensions are of the magnitude of the wavelength of light, we must take into account its wave nature. A simple examle is the rectangular slit of Fig. 1, whose width w is about equal to the wavelength λ. Consider a plane wave striking this slit normally. Some energy from this wave will be absorbed and reradiated by the edges of the slit; the interaction of the initial and reradiated waves produces a change in direction, which we call *diffraction*.

The phenomenon of diffraction can be expressed quantitatively by using the fact that waves are specified in terms of sines or cosines; for mathematical convenience, we shall use the equivalent function $\exp(ikr)$, where r is the displacement along the wave. Since the wave is periodic, its amplitude at $r = 0$ and $r = \lambda$ is unchanged. Hence, $\exp(ik\lambda) = 1$, $k\lambda = 2\pi$, or

$$k = 2\pi/\lambda \tag{1}$$

gives the defining equation for the propagation constant k. To find the amplitude A that this diffraction wave has on a screen at some arbitrary distance to the right, we integrate over the area S of the slit, obtaining

$$A = C \int e^{ikr}\, dS \tag{2}$$

where C is the constant involving the maximum strength of the wave and dimensionality factors. As Fig. 1 shows, $r = r_0 + x \sin\theta$; taking $dS = l\,dx$, and integrating from $-w/2$ to $w/2$, we obtain

$$A = Ce^{ikr_0} l \, \frac{\sin[(kw \sin\theta)/2]}{k \sin\theta}. \tag{3}$$

But since we are interested in the intensity I, which is the square of the amplitude, we find that

$$\frac{I}{I_0} = \frac{\sin^2 \alpha}{\alpha^2} \tag{4}$$

where $\alpha = \frac{1}{2} kw \sin\theta$, and I_0 incorporates all the constants.[1]

The function $(\sin^2 \alpha)/\alpha^2$ (which is the square of what is sometimes called the sampling function) is shown in Fig. 2; the alternate light and dark bands are the *Fraunhofer diffraction pattern* for a long, thin slit.

A similar calculation[1] for a circular aperture of radius R gives the expression

$$\frac{I}{I_0} = \left(\frac{2J_1(\rho)}{\rho}\right)^2 \tag{5}$$

where $\rho = kR \sin\theta$ and J_1 is a well-known Bessel function. Tabulated values gives the plot of Fig. 3, which is qualitatively similar to Fig. 2.

The bright central spot, the *Airy disk*, contains about 84% of the energy which passes through the aperture. Its periphery corresponds to the first zero of $J_1(\rho)$, for which $\rho = 3.832$. The angle is then given by

$$\sin\theta = \rho/kR$$

or, approximately,

$$\theta = 3.83\lambda/2\pi R = 1.22\lambda/D. \tag{6}$$

This formula indicates the angular resolving power of a lens of diameter D, showing that Fraunhofer diffraction imposes a fundamental limit. The same result applies to the problem of resolving two separate points; if their Airy disks overlap in the fashion indicated by Fig. 4, they are considered to be just distinguishable; this is the famous *Rayleigh criterion*.

It is possible to improve on this limit by putting more of the radiant energy into the central spot. This is done by *apodization* (from the Greek "without feet," which refers to the reduction of the side lobes in Figs. 2 or 3). The method involves placing a nonuniformly transmitting plate in front of the lens. For example, let a coating of the form

$$A(x) = \cos(\pi x/w)$$

be used with the slit of Fig. 1. This additional term inside the integral of (2) will lead to a transmission curve as shown in Fig. 5. The central bright line is now wider and more intense.

Spatial Filtering We next consider the diffraction process for a series of N slifts of width w with a uniform spacing d (Fig. 6); such a structure is called a *Ronchi diffraction grating*.

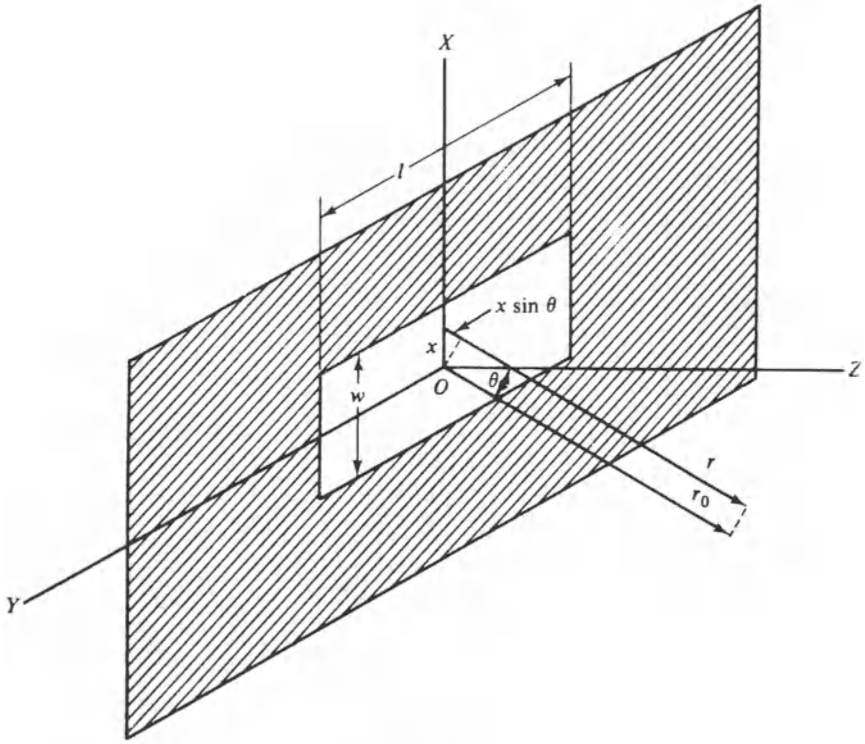

FIG. 1.

The integral in Eq. (2) is generalized to a sum of N integrals, one for each slit, and the result of the combined summation and integration is

$$\frac{I}{I_0} = \left(\frac{\sin \alpha}{\alpha}\right)^2 \left(\frac{\sin N\gamma}{N \sin \gamma}\right)^2 \tag{7}$$

where $\gamma = \frac{1}{2} kd \sin \theta$. The first term on the right is like Eq. (4), and comprises the *shape factor*, representing the contribution of the N identical slits to the pattern. The other term is the *grating factor*, and indicates the effect of repeating the slits. Figure 7 shows the shape factor as a

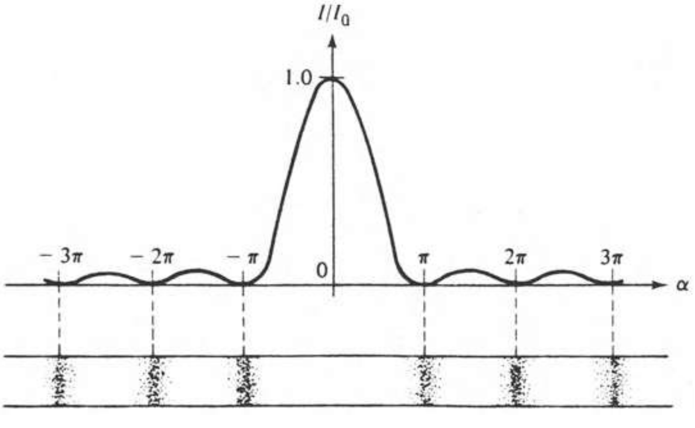

FIG. 2.

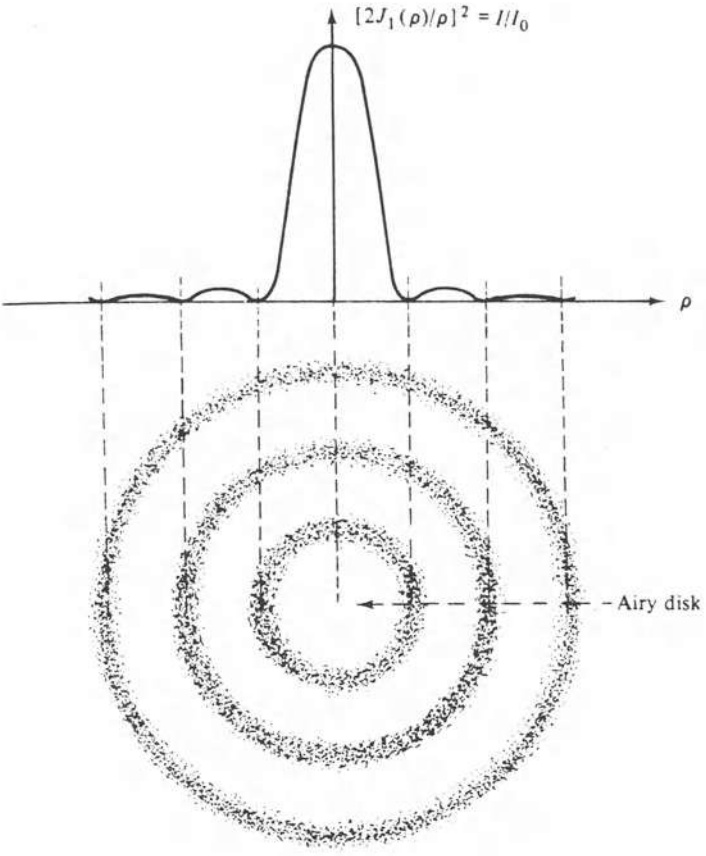

FIG. 3.

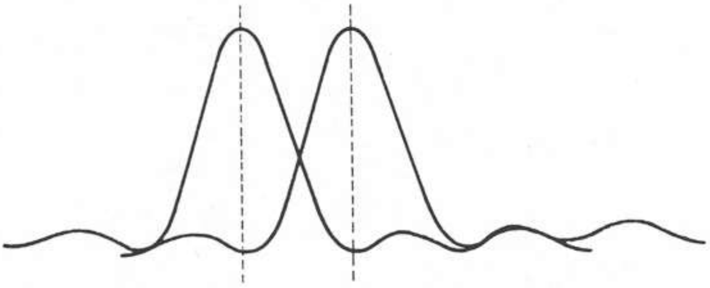

FIG. 4.

dotted envelope for the complete pattern; note how raising N from 5 to 20 (or higher) sharpens the bright lines forming the diffraction pattern. The pattern we show here is found in connection with other physical phenomena as well; electron and X-ray diffraction are examples (see discussion in DIFFRACTION BY MATTER AND DIFFRACTION GRATINGS).

The application we wish to consider involves the combination of a grating and a lens (Fig. 8a). There will be the usual image of the grating (Fig. 8b) at the place specified by the Gaussian lens equation (see OPTICS, GEOMETRICAL). In addition, the diffracted beams corresponding to $\gamma = 0, \pm\pi$ in Fig. 7, or to $\theta_0 = 0, \theta_1 = \lambda/d, \theta_{-1} = -\lambda/d$ (the zero and first order beams) are shown

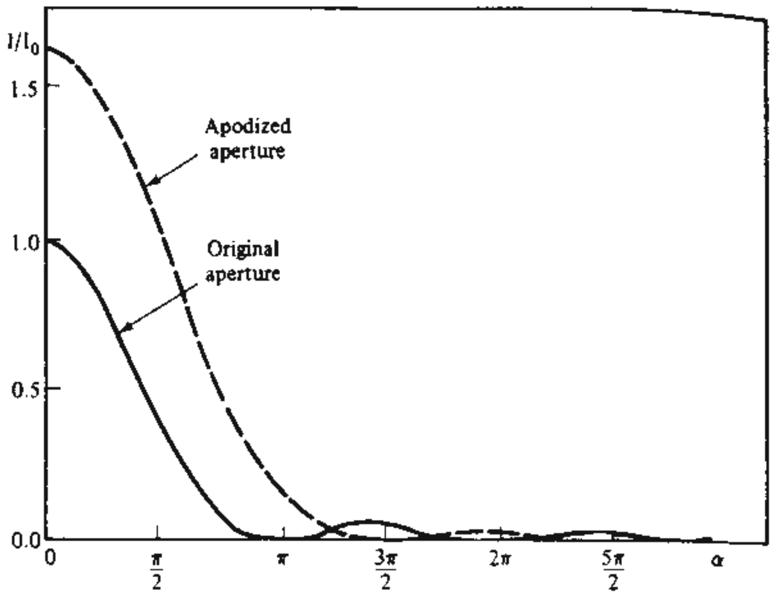

FIG. 5.

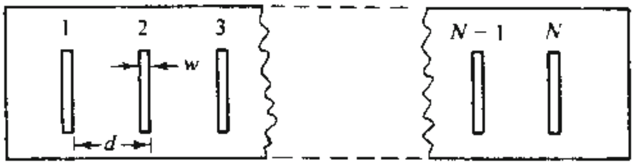

FIG. 6.

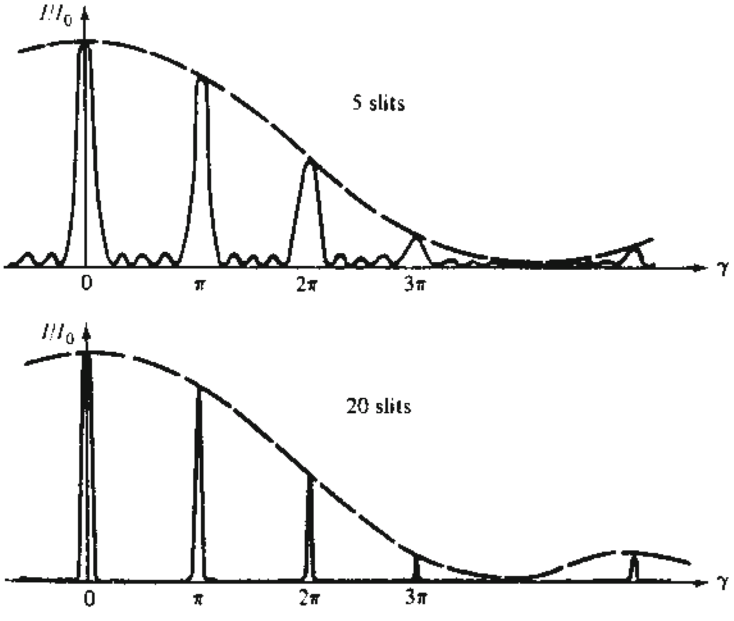

FIG. 7.

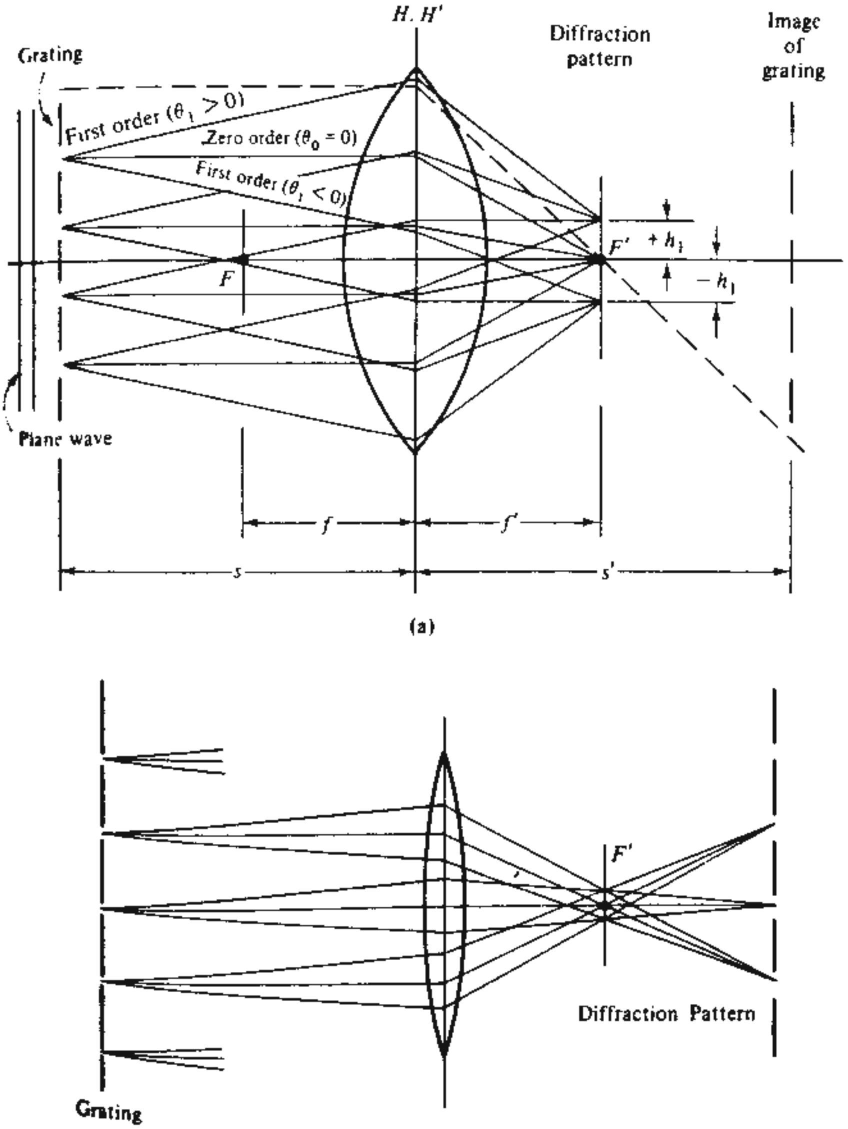

(a)

(b)

FIG. 8.

in detail in Fig. 8a. It is quite clear that the parallel zero-order beams will meet at the focal point F'. It can easily be shown by using the paraxial matrices of OPTICS, GEOMETRICAL, ADVANCED, that a set of rays which are parallel to themselves but not to the lens axis (such as the four for $\theta_1 > 0$) will meet on the plane through F' but off-axis.

Now we place an opaque aperture at F' which blocks all diffraction orders except for θ_0; this is the process of *spatial filtering*. If we think of the transmission properties of the grating as being specified by the square wave of Fig. 9a, this is equivalent to removing the high frequency components of the Fourier series representing the wave and the result is Fig. 9b; i.e., the sharp corners of the image have been rounded or smoothed. This procedure could be applied in principle to satellite photographs, which are composed of strips; low-pass spatial filtering will remove the sharp boundaries. The converse situation—an opaque disk at F'—will then give high-pass spatial filtering (Fig. 9c), and one application could be to improve the readability

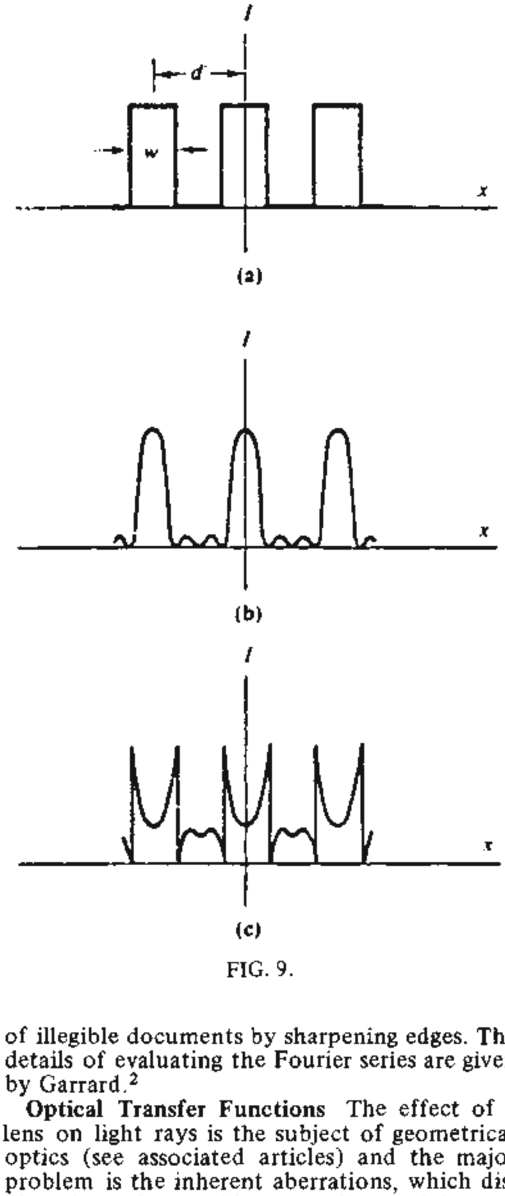

FIG. 9.

of illegible documents by sharpening edges. The details of evaluating the Fourier series are given by Garrard.[2]

Optical Transfer Functions The effect of a lens on light rays is the subject of geometrical optics (see associated articles) and the major problem is the inherent aberrations, which display themselves as blurry or distorted images. Light treated as waves brings in additional problems. The first of these is a direct consequence of Eq. (6), which indicates that the finite diameter of any optical system imposes a limit on its ability to resolve closely spaced objects. It is customary to use a test object in the form of alternate black and white bars; the resolution is expressed in terms of the largest number of line-pairs/mm that can be distinguished at the image plane. The other limitation is imposed by the ability to distinguish bars from spaces, i.e., the image contrast.

Both resolution and contrast are affected by the fact that when a light wave passes through a lens of variable thickness from center to edge, the time of transit varies with distance travelled in the glass, causing a shift in the phase of the wave from one part to another. This shift simply contributes an additional term in the exponent of the diffraction integral (2), where it has an effect analogous to the apodization mentioned above. It can be shown[1] with some elementary geometry and some very formidable algebra that the phase shift due to a spherical lens has a quadratic dependence on the x and y coordinates but that by positioning object and image so that they obey the Gaussian lens equation, this dependence reduces to a linear one. It will then be recognized that the diffraction integral (2), involving an exponential term of the form $\exp\,[(ik(x+y)]$, is generating a two-dimensional Fourier transform of the remaining factors inside that integral, these factors specifying the nature of the incoming wave. Thus, a lens is a device which performs a Fourier transform on an object, and also forms an image. We have already seen an example of this in Fig. 8; the Fourier transform of a periodic object, the grating, reduces to a discrete Fourier series, the result being located at the focal plane.

Fourier transform methods are used in science and engineering to solve the differential equations associated with transient phenomena; they give a way of computing the response of a circuit to an electrical impulse, for example. This response is identified as the admittance (the reciprocal of the impedance) and it is also called the transfer function. The optical equivalent of an impulse is a point source and the response is the *optical transfer function*. Like admittance or impedance, it will depend on frequency, but this is measured in line pairs/mm and is known as the *spatial frequency* ν_x. It is possible to calculate the dependence of the transfer function I on spatial frequency, with results as shown in Fig. 10. As already predicted, there is a maximum value ν_{x0} of ν_x beyond which the resolution vanishes. The curves shown represent the situation for a perfect lens; the presence of aberrations will

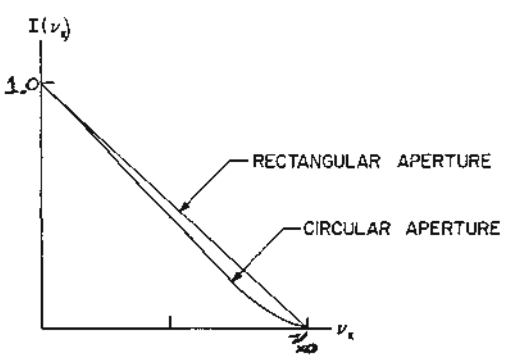

FIG. 10.

degrade these results. In addition, the transfer function can be shown to depend as well on the relative contrast of object and image and predict how this aspect of image quality decays with increasing spatial frequency.

FREQUENCY STANDARDS

Introduction A frequency standard is simply an oscillator whose characteristics of either frequency stability or accuracy satisfy certain subjective performance criteria. Such a device is approximately characterized by its nominal frequency and nominal amplitude of oscillation. But noise and systematic effects cause the actual frequency and amplitude of operation to differ from nominal. The level of the noise-induced frequency deviations is characterized by the quality called *frequency stability*, while the ability of the oscillator to achieve a predetermined frequency without calibration is called *accuracy*. Both quantities are usually stated on a fractional basis, $\Delta f/f_0$, where f_0 is the minimal operating frequency. Although oscillators cover the entire range of frequency stabilities smaller than 10^{-2}, for the purpose of this article frequency standards are considered to cover the range of stabilities smaller than 10^{-6}. Their size and weight can range anywhere from 10 cc and 50 gms to 1000 liters and 100 kilograms.

Nearly single frequency oscillation results from the use of a frequency selective element called a *resonator*. Two types of circuitry are used to produce a voltage output. An active oscillator is constructed by combining the resonator with an amplifier and a limiter in a feedback loop. However, it is sometimes desirable to obtain the characteristics of more than one resonator in a frequency standard. This is accomplished by using an active oscillator of the type just described to probe a second resonator. Feedback maintains the frequency of the active oscillator equal to the nominal center frequency of the second resonator.

The range of frequency stability from 10^{-6} to 10^{-9} is generally important for frequency control applications, such as maintaining broadcast transmitters and receivers within allocated frequency bands or providing signals for laboratory equipment such as counters and spectrum analyzers. The most commonly used device for such applications is the quartz crystal oscillator. Other applications require timekeeping in addition to frequency control. Precise navigation on earth, navigation in space very far from the earth, and certain digital communications applications require much greater performance than may be obtained with quartz crystal oscillators. These more stringent requirements are generally provided by atomic or molecular frequency standards called ATOMIC CLOCKS. In addition, scientists require a very precise and accurate frequency standards for applications such as precision spectroscopy and the measurement of relativistic effects. These special applications make use of a wide variety of frequency standards including those mentioned above, but also including such unusual devices as superconducting cavity stabilized oscillators, saturated absorption stabilized lasers, or even the Mössbauer effect.

Operating Principles For frequency standard applications, the most critical parameter of the resonator is its *relative linewidth*. The *loaded Q* of the resonator is the most commonly used figure of merit. It is equal to the total stored energy divided by the energy dissipated in one cycle of the oscillation and is inversely proportional to the linewidth. Quartz crystals have Q's as high as a few million. Superconducting cavities operating at microwave frequencies may have Q's as high as 10^{11}, and atomic resonances suitable for use in frequency standards today have Q's ranging from 10^7 to 10^{12}. A fundamental limitation on a frequency stability of the device is determined from the Q and signal-to-noise-ratio, S/N: The stability cannot be better than $(1/Q)(S/N)$.

There are many different types of noise sources. For quartz crystal oscillators, the fundamental sources are *thermal (Johnson) noise* which is associated with the dissipation of energy in real resistors and *shot noise* which is associated with the discrete nature of the charge carriers in the electrical circuitry. Since the frequency of the atomic standard is derived from the observation of a small number of atoms or molecules, frequency instabilities are observed which derive directly from the probabilistic nature of quantum mechanics.

Noise affects the performance in two distinct ways. First there is noise in the amplifiers which buffer or isolate the frequency standard from the user. Thermal or shot noise in these amplifiers adds to the output signal. The resultant frequency fluctuations have a low pass characteristic, i.e., they become smaller at higher frequencies. There are also noise sources within the feedback loop of the standard which do not simply add to the output signal, but perturb the frequency of the oscillator directly.

In this case a white voltage noise source produces white frequency fluctuations.

Accuracy is a property of atomic frequency standards. High accuracy is obtained by minimizing perturbations on the atomic system due to collisions with other atoms, interaction with electric and magnetic fields, and the effect of the velocity of the atoms themselves. For example, the definition of the second is 9,192,631,770 oscillations of the radiation from the cesium 133 atom in its ground state. The term *ground state* refers to the lowest energy state of an atom which is at rest in a field-free region of space. All present-day atomic frequency standards actually observe atoms in thermal equilibrium with their surroundings and therefore moving at velocities on the order of 100 m/s. From the point of view of the observer, the frequency emitted by such atoms is perturbed by two effects. The *first-order Doppler effect* is proportional to the velocity vector of the atom. It is analogous to the change in pitch of a train whistle passing a stationary observer. The *second-order Doppler effect*, so called because it is proportional to the square of the velocity, is a relativistic effect resulting from the property of time dilation. A radiating atom in motion behaves like a clock and according to the special theory of relativity, runs slow compared to a stationary clock.

One might think that the ideal frequency standard would combine the best characteristics described above. It would have as high a Q as possible, very small interactions, very small velocity for the atoms and a very high signal-to-noise ratio. However, these characteristics are inconsistent. For example, in an atomic standard, high signal-to-noise ratio generally means observing large numbers of atoms which in turn implies frequent atomic collisions and substantial interactions. The required compromises have resulted in the development of a wide variety of different frequency standards emphasizing different aspects of performance: accuracy, stability, size, weight, power, reliability, and cost.

Quartz Crystal Oscillators A quartz resonator is fabricated from a thin slice of material cut from a commerical or naturally grown quartz crystal. Since the material is piezoelectric, an acoustic vibration results in an electric potential between the two faces of the crystal. Coupling is provided by depositing thin film metal electrodes on the two faces of the crystal. To a first-order approximation the crystal acts like an electrical resonator composed of an inductor, capacitor, and resistor and is used by installing it in a standard oscillator circuit.

The center frequency of the resonance is determined from the dimensions of the resonator and is therefore inherently very sensitive to temperature. Frequency standard operation therefore requires some means of temperature compensation or control. At the 10^{-6} stability level, temperature compensation is the technique most often used. The circiut of the oscillator is modified by adding a second temperature sensitive element such as a thermistor which compensates for the temperature dependence of the resonator. Such devices can achieve frequency stability of 10^{-6} over wide temperature ranges and are both small and inexpensive, finding wide application in communications, radio, and television.

When higher precision is required, compensation is usually abandoned in favor of temperature control. The frequency of the resonator is a cubic function of the temperature, and there are two temperatures called the *turnover points* at which the frequency variation with temperature is zero. The crystal is placed in an oven and operated very near one of the turnover points. The stability of oscillators containing ovenized crystals varies between approximately 10^{-9} to 10^{-12} for one-second averages and the aging rate typically varies between 10^{-10} and 10^{-11} per day. Typical applications include high-quality laboratory instrumentation such as frequency counters and clocks for space vehicles which stress the small size, low power, and high reliability of quartz crystal oscillators.

Atomic Frequency Standards The change in state of an atom or molecule between two of its discrete energy levels is a resonance which may be used in a frequency standard. The frequency associated with the transition is the energy difference divided by Planck's constant. It is generally not convenient or practical to use most of the allowed transitions between energy states of an atom because the frequencies are usually too high for coherent signal processing techniques or because the transitions are extremely sensitive to either electric or magnetic fields. Consider a simple atom having a single unpaired electron such as hydrogen or any of the alkalai metals. The frequency corresponding to the transition of the electron between two of its discrete energy levels is typically in the ultraviolet or visible portion of the spectrum and therefore the atom must be used in its ground electronic state. If the electron has an asymmetric orbit, then it will have an associated magnetic moment which can interact with the magnetic moment of the nucleus. This interaction separates the ground state into several energy levels called *fine structure*. However, the transition frequencies are usually in the infrared, still too high for practical applications. If the electron is in a symmetric orbit then it has no orbital angular momentum but it still has a magnetic moment due to its spin. The interaction of this magnetic moment with the magnetic moment of a nucleus produces a set of energy levels called *hyperfine structure* which are typically at microwave frequencies. Transitions between such energy levels form the basis for all commercially available atomic clocks. Not until practical methods of frequency synthesis are developed for frequencies higher than 100 GHz will atomic clocks be used extensively in that range. Nevertheless, various laser techniques are used today at quite high frequencies as standards for atomic and molecular spectroscopy and length.

Conventional electronic or acoustic resonances are observed through the frequency selective nature of their power absorption. When coupled to an amplifier they can be used to provide frequency selective gain. The analogous situation holds for atomic resonances provided that an ensemble of atoms can be produced in one of the two energy states of the desired transition. In the case of hyperfine spectroscopy, the upper and lower energy states have very nearly equal populations, since their separation is very small compared to the thermal kinetic energy of the atoms. Microwave frequency standards generally employ either magnetic or optical state selection to create imbalance in the state populations.

Magnetic state selection depends upon the fact that the two hyperfine energy levels behave very differently in a strong magnetic field whose effect on the electron is larger than the electron's interaction with the nuclear magnetic moment. In an inhomogeneous magnetic field, the atoms feel a force proportional to the field gradient and the atoms in one state are deflected oppositely from the atoms in the other state. By intercepting one state while allowing the other to pass through an aperture, an atomic beam composed of atoms in the desired state is obtained.

Alternatively, optical state selection is accomplished by inducing a transition to a higher electronic energy level from which the atom decays spontaneously to the ground state. The light source must be narrower than the separation between the upper and lower ground-state hyperfine levels. Atoms induced to make transitions out of one hyperfine level to an excited state relax back to the two ground-state hyperfine levels in nearly equal proportions. Thus the hyperfine level to which the light source is tuned is depopulated.

The lifetime of the hyperfine transition is extremely long compared to the maximum length of time the atom could be observed in a practical spectrometer. However, without taking suitable precautions the observer will detect only a very broad line due to the Doppler shifts from many atoms traveling in random directions. Various techniques are used to eliminate the first-order Doppler effect. For example, in an atomic beam spectrometer the microwave radiation is applied to the atoms perpendicular to the mean velocity vector of the atomic beam and is reflected back upon itself. The net effect is to reduce the observed width of an atomic resonance to a value equal to the inverse of the observation time.

The operation of a cesium beam frequency standard illustrates all the aspects of the atomic beam frequency standard. The atomic transition used is the hyperfine transition in the ground state. This transition has a very small dependence on electric fields and is independent of magnetic field to first order at zero applied field. The atomic beam is formed by placing the cesium metal in an oven with a small exit hole. Cesium metal melts at 37°C, making it very easy to form an atomic beam of reasonable density. The desired hyperfine level is selected by passing the beam through the inhomogeneous magnetic field of a dipole magnet which deflects the desired atoms through a region containing a microwave cavity. A microwave field at the transition frequency of 9.2 GHz stimulates a change in atomic state which is analyzed by a second region of inhomogeneous magnetic field. The number of cesium atoms which make the transition between the two hyperfine levels is measured using a hot wire detector which ionizes the cesium atoms that successfully passed through the spectrometer. The microwave signal applied to the spectrometer is swept slowly back and forth across the resonance while the atom flux is measured. The signal is maximum when the frequency of the applied microwave field is equal to the frequency of the atomic transition. Electronic circuitry provides a correction signal which is used to maintain the average frequency of the microwave oscillator at the center of the atomic transition.

Commercial cesium standards have frequency stabilities which vary between six parts in 10^{13} and six parts in 10^{12} for observation periods of 100 s and the frequency stability improves inversely as the square root of the observation time. The best stabilities for cesium beam frequency standards generally vary between a few parts in 10^{14} and one part in 10^{13}. Laboratory cesium standards, called *primary cesium standards*, are constructed in such a way that the systematic effects which perturb the atomic resonance frequency may be measured very precisely. As a result, they are accurate and reproducible to a few parts in 10^{14}. Accuracy is limited principally by the ability experimentally to determine the residual first-order Doppler shift, although several other affects such as the relativistic time dilation, the effect of electric fields and the stability and homogeneity of the magnetic field also contribute to the inaccuracy. Fundamental advances in the accuracy of atomic frequency standards will probably come from devices which more nearly observe atoms at rest in free space.

FRICTION

Introduction Friction is the resistance to motion which exists when a solid object is moved tangentially with respect to the surface of another which it touches, or when an attempt is made to produce such motion. Friction thus takes its place as one of the general systems of force which are considered in MECHANICS (others being GRAVITY, ELASTICITY, etc.). Unfortunately friction depends to a marked extent on the material properties of the contacting surfaces, and even more importantly, on any surface contaminants which may be present, so that it is very difficult to estimate values of the friction force theoretically, with an uncertainty of less than about 20 per cent. In many calculations in solid mechanics, this uncertainty in the friction constitutes the limiting factor in determining the accuracy of the over-all calculation.

The friction force arises from the fact that, when two solids are pressed together, bonding between their surface atoms occurs, and these bonds have to be broken before sliding can commence. Bonding of any considerable strength occurs only in places where the surface atoms come within range of each other's strong force-fields (i.e., closer than about 3×10^{-10} m); thus, when ordinary solids with appreciable roughness are used, bonding is confined to a few small patches (called junctions) over their interface, where the high spots (or asperities) of one material have made contact with asperities on the other material.

The energy used up in the friction process appears almost entirely in the form of heat. Generally this consists of a moderate temperature rise over the contacting bodies, and superposed on this there are higher "flash temperatures" at the junctions. At high sliding speeds, softening or even melting of the tips of the asperities may occur.

In addition to the bonding or "adhesion" effect, which is the principal cause of friction, there are four other mechanisms which use up energy during sliding; energy which must be supplied by the friction force. These mechanisms are:

(1) A roughness effect, caused by the interlocking of asperities and the need to lift one surface over the high spots of the other;

(2) A ploughing effect, whereby an asperity on a hard material can dig a groove in a softer material;

(3) A hysteresis effect, whereby there is elastic and plastic deformation of the material at or near the junctions, and not all the deformation energy is recoverable;

(4) An electrostatic effect (with electric insulators), where work must be done to separate electrically charged regions on the sliding surfaces.

In a great majority of applications these four mechanisms do not account for as much as 20 percent of the total resistance to sliding. The widely held belief that friction is due mainly to a roughness effect does not find experimental support. Cleaved mica (smooth to an atomic scale) shows very high friction.

Laws of Friction If a normal load L presses two surfaces together, then we may apply a tangential force up to some limiting value F_s, and the surfaces will remain at rest. Sliding occurs when the tangential force exceeds the static friction force F_s, and almost as soon as motion starts the tangential force takes on a characteristic value, F_k, and always acts in a direction opposite to the relative velocity of the surfaces. F_s is often some 30 per cent larger than F_k, but sometimes they are equal.

The ratio F_s/L is the static friction coefficient f_s(or μ_s), while the ratio F_k/L is the kinetic friction coefficient f_k. We may cite quite general statements, or "laws," involving these coefficients of friction. The three classical laws, dating back to the seventeenth and eighteenth centuries, are:

(1) The friction coefficient is independent of the load.

(2) The friction coefficient is independent of the contact area.

(3) The kinetic friction coefficient is independent of the sliding velocity.

More recently, it has been found possible to make another general statement about the friction coefficient:

(4) The friction coefficient is independent of the surface roughness.

We may summarise these laws in the comprehensive statement.

(5) The friction coefficient is essentially a material property of the contacting surfaces, and of the contaminants and other films at their interface.

Although in practice these "laws" are reasonably well obeyed, there are often systematic divergencies, some of which have important consequences. In the rare cases in which the friction coefficient varies with load, it is often because of some special effect (e.g., a surface coating which is broken up at heavy loads); however, materials with a high elastic limit (e.g., polymers) generally show a friction coefficient which goes down somewhat as the load is increased. The fourth law applies closely to the intermediate ranges of surface roughness, but it is found that very smooth surfaces have higher friction because they tend to seize, and very rough surfaces have higher friction because of asperity interlocking.

Velocity and Time Effects in Sliding Violations of the third friction law are important because they can lead to friction-induced oscillations. With some materials f_k is almost independent of velocity over a very wide range; however, with hard materials the friction generally goes down as the speed goes up (a so-

TABLE 1. COEFFICIENTS OF FRICTION

Materials	Surface Conditions	f_s	f_k
Metals on metals (e.g. steel on steel, copper on aluminum)	Carefully cleaned	0.4–2.0	0.3–1.0
	Unlubricated, but not cleaned	0.2–0.4	0.15–0.3
	Well lubricated	0.05–0.12	0.05–0.12
Nonmetals on nonmetals (e.g., leather on wood, rubber on concrete)	Unlubricated	0.4–0.9	0.3–0.8
	Well lubricated	0.1–0.2	0.1–0.15
Metals on nonmetals	Unlubricated	0.4–0.6	0.3–0.5
	Well lubricated	0.05–0.12	0.05–0.12

called negative characteristic), while soft materials show a negative characteristic at high sliding speeds and a positive characteristic at low sliding speeds. Often, f_k changes by about 10 per cent during a factor-of-ten change of velocity. In a sliding system which has elastic compliance, a negative characteristic introduces an instability, and at high speeds this takes the form of harmonic oscillations (e.g., a violin string), while at low speeds relaxation oscillations occur (e.g., a creaking door). The relaxation oscillations are usually referred to as stick-slip, because during a part of each cycle the surfaces are at rest. The severity of the stick-slip is enhanced because, while the surfaces are at rest, f_s increases somewhat with time of stick (about 10 per cent for every factor-of-ten increase in time of stick above 10^{-3} seconds).

Value of the Friction Coefficient In most situations the total real area of contact, or sum of all the asperities, is produced by plastic deformation of the asperities, and if we assume that strong bonds are formed joining the materials across the interface we find that the friction coefficient is given by

$$f = s/p$$

where s is the plastic shear stress, and p the plastic indentation hardness, of the softer of the two contacting materials. Since s and p are similar plastic strength parameters, their ratio tends to be constant, within the range 0.3 to 0.6, for a wide variety of materials. With some materials the real area of contact increases during sliding, and friction coefficients above 1.0 are then commonly observed. Especially bad in this connection are materials with a high ratio of surface energy to hardness, namely clean soft metals such as lead, aluminum and copper.

A lubricant acts by introducing a layer of lower shear stress s_1 at the interface, and lowers the friction coefficient accordingly, down to 0.05 in favorable cases. Many nominally clean materials also give low friction, as result of contamination during manufacture or handling. Slight differences in the degree of contamination can produce drastic differences in the friction.

Some typical friction values are given in Table 1.

Materials with Unusual Frictional Properties In this category we may place the hard nonmetals (diamond), which give low friction (~0.1); the elastomers (natural rubber) which give very high friction (~0.9); the layer-lattice substances (graphite, molybdenum disulfide, cadmium iodide) which give low friction (~0.1) and are used as solid film lubricants; the hexagonal close-packed metals (rhenium, magnesium, titanium, cobalt) which when clean give lower friction coefficients (~0.5) than do other metals; "Teflon," which adheres very poorly to other solids and accordingly gives very low friction (~0.05); and metals in group IVa of the periodic table (titanium, zirconium, hafnium) which cannot be well lubricated by any known liquid substances. Generally, the frictional anomalies of solids may be traced to peculiarities in their structure or surface properties.

Current Problems and Areas of Research Interest At one extreme there is concern with obtaining high and reproducible friction for traction purposes, as in the development of better brakes and clutches, and in the design of runway surfaces at airports which give high friction even in very wet weather. At the other extreme, work is being done to reduce friction in devices which run continuously and dissipate energy, such as automobile engines. Often, problems arise when new materials must be used. Thus the reduction in the use of asbestos because of health hazards and of cobalt because of restricted availablity has stimulated much research and development work. Perhaps the most persistent problem is that of controlling stick-slip, which is responsible for much of the noise pollution of our environment.

Related Fields of Interest Friction is considered one of a group of mechanical interaction phenomena, and research in the other members of the group, generally referred to as *tribology*, is of great interest to workers in the friction field. There is an extensive common literature. The other tribological phenomena are wear (the removal of surface material as result of mechanical action), lubrication (the properties of surface films which reduce friction and wear), adhesion (the tendency of solid objects pressed together to remain together), and electrical contact effects (the electrical resistance at the interface between contacting or sliding solids).

Other effects which are often classified as basic tribological effects are erosion (the wear produced by particles traveling in a fluid and impinging on a solid surface) and fretting (the friction and wear produced as result of vibration at the interface between contacting surfaces).

There has been a recent upsurge of interest in these fields, based on the realization that the various tribological phenomena have great practical importance. Thus, in a modern industrialized country excessive friction wastes about 0.5% of the Gross National Product, while the damage done by wear is about an order of magnitude greater.

FUSION POWER

Introduction When nuclei of certain light elements fuse together an excess binding energy is liberated. This is the energy source of stars, and it is the object of fusion research to find ways of using the energy for electrical power production on earth. Because of the abundance of suitable light elements the energy source is virtually unlimited.

In order to fuse, the reacting nuclei must have sufficient energy to overcome their coulomb repulsion, so nuclei with a high ratio of mass to charge heated to a high temperature are most suitable. The fusion reaction of interest is

$$\mathrm{D} + \mathrm{T} = {}^4\mathrm{He}\ (3.5\ \mathrm{Mev}) + n\ (14.1\ \mathrm{Mev}) \quad (1)$$

where the fuel is deuterium (D) and tritium (T) and the reaction products are helium (the α particle, ^{4}He) and a neutron (n); the numbers in parenthesis are their energies. The energy from fusion may be appreciated by noting that 36 m^3 of natural water contains 1 kg of deuterium, which on fusion with tritium produces an energy equivalent to 5×10^4 m^3 of gasoline. The deuterium is easily extracted from water, but the tritium, which does not occur naturally, is made by allowing the neutrons to combine with lithium, using the nuclear reactions

$$\begin{aligned} {}^6\mathrm{Li} + n &= \mathrm{T} + {}^4\mathrm{He} + 4.8\ \mathrm{Mev} \\ {}^7\mathrm{Li} + n &= \mathrm{T} + {}^4\mathrm{He} + n - 2.5\ \mathrm{Mev}. \end{aligned} \quad (2)$$

There is sufficient high grade lithium ore to supply the world's electricity requirements for thousands of years. The possibility of an abundant energy source combined with low potential radioactive hazard make fusion power attractive. Even allowing for the radioactive tritium, the hazard is much less than that for fission reactors, in that no actinides, iodine, cesium, strontium, or plutonium are produced.

Ultimately there is the possibility of fusion between deuterium nuclei alone using the reactions

$$\begin{aligned} \mathrm{D} + \mathrm{D} &= \mathrm{He}^3\ (0.82\ \mathrm{MeV}) + n\ (2.45\ \mathrm{MeV}) \\ \mathrm{D} + \mathrm{D} &= \mathrm{T}\ (1.01\ \mathrm{MeV}) + \mathrm{H}\ (3.02\ \mathrm{MeV}) \end{aligned} \quad (3)$$

thereby eliminating the need for lithium. However the energy produced is less, and the peak reaction rate for D/D fusion occurs at a temperature that is nearly ten times that for D/T fusion and is about ten times smaller. This results in a ratio of energy produced by the D/D fusion reactions to energy supplied as heat in the reactants of about 70, compared to about 1800 for D/T fusion reactions, making an overall energy gain more difficult to achieve. Thus attention is primarily directed first to achieving fusion power using D/T fuel. It is worth noting that D/D reactions are appreciable in a D/T fuelled reactor, increasing the average energy per reaction from the 17.6 MeV given in Eq. (1) to 22.4 MeV.

The D/T fusion cross section as a function of energy rises rapidly to a peak at 110 keV, equivalent to a temperature of 10^9 K. If the density is sufficient for a thermal distribution of particle velocities, the rapid rise in cross section results in the few particles with energies in the Maxwellian tail contributing most to the reactions and so the peak reaction rate is at a rather lower temperature, around 6×10^8 K, and conceptual fusion reactors are often designed to operate at a temperature of 10^8 K or so. At this temperature the fuel is fully ionized by collisions, so the electrons are not attached to any particular nucleus and electron charge density equals the nuclear charge density. This state of matter is called a *plasma*, and the problems of fusion power generation are mainly plasma physics combined with engineering, rather than nuclear problems.

Research into the feasibility of thermonuclear fusion power began in the mid-1950s, and for 25 years has been concentrated on the problems of heating and containing high temperature plasma. Progress in plasma physics has been sufficiently encouraging for a number of countries to start constructing large experiments to investigate plasma heated by its own thermonuclear fusion reactions: these will begin in the latter part of the 1980s. Successful operation of the experiments will demonstrate the scientific feasibility, and lead to research reactors to investigate the engineering and commercial potential of fusion power near the beginning of the next century.

The demonstration of the feasibility of fusion power is taking longer than fission because of the large characteristic dimensions required for thermal isolation of the plasma, and because a very high temperature is required to start the reactions. This means that comparatively expensive inflexible experiments are required to explore new ideas.

Fusion Reactor Parameters A fundamental problem of fusion power is thermally to isolate and confine the plasma while it is heated and the reactions occur. In stars the plasma is held by gravitational force, but this force is too weak to hold the small mass of plasma in a reactor. Also, practical electrostatic fields are too weak, even if Ernshaw's theorem (that there is no equilibrium for a system of charged particles in an electric field) can be overcome. Two approaches to solve the containment problem are being studied: one, which uses magnetic forces, is described in this article; the other, which uses inertial forces, is described in the article on LASER FUSION.

A magnetic field can exert pressure on plasma because the free electrons make the plasma a good electrical conductor. A magnetic field B external to the plasma causes an induced current in the plasma surface which interacts with the field to produce a pressure perpendicular to the magnetic field lines proportional to B^2; this follows from the fundamental laws of electromagnetics. The pressure of plasma that can be supported is usually appreciably lower than the applied magnetic field pressure because some magnetic field must be mixed with the plasma to make the overall system stable. The external magnetic field pressure must then balance the sum of the plasma pressure and the internal magnetic field pressure. A measure of the efficiency of using the confining magnetic field is β, defined by the ratio of plasma pressure divided by the external magnetic field pressure, i.e. $\beta \propto nT/B^2$, where n is the particle number density and T is the temperature.

The magnetic field also hinders the escape of the charged particles produced by the thermonuclear reactions, provided the plasma dimensions exceed the particle cyclotron orbit diameter. This makes a self-sustained thermonuclear reaction possible because the energy from the particles can thermalize with fuel particles and balance power lost from the plasma as a whole. The minimum temperature for a self-sustained thermonuclear reaction is called the *ignition temperature*, and the plasma must be heated by external sources supplying power greater than the power loss up to the ignition temperature. At a minimum, the power loss is by bremsstrahlung photon radiation from free electrons deflected in coulomb collisions. With bremsstrahlung loss the ignition temperature is about 4×10^7 K. Much greater power loss may be produced by excitation radiation from electrons tightly bound to partially ionized heavy impurity atoms: only 0.1% of iron atoms will increase the ignition temperature to 7×10^7 K and $\geqslant 2.5\%$ of iron will prevent ignition completely. Since the fusion and radiation powers scale with density in the same way, the ignition temperatures are independent of density. It is therefore important to keep the plasma very pure.

Theoretically a uniform static magnetic field reduces the particle diffusion coefficient by about a factor $(\omega\tau_c)^2$, where τ_c is the collision time, ω $(=eB/m)$ is the cyclotron frequency, and e/m is the charge-to-mass ratio of the particle. This is because the magnetic field restricts the trajectory of charged particles to small circular orbits so that the displacement at each collision is a cyclotron orbit diameter rather than a mean free path. The reduction of diffusion velocity is proportional to the square of the magnetic field intensity, and since e/m is larger for the electron than for ions, the electrons determine the overall plasma diffusion velocity; the ion density follows the electron density closely because very little charge imbalance can exist in a plasma. When the electron-ion collisions are simple two-body coulomb collisions, the diffusion is called *classical*. Fusion reactor parameters are such that $\omega\tau_c$ is sufficient for classical containment for the period of the fusion burn. However, in practice it is found that there are waves and instabilities in the plasma-magnetic field system and the particles act together in groups which effectively collide even under conditions where two-body coulomb collisions are negligible. The mechanism of these "cooperative phenomena" is not completely clear, but it appears that gradients of temperature, current, and density play a part. It has been argued that, at worst, the diffusion velocity in the absence of a magnetic field may be reduced by a factor $\omega\tau_c$ and not $(\omega\tau_c)^2$ as with classical diffusion. Such enhanced diffusion, with an appropriate numerical factor, called *Bohm diffusion*, scales as T/B and is independent of the collision frequency. Early experimental results indicated diffusion times of only a few times the Bohm rate, which is inadequate for a reactor, but in the last ten years the ratio has been increased to 10^3-10^4, which is good enough.

Theoretically the thermal conduction should also be reduced by a factor of about $(\omega\tau_c)^2$ by the magnetic field, but, as with particle diffusion, much greater values are observed experimentally and often dominate the loss power. An increase of ~100X for electron thermal conduction and up to ~10X for ion thermal conduction are commonly observed. The loss is expressed in terms of an empirical energy containment time (τ) defined by the plasma energy density (nT) divided by the loss power. The fusion power balanced against the loss power gives the product $n\tau$ as a function of temperature. This has a minimum of

$$n\tau = 1.6 \times 10^{20} \text{ s/m}^3 \qquad (4)$$

at about $T = 3 \times 10^8$ K, corresponding to another condition for ignition. Over a wide range of temperature near ignition the thermonuclear power is proportional to n^2T^2, which together with the definitions of τ and β gives related ignition conditions $nT\tau \geqslant 4 \times 10^{28}$ or $\beta\tau > 3.3/B^2$ in the range of temperature of interest. For example, with $T = 1 \times 10^8$ K and $n = 2 \times 10^{20}$ m^{-3} an energy containment time of 2 seconds is required for ignition, which, with a typical value for the magnetic field of 5 Tesla, gives a requirement on β of 6.6%.

It is an important object of present research to understand the scaling and physical processes that determine τ and β and obtain ignition. The ignition condition given in Eq. (4) is similar to the condition for net power output from the reactor, derived by Lawson. If the efficiency of recycling the total power output to heat more plasma is 0.2 (probably optimistic), Lawson's condition gives $n\tau > 1 \times 10^{20}$ s/m^3 for a net power output.

Since the thermonuclear power density at the operating temperature is proportional to n^2T^2, it follows from the definition of β that it is also proportional to $B^4\beta^2$. This shows that it is very important to operate at a high magnetic field and β. The limit on magnetic field is the strength of the magnet coils (which must support the magnetic pressure) or the loss of superconductivity. Typically, fusion reactors are designed for a magnetic field of between 5 and 10 Tesla. The limit on β is determined by equilibrium and stability of the plasma in the magnetic field which depending on the magnetic configuration of the system, may range from a few times 10^{-2} to a few times 10^{-1}.

The β, temperature and magnetic field determine the operating particle density of the fusion reactor to be near 10^{20} m^{-3}, which is about 10^{-5} of atmospheric particle density. After ignition some means of controlling the energy containment time is required to control the plasma temperature and therefore the thermonuclear burn, which could last hundreds of seconds. Too high a temperature may cause the β to exceed a stability limit, causing the plasma to expand and the burn to extinguish. Ideas to control the temperature are to vary the density, or inject particles, or adjust the loss by producing nonuniformities in the magnetic field, or change the magnetic field slightly to compress/decompress the plasma. Although the temperature of a thermonuclear fusion reactor is high, the low density means that the heat content is so low that there is no explosion hazard if the plasma were to expand to the wall of the containment vessel.

At the operating density and temperature, thermonuclear power density averaged over the plasma and blanket is considerably less than the power density in the core of a fission reactor. For instance, with $n = 2 \times 10^{20}$ m^{-3} and $T \approx 10^8$ K the total fusion power density is ~4 MW/m^3 compared to ~80 MW/m^3 core power density in a PWR fission reactor and ~500 MW/m^3 in a fast fission reactor. An important difference between fission and fusion reactors is the form in which the power appears. In fission the power is mostly thermal, whereas the power from D/T fusion is produced in two parts: 25% in α power and 75% in very fast neutrons. The neutrons pass out of the plasma and generate heat in a "blanket," which is a heat exchanger combined with a tritium breeder; it is coaxial with the plasma and has a thickness of ~0.5 m, fixed by the neutron mean free path. The minimum diameter of the tube containing the plasma (the "first wall") is determined by the thermal insulation produced by the magnetic field and the economic need to make it $\lesssim$ the thickness of the blanket and neutron shield. In practice the first wall diameter is in the region of 4 m.

The large minimum diameter of the first wall in fusion reactors also means that the first wall power load, which is proportional to the diameter, is an important limiting parameter in the reactor economy. The first wall conditions are more severe than for the pin clad in a fission reactor because of the following factors; a larger temperature gradient; a higher neutron energy (~10 times fast reactor value); thermal cycling due to pulsed burn of tens to hundreds of seconds; it must not liberate impurities; it must withstand the external atmospheric pressure; and it is more difficult to change because the complicated magnetic field coils and blanket system must be moved. At present, tentative fusion reactor designs are based on first wall total power loadings in the region of 1 MW/m^2 and allow for a new wall every 1 or 2 years. The crucial design base values for the first wall loading must await experimental measurements with high energy, high fluence neutrons to be produced in fusion engineering test facilities.

Although the size and cost of these facilities will be a considerable fraction of a full scale fusion reactor cost, a number are in the conceptual design stage, aiming at operation near the end of the 1990s.

The large characteristic dimension of the plasma and the limitation of power loading in the first wall may make the cost of the fusion nuclear island larger than that of the fission case. Recent estimates indicate a cost ratio of ~8, and, taking into account the cost of the conventional plant, the overall fusion cost has been estimated to be ~2 times that of a PWR. However, because so many of the factors are difficult to quantify, the costing of a fusion power station can at best be only very approximate.

Plasma Heating It can be shown simply from a balance of thermonuclear fusion power and power loss, allowing for a contribution from the hot α particles, that the power required to ignite the plasma is $\sim B^4\beta_I^2/2$ MW/m^3 where β_I, the value of β at ignition, is $\sim 1.3/\tau_E B^2$. For example, a thermonuclear fusion reactor with a plasma volume of 200 m^3, $B = 5$ T and β_I of 6% would require a pulse of ~56 MW heating power lasting for a few energy containment times (of ~1 second). With a heater efficiency of 15%, the power input to the heater would be ~380 MW. After ignition, the fusion burn may last for 100 seconds at a power output of 1 GW, so the total fusion energy produced is ~150 times the energy required to heat the plasma.

Many fusion reactor designs employ ohmic power to ionize and start heating the fuel charge. When the electron temperature (T_e) rises, the ohmic heating power falls because the resistivity is proportional to $T_e^{-3/2}$, and to ignite the plasma additional heating is required. Adiabatic compression heating, produced by suddenly increasing the confining field, is unsuitable because of the limited vacuum space left around the plasma which must be filled by expensively produced magnetic flux, and also because of engineering limits on the maximum field available. There are two methods being developed for the additional heating: neutral injection and the application of electromagnetic waves. At the moment which method is best is not clear.

The principle of neutral injection heating is to use a very high power beam of atoms which, being neutral, penetrates the magnetic field. When the beam collides with the plasma it is ionized and so is confined by the magnetic field, subsequently sharing its energy with the plasma. The neutral beam is made by passing positive ions from a high current ion source through a gas cell so that they pick up electrons from the gas atoms by charge exchange. Neutral injection heating has some fundamental limitations. First, the gas source current is limited by heating of the acceleration electrode grid to ~2 kA/m^2. Second, to optimize the charge exchange efficiency in the gas cell, the beam energy should be chosen such that the velocity is approximately the orbital velocity of electrons in the atoms; against this the heating increases with energy so a compromise is chosen, typically ~160 keV for a deuterium beam with a corresponding efficiency of ~15%. Third, the plasma density must be such that the beam is absorbed in the plasma—too great a density causes absorption at the surface and too little density allows the beam to pass through the plasma. The density is probably rather lower than the density required for the thermonuclear burn, so further fuelling may be required, even allowing for fuel added by the beam. Last, because of the beam cross section, which is determined by the ion source current density limitations and beam divergence, a number of large holes are required in the vessel containing the plasma to allow the beams to enter. A significant fraction of fusion power and tritium production may be lost when neutrons escape through the holes, and, perhaps more important, neutron bombardment of the ion source will cause activation and maintenance difficulties. A way of overcoming the energy limitations which is at an early stage of development is to use a negative ion source. To produce the beam of neutral atoms, electrons can be removed from negative ions with a much higher efficiency (50–90%) than the charge exchange efficiency to positive ions. The efficiency is insensitive to the beam energy, enabling beam energies of 500 keV and a higher plasma density to be contemplated. At high beam energies, the time to thermalize the beam energy with the plasma may be important, during which a significant fraction of the fusion power may come from nonthermal particles.

Electromagnetic (RF) heating is at an earlier stage of development than neutral injection heating using positive ion sources. It has the advantages of higher efficiency and reduced size of the access holes in the blanket. There are three types of interest: electron cyclotron resonance heating (ECRH) which, typically, occurs at a frequency of 200 GHz (wavelength $\sim 1.5 \times 10^{-3}$ m); lower hybrid resonance heating, which occurs at a frequency around 3 GHz (wavelength $\sim 10^{-1}$ m); and ion cyclotron resonance heating (ICRH) with a frequency of about 65 MHz (wavelength ~5 m). Generation problems increase with frequency, whereas coupling the power to the plasma is best for ECRH.

The most successful method so far has been ICRH. This employs standard low frequency sources which have a high efficiency (around 90%) and overall, the efficiency of heating the plasma is between 20 and 60%. Input power densities of ~50 MW/m^2 have been investigated. The RF is launched from antennae near the plasma edge, producing a compression wave which propagates across the magnetic field towards the plasma center. The magnetic field is slightly nonuniform and the wave frequency is chosen to resonate with the ion cyclotron frequency at the plasma center so that absorption occurs. Originally it was intended to use absorption of the wave at the second harmonic because no absorption is possible in the fundamental mode. Although absorption at the second harmonic is expected to be strong near reactor temperatures it is rather weak in present experiments. Fortunately it was found that the presence of a few per cent concentration of another species (e.g., H or He) greatly increased the absorption efficiency because of the ion hybrid resonance and subsequently the majority species is heated by collisions. Potential difficulties with ICRH in a reactor are neutron bombardment and electrical breakdown of the insulator which support the antennae and power absorption near the wall which may liberate impurities. It may be possible to reduce the latter problem by focusing the waves toward the plasma center, but with ICRH it cannot be eliminated because the wavelength is appreciable compared to the plasma dimensions. A further problem is that the density must exceed $\sim 10^{19}$ m^{-3} for the waves to propagate, so that the antennae must be placed in the surface plasma.

In contrast, ECRH waves have no launching problems as long as the frequency exceeds the electron plasma frequency, which is proportional to the square root of the plasma density. The generation of powerful very high frequency fields has only recently been possible with the development of the gyrotron oscillator and the frequency condition should not seriously limit the plasma density. The waves are directed to the plasma via guides which are overmoded (approximately a few cm dimensions) to enable the high power densities to be carried. It is envisaged that ~200 0.3-MW gyrotons will be used. Advantages over ICRH are that because of the small wavelength the heating can be better focused at the plasma center; smaller holes are required in the blanket; and dog-leg waveguides can be used to avoid neutrons escaping. The overall efficiency is similar to ICRH, ~50%. A crucial element of success will be the development of reliable high power sources.

Lower hybrid heating uses compression waves, like ICRH. The frequency, which is between the electron cyclotron frequency and the ion plasma frequency, is around a few GHZ, so dog-leg waveguides can be used, as with ECRH, avoiding neutrons escaping. The wave electric field must be polarized parallel to the plasma magnetic field for absorption. At the resonance, the wave becomes electrostatic and ions are heated directly. Difficulties are that the absorption depends on the plasma temperature, and the frequency of the waves must be changed as the heating proceeds; rather than move radially, the wave spirals slowly to the plasma center, so that is spends a long time near the surface where it may heat the walls and liberate impurities; and lastly, like ICRH, the density must exceed a critical value for the wave to propagate. Powerful klystron (~1 MW/unit) sources are available to generate the waves, although development is required for long pulse operation. Low power experiments indicate an overall efficiency of ~30%.

ECRH may have the potential for controlling certain plasma instabilities associated with adverse plasma current profiles as a function of radius. It is hoped to avoid the wrong current profile by using the heating to control the temperature and thereby the conductivity as a function of radius.

The currents are induced by a changing magnetic flux. Because of the limited magnetic flux swing that is possible in a transformer, fusion reactors that depend on plasma current may only be suitable for a pulsed burn. Pulsed systems are not desirable because the thermal and mechanical strains impose severe engineering limitations. A potential way of overcoming the problem is to use the heating method to drive the current continuously. This has been demonstrated in principle with lower hybrid heating, tangental neutral beam injection, and ECRH. Driven systems may have some economic penality in that about 10% of the reactor electrical output might be required to drive the current.

Magnetic Containment Although a uniform magnetic field greatly restricts diffusion perpendicular to the field lines, it has no effect on transport parallel to the field lines. To confine the plasma parallel to the field, the lines must be curved to form either a *toroid* or a *mirror*. A toroid is effectively a doughnut shape produced by bending a cylinder into a circle so that there are no ends through which the plasma can escape. The axis of the cylinder is called the *minor axis* and the axis about which it is bent is called the *major axis*. The magnetic field is produced by solenoidal coils placed around the bent cylinder. The magnetic mirror geometry is a straight cylinder with magnetic field again produced by coaxial solenoid coils. To restrict plasma flow parallel to the cylinder axis the magnetic field is increased near each end so that the field lines are curved near the region of increased field, creating a component of magnetic pressure which reflects particles moving axially back toward the main plasma. Unfortunately there is always a fraction of particles with sufficient energy directed parallel to the axis to overcome the magnetic pressure and escape. Furthermore, the fraction is maintained by collisions in the main body of the plasma. The great majority of magnetic confinement experiments are now toroidal, although in the US and USSR there is a "second line" of work on the mirror geometry. Advantages of mirror over toroid are better access, possibly better stability, and smaller unit size, but adequate containment of the axially moving particles remains a severe problem.

In a toroid, the magnetic field gradient is inward along the major radius because the solenoid coils must be more closely spaced on the inside of the cylinder, so concentrating the field. In this simple form, there would be loss of containment because the ions and electrons shift in opposite directions in the field gradient and the resultant charge separation causes an electric field to develop which, combined with the magnetic field, cause an outward drift of both ions and electrons. Containment can be restored by adding another magnetic field orthogonal to the first, looping the minor axis. The resultant magnetic field is then helical about the minor axis, and the angular displacement of the field line about the minor axis for one revolution about the major axis is known as the rotational transform. The effect is to allow particles moving parallel to the helical field lines to reduce the charge accumulation, thereby reducing the drift.

Three types of toroidal confinement geometry are being investigated: the stellarator, the tokamak, and the reversed field pinch. In a *stellarator* toroid, the helical transform field is generated by l pairs of helical coils outside the plasma, wound around the cylinder. Experimentally, values of $l = 2$ or 3 are investigated. The windings in each pair carry a positive and a negative current. A disadvantage of the stellarator field configuration is the fall-off of field from the coils, making a given field more expensive to produce and the maximum magnetic field in the plasma less than with a simple solenoid. Another problem is that, to accommodate the stellarator coil structure, a large ratio of major radius to minor radius is required which may result in an inconveniently large reactor size. Against this, there are the important potential advantages that the confining field is determined by currents in fixed conductors external to the plasma enabling the possibility of continuous operation, and containment and heating are possible without the necessity of currents in the plasma which may cause instabilities.

The second and most developed confinement system is the *tokamak* toroid; it originated in the USSR and its name derives from the Russian words for toroidal chamber and magnetic field. A simple solenoid, coaxial with the minor axis is used to produce the main or (toroidal) magnetic field (B_T), and the transform is made by a toroidal plasma current parallel to the minor axis instead of by external coils. This produces a weak component of magnetic field (the poloidal field, B_p) around the minor axis; typically $B_p/B_T \approx 0.1$. The current is induced by transformer action (either air-core or iron-core). A measure of the effectiveness of using the poloidal field to achieve confinement is the *poloidal beta*, defined by $\beta_p \propto nT/B_p^2$ which is ≈ 1. Since the current must not be allowed to fall to zero, the thermonuclear burn must be produced in a pulse lasting for the period of the transformer action.

The helical transform in the tokamak is not able to provide equilibrium because, unlike the stellarator, the current that produces the helical field is not flowing in a rigid conductor. Equilibrium is, however, easily achieved either by using a conducting wall (called a *flux-conserving tokamak*) so that the outward pressure compresses flux between the plasma and wall, or, more commonly, by applying a vertical magnetic field (B_V) which, acting with the plasma current I, produces a force $I \times B_V$ to balance the outward pressure force. With the latter method, B_V may be varied by a feedback circuit controlled by optical sensors of the plasma position. This method of maintaining equilibrium does, however, limit the plasma pressure, because of the condition that there should be no null field point in the plasma which would be a source of plasma loss. This gives a maximum $\beta_p \lesssim 1/2\epsilon$ where ϵ = plasma inverse aspect ratio = minor radius/major radius. For a typical ϵ of $\frac{1}{3}$, $\beta_p \lesssim \frac{3}{2}$.

A third type of toroidal confinement geometry is the *reversed field pinch*. It differs from the tokamak in that a shear condition for plasma stability is used. The condition is obtained by making $B_p \sim B_T$ with the field reversed near the plasma surface. As with the flux-conserving tokamak, equilibrium is obtained by using a conducting shell.

An important theoretical aspect of toroidal systems is the effect of the helical geometry on confinement. Particles moving along helical magnetic flux tubes experience a decrease in magnetic field as the flux loops around the outside of the minor axis, causing the tube to bulge. Thus, if a length of helical flux is unwound it would have a series of constrictions which act like a succession of magnetic mirrors. Thus particles with a low velocity parallel to the flux tend to congregate in the low magnetic field regions: these are called *trapped particles*. The rest of the particles, which have a high parallel velocity, pass unimpeded along the flux tube; these are called *passing particles*. Because of either trapping or collisions some particles cannot move around the helix to allow cancellation of the charge separation due to drifting in the magnetic field gradient. The noncancellation results in an outward drift, enhancing the diffusion rate above the classical value. Three regimes of enhanced diffusion (called *neoclassical*) have been identified, depending on the electron-ion collision rate ν. At low density the collision rate is so low that some particles can bounce back and forth many times between the mirrors. This is called the *banana diffusion regime*, which is named after the shape of the trajectory of the particle motion. The diffusion rate is $q^2\epsilon^{-3/2}$ times the classical value where the safety factor $q = \epsilon B_T/B_p$. Typically, $q \sim 2$ and $\epsilon \sim \frac{1}{3}$ and the classical diffusion is increased by $\sim 20\times$. When collisions within the mirror are much more frequent than the bounce frequency there are no trapped particles and charge cancellation is inhibited by collisions of the passing particles, increasing the classical diffusion by a factor $1 + q^2$ which is $\sim 5\times$; this is called the Pfirsch-Schlüter regime. In the intermediate collisional regime the enhancement factor is $v_e/Rq\nu$ where v_e is the electron thermal velocity. Since the classical diffusion is proportional to ν, the enhanced rate is independent of ν, producing a flat region of the graph of diffusion vs. ν. Consequently this is called the plateau regime.

Other nonuniformities in the magnetic field may lead to other trapped particle effects. For example in stellarators, the multipole fields cause helical modulations which make the mean position of the bananas drift, leading to plots of the orbit positions that look like large bananas, and consequently called *super-bananas*.

A related effect of gradients on particle trapping is ripple caused when solenoidal cells are used. A ripple of a few per cent on the minor axis can cause serious loss, particularly for α particles because of their large cyclotron orbits.

Further theoretical predictions of trapped particles effects include the *bootstrap current* and the *trapped particle pinch effect*. The bootstrap current is caused by the radial diffusion velocity (v_r) of electrons in the banana regime. The diffusion velocity acting with the poloidal magnetic field produces a force proportional to $v_r B_p$ along the minor axis acts on the untrapped ions and electrons to produce an axial current. The current is predicted to be sufficient to provide a tokamak rotational transform up to a $\beta_p \approx 4\epsilon^{-1/2}$, offering a possible method for a continuously operating tokamak fusion reactor. The trapped particle pinch effect (also called the *Ware pinch effect*) is caused by the toroidal electric field used to drive the tokamak current. It makes the banana orbits drift towards the minor axis until the pinch force is balanced by the pressure gradient force.

Stability The temperature and density in a fusion reactor correspond to conditions in the banana neoclassical regime, and gives an $n\tau$ value easily satisfying the ignition and Lawson conditions. However the experimentally measured diffusion coefficients often exceed the neoclassical values. This is thought to be due to various instabilities in the plasma-magnetic field system. The instabilities are characterized by two mode numbers: m, corresponding to the number of perturbations in the minor cross section, and n, corresponding to the number of perturbations parallel to the plasma minor axis. The lowest surface mode, $m = 0$, is symmetrical about the minor axis and is due to the poloidal magnetic field (B_p) produced by the plasma current when the toroidal magnetic field is comparatively small. The system is unstable because B_p increases as the plasma radius decreases and so a given initial inward perturbation grows. The resultant deformation, known as the *sausage instability*, may be stabilized by an axial field inside the plasma of magnitude $> B_p/\sqrt{2}$. The next surface mode, when $m = 1$, $n = 1$, is caused by increased pressure inside a given kink perturbation, where the field lines are close together, increasing the amplitude of the perturbation. It is stable when q at the plasma surface is greater than 1; this is the *Kruskal-Shafranov condition* and is basic to tokamak operation. In a tokamak higher mode stability can be achieved by suitably peaking the current profile toward the plasma axis. Kink modes may also be stabilized by image currents if a conducting wall is put close to the plasma.

Inside the plasma the interchange of plasma and tubes of magnetic flux can cause instability (called internal pressure driven modes). For stability, the average curvature of the lines of force must be convex towards the plasma, leading to the "minimum B" condition $\delta \int dl/B > 0$ taken along a flux tube. These internal modes are localized near surfaces at which the lines of force join on themselves when they pass around the torus, i.e., when $q = m/n$. Suydam showed that they can also be stabilized by changing the angle of the helical magnetic field as a function of distance from the minor axis by an amount depending on the pressure gradient. The sheared field acts like a basket weave that prevents interchange of plasma and flux.

However nonlinear effects can cause a more complicated situation. For example, the plasma current causes heating which changes the conductivity, so affecting the current and magnetic field distribution. Also the finite resistivity, which is a function of temperature, allows magnetic field diffusion such that oppositely directed field lines may join to form loops in the plasma. This is called *resistive instability* and the loops are called *magnetic islands*; resistive instabilities may limit the effectiveness of shear to stabilize internal modes. Further, various radial regions of the plasma may be connected by rapid parallel diffusion along wandering magnetic flux lines. These are called *ergodic regions*. Overall, it seems that while the plasma under some conditions may be grossly stable, mild nonlinear effects of instabilities within the plasma may tend to flatten the internal pressure profile, increasing the pressure gradient near the surface and enhancing diffusive loss processes.

Finally, a class of interchange instabilities called *ballooning modes* should be mentioned. These are local (high m, n) modes associated with the unfavorable curvature of magnetic field near the outer regions of the toroidal plasma. Ballooning may be imagined as like the unstable bulge at the weak point of an overpumped bicycle inner tube. Calculations indicate that these modes may limit the maximum β in a tokamak to between 5 and 10%, although it is possible that nonlinear effects may allow the limit to be exceeded without disastrous loss.

It should be emphasized that plasma currents may be the source of many of these instabilities. Thus stellarators, in which the transform may be produced without plasma current, is likely to be most stable, followed by tokamaks and lastly by the reversed field pinch. The reversed field pinch operates with $q < 1$, relying on image currents in the conducting wall and magnetic shear for stability. Its cylindrical geometry necessitates a region of reversed magnetic field near the plasma surface. This automatically develops at an early unstable phase of the discharge, and is probably maintained by continuous mild resistive instabilities. The advantage of the reversed field pinch is its ability to operate at a much higher β than the tokamak; theoretically the maximum is 0.5.

Experiments In the last ten years world fusion research has mainly concentrated on the tokamak geometry showing continuous progress in extending the plasma parameters towards ignition with increased size of apparatus. Recent experiments have a major radius of ~1.3 m, a minor radius of ~0.5 m, $B_T \sim 5$ T and $I \sim 6 \times 10^5$ A, giving the record plasma parameters: $T \sim 7 \times 10^7$ K (at $n \sim 5 \times 10^{19}$ m^{-3}), $n\tau \sim 3 \times 10^{19}$ (at $n \sim 10^{21}$ m^{-3} and $T \sim 10^7$ K), $\beta \sim 4\%$ and $\tau \sim 10^{-1}$ s; these values were not all obtained at the same time, or in the same apparatus. In many respects the scaling of these quantities encourages the belief that a tokamak fusion reactor with reasonable dimensions may be physically feasible. A major milestone will be the control of plasma heated by thermonuclear fusion, which is an object of experiments at present being constructed.

However, although much sophisticated theory has been developed, many of the basic results continue to defy satisfactory explanation. The tokamak results give little support for neoclassical diffusion in that for years the electron thermal diffusion coefficient was observed to scale as $1/n$ and be independent of T and B. This corresponds to an energy confinement time scaling $\tau \propto na^2$ first discovered on the experiment Alcator. Recent larger experiments show the rather different scalings $\tau \propto na^2 T^{1/2}$ or $na^2 q^{3/4}$ at lower density and a peak of τ as a function of density at high density. Also no bootstrap current has been observed, the observed β as a function of heating saturates at high heating power, and the plasma is catastrophically unstable (disrupts) above an average density (the Murakami limit) which is proportional to the current density. The limits on τ, β, and n may cause difficulties in achieving ignition or obtaining economical operation. However, they may be connected with the evolution of impurities at high power operation so that improvements can be expected from methods to improve plasma cleanliness.

Many of these effects seem to be connected with the presence of instabilities. Under many conditions ripples move along the plasma (Mirnov oscillations) and flat regions of the temperature profile have been observed which could be interpreted as the effect of magnetic islands. At the Murakami density limit the plasma may catastrophically disrupt. Although the plasma energy in a reactor is small (~1 MJ), there is concern that rapid release of magnetic energy may strain the system.

A number of tokamak experiments are aimed at finding ways of injecting fuel and keeping the plasma clean. Fuel injection is normally by puffing gas on the outside of the plasma, relying on an inverted density gradient or perhaps the trapped particle pinch effect to transport new fuel inward. Other experiments are to investigate the practicality of injecting small pellets of fuel. Experiments to cleanse the plasma involve scraping the outer layer of impure plasma into a special chamber where it is neutralized and pumped away. The scraping is achieved by diverting the magnetic field lines by using either special coils for a cooled deflector, called a *pumped limiter*.

The second type of toroidal system, stellarator, has received less support than tokamaks. This is probably because of the relative success of tokamaks in the early days when stellarators gave containment times of only a few Bohm times, probably due to a combination of impurities, field errors, and the heating method. However in the last decade stellarator progress has been encouraging. Small low temperature (~10^4 K) devices give classical containment, while larger devices ($T \sim 3 \times 10^6$ K) are beginning to give neoclassical results in the plateau regime, as expected. Recently ion temperatures of ~7×10^6 K, densities of 10^{20} m^{-3}, $\beta \sim 1\%$ and $n\tau \sim 4 \times 10^{18}$ have been reported with a radius of only 0.1 m and $B \sim 3$ T. In some experiments the plasma is heated by an axial current which causes an added transform; it is found that as the current is reduced, the energy confinement time increases. Experiments, where there is no current and the plasma is either heated by neutral beam injection or RF, show the best confinement time and have no MHD activity or major disruptions. This indicates that the plasma currents, essential for the tokamak configuration, are detrimental to containment and may be responsible for the density limitations. Theoretically $l = 2$ or 3 stellarator equilibria exist for β up to 5%, and there should be stability up to $\beta \sim 10\%$ when small ϵ (~0.05) and superimposed fields of different pitch are used. It appears that because of resistive instabilities, shear in the magnetic field may not be sufficiently maintained to suppress instabilities, and a minimum B magnetic configuration is required.

The origin of the reversed field pinch is the observation of a quiescent period that automatically developed in unstable plasma in the large Zeta toroidal experiment of the early 1960s. The parameters were major radius 1.5 m, minor radius 0.5 m and toroidal current 4×10^5 A, giving a plasma temperature $\sim 1.5 \times 10^6$ K, density $\sim 5 \times 10^{19}$ m^{-3}, $\beta \sim 0.1$ and energy containment time ~ 0.003 to 0.01 s. This was explained by subsequent low β theoretical analysis which showed that, in certain ranges of poloidal and toroidal magnetic field, a force-free shear-stabilized magnetic field configuration with reversed field near the surface is possible. In the 1970s the results were confirmed and experiments to extend them to higher temperature and β were started. A major objective is to determine whether the magnetic configuration can be maintained for the burn period of a fusion reactor either automatically by noncatastrophic small-scale instabilities or by the application of a reversed field at the plasma surface.

The only linear containment system with fusion reactor potential is the mirror. In its simple form it is unstable because interchange instabilities may develop where the magnetic field lines are concave towards the plasma. This was overcome by adding an extra field produced by current flowing in conductors placed outside of the plasma. This produces a complicated magnetic field configuration that is minimum β stable; the curved field lines are, of course, only required near the ends when the system is long. Although the containment is grossly stable too many particles acquire enough parallel velocity to penetrate the mirrors. A possible way to overcome the problem that is being investigated is to heat the plasma in the mirror regions preferentially, so that the axial temperature gradient produces an electrostatic field directed to reduce the loss. Encouraging results of $T \sim 3 \times 10^6$ K, $n \sim 3 \times 10^{19}$ m^{-3}, $\beta \sim 0.1$–0.5, and $\tau \sim$ a few times 10^{-3}, have been achieved and work is proceeding on larger experiments to investigate the scaling.

Toward Reactors Although there are problems to be overcome in all confinement systems, the reactor potential of tokamak has received most attention, followed by stellarators, mirrors, and reversed field pinches.

Table 1 shows the parameters and objectives of large tokamak experiments on the path to a reactor. The first three will be in full operation by the mid 1980s. The largest, JET, has a D-shaped cross section which maximizes the β. The total cost will be $\sim$\$450 million. It will operate at high density, and may even achieve the ignition $n\tau$ product. In constrast, TFTR aims to operate at a lower density where nonthermal reactions rather than ignition are significant, possibly just achieving the Lawson $n\tau$ product for energy breakeven. As a physics milestone in fusion, the $n\tau$ value has been compared to criticality in fission development, although it should be emphasized that it is not so definitive.

The next three tokamak experiments listed

TABLE 1.

Experiment	Objective	R (m)	a (m)	B_T (T)	I_T (MA)	Pulse Time (s)
JET (Euratom)	Approach to ignition Maximize β Long pulse	3.0	0.3×2.1	3.4	4.8	20
TFTR (USA)	Approach to energy breakeven	2.7	0.9	5.2	2.5	1.6
JT60 (Japan)	Ignition parameters in hydrogen plasma Impurity control	3.0	1.0	4.5	2.7	5.0
TORUS II (France)	Superconducting coils Long pulse RF heating	2.2	0.7	4.5	1.7	–
T-15 (USSR)	Superconducting coils Approach to ignition	2.4	0.8	3.5	1–2	–
INTOR (IAEA)	Ignition Blanket design Fusion burn control Technology of electricity producing systems	5.2	1.3	5.5	6.4	100

are to investigate particular reactor requirements: impurity control, long pulse, RF heating, superconducting coils, etc. Lastly, INTOR is an ignition experiment to test crucial engineering aspects such as blanket design, materials, tritium handling, plasma burn control, and even limited electricity production. In 1982 it was in a conceptual design stage, the final design awaiting results on near-ignition conditions from the JET generation of experiments. It is hoped to be able to start construction of INTOR late in the 1990s. The subsequent stage of development will be a full scale prototype reactor. One of the major problems will be first wall erosion caused by the high energy neutrons, estimated to be ~100 metric tons of material per gigawatt (electric)-year.

It has been suggested that advantage could be taken of the high neutron energies by using the neutrons to produce fission power from U^{238}, or to breed plutonium from U^{238} which is ~10 times more efficient than in fast reactors because of the harder neutron spectrum. These schemes are known as *hybrid fusion-fission*. They have the advantage of lower energy break-even $n\tau$ than pure fusion, but at the expense of complicated engineering construction and the loss of low radiation hazard compared to fission reactors.

The cost of magnetic confinement fusion research in 1982 was ~$330 million in Europe, $200 million in Japan, $460 million in the USA, and probably a similar amount in the USSR. These amounts are small compared to that spent on energy as a whole. Fusion power has a large number of unresolved problems which may only be investigated with large apparatus; the risk of failure is far from negligible, but the benefit of success would be great.

G

GAS LAWS

The term "gas law" refers to the thermodynamic equation of state of a gas, which is an equation relating the pressure p, the volume V, the absolute temperature T, and the number of moles ν. The equation of state is a valid relation when and only when the gas is in a state of thermodynamic equilibrium; the pressure and temperature are then constant and uniform throughout the volume occupied by the gas.

Ideal or Perfect Gas The ideal or perfect gas is defined thermodynamically by the two conditions: (1) it obeys the equation of state: $pV = \nu RT$ where R is the gas constant per mole ($R = 8.3169 \times 10^7$ erg mole^{-1}°C^{-1}), and (2) the internal energy U is independent of pressure and volume and is a function only of the temperature ($(\partial U/\partial V)_T = 0$). The statistical-mechanical definition of an ideal gas is that it is a gas of noninteracting molecules, i.e., the molecules exert no appreciable forces of attraction or repulsion on each other. Since the notion of a finite "size" of a molecule connotes the existence of a repulsion which prevents two molecules from overlapping each other, the molecules of an ideal gas must be of negligible "size." The two thermodynamic properties can be deduced from the statistical mechanical definition.

The ideal gas equation: $pV = \nu RT$ embodies the experimental laws of Boyle, Charles and Gay-Lussac. It can be derived either from kinetic theory or from statistical mechanics. It is often written in the form: $p = nkT$ where n is the molecular number density and k is Boltzmann's constant ($k = 1.3804 \times 10^{-16}$ erg °C^{-1}). In the case of a mixture of inert, ideal gases, each gas obeys the equation: $p_i = n_i kT$ where p_i and n_i are, respectively, the partial pressure and partial density of the ith component gas. Boyle's law will not hold if the gases in the mixture react chemically since a change in p or V will in general change the value of ν.

Real or Imperfect Gas The ideal gas law is, of course, only an approximation which holds at temperatures sufficiently far above the critical temperature and at sufficiently low densities. The ordinary properties of bulk matter in the liquid and solid states require the existence of strong intermolecular repulsions which endow the molecules with a finite "size" and also require the existence of attractive forces to hold the molecules together. The equation of state of a real gas is therefore determined by the nature of the intermolecular forces. One of the earliest, simplest, and most useful equations is that of van der Waals

$$\left(p + \frac{a}{V^2}\right)(V - b) = RT \text{ (for 1 mole)} \quad (1)$$

where a and b are constants, determined empirically for each gas, which are related to the attractive and repulsive forces, respectively. This equation can be related theoretically, in first approximation, to a molecular model in which the molecules are represented by rigid elastic spheres that weakly attract each other. The van der Waals equation accounts qualitatively for the liquid-vapor phase transition. The constants a and b can be determined from critical point data.

Other equations of state for an imperfect gas have been proposed which are more accurate than the van der Waals equation, e.g., the equations of Dieterici, Berthelot, Beattie-Bridgeman, and Benedict-Webb-Rubin. These empirical equations are useful in treating the thermodynamic properties of gases at high densities. At low densities, the empirical equations have been superseded by *the virial equation of state*

$$\frac{pV}{RT} = 1 + \frac{B(T)}{V} + \frac{C(T)}{V^2} + \frac{D(T)}{V^3} + \cdots \text{ (for 1 mole)} \quad (2)$$

where $B(T)$, $C(T)$, and $D(T)$ depend on the nature of the gas and are called the second, third and fourth virial coefficients, respectively. The departures of a gas from ideality are represented in this case by a power series in the density. We may rewrite Eq. (2) as

$$p/kT = n + \hat{B}(T)n^2 + \hat{C}(T)n^3 + \hat{D}(T)n^4 + \cdots \quad (3)$$

where $\hat{B}, \hat{C}, \hat{D}$ are the virial coefficients referred to one molecule.

The basic experimental problem in this field is to measure the virial coefficients of different gases as functions of the temperature. The higher-order coefficients beyond $B(T)$ and $C(T)$

are very difficult to measure. The basic theoretical problem is to calculate the virial coefficients from an assumed form for the intermolecular potential energy and, ultimately, to derive the intermolecular potential from quantum mechanics.

Statistical Mechanics of the Imperfect Gas The derivation of the virial equation of state from the intermolecular potential involves several steps which may be summarized as follows:

$$\text{Virial Equation} \begin{array}{l} \leftarrow \text{Helmholtz Function} \\ \leftarrow \text{Grand Potential } (PV) \end{array} \begin{array}{l} \leftarrow \text{Canonical Partition Function} \\ \leftarrow \text{Grand Partition Function} \end{array}$$

$$\leftarrow \text{Configuration Integral} \leftarrow \text{Cluster Integrals} \leftarrow \text{Intermolecular Potential}$$

The two routes indicated are via the canonical and the grand ensembles. The most difficult step is the evaluation of the configuratior integral:

$$Q_N = \int \cdots \int \exp\left[-\Phi(\mathbf{r}_1, \mathbf{r}_2, \cdots \mathbf{r}_N)/kT\right] d\tau_1 \, d\tau_2 \cdots d\tau_N \quad (4)$$

where Φ is the total intermolecular potential energy of the gas of N molecules. The proper way to evaluate Q_N was first sketched by Ursell and later carried through by Mayer who assumed central forces that were pairwise additive, i.e.,

$$\Phi = \sum_{i<j} u(r_{ij})$$

where $u(r_{ij})$ is the potential between molecules i and j. Neither of these assumptions is correct, but they appear to be good approximations, and with their aid, it is possible to evaluate Q_N rigorously in terms of the so-called cluster integrals, b_l, which are integrals over the coordinates of l molecules only. $B(T)$ is obtained directly from b_2, $C(T)$ is obtained from b_3 and b_2, and the lth virial coefficient requires evaluation of the cluster integrals up through b_l. Explicit formulas for $\hat{B}(T)$ and $\hat{C}(T)$ are:

$$\hat{B}(T) = -\frac{1}{2V} \iint f_{12} \, d\tau_1 \, d\tau_2 \quad (5)$$

$$\hat{C}(T) = -\frac{1}{3V} \iiint f_{12} f_{23} f_{13} \, d\tau_1 d\tau_2 d\tau_3 \quad (6)$$

where $f_{ij} \equiv \exp\left[-u(r_{ij})/kT\right] - 1$. Higher coefficients in the virial series are increasingly more difficult to evaluate.

The calculations just described are based on the classical Maxwell-Boltzmann statistics and are sufficiently accurate for most gases at ordinary temperatures. However, in the case of the lightest gases H_2 and He and especially at low temperatures, it is necessary to introduce quantum corrections in the equation of state.

Intermolecular Forces and the Equation of State In order to calculate the cluster integrals and virial coefficients, one must first choose a form for the intermolecular potential $u(r)$. In principle, the potential $u(r)$ is determined by quantum mechanics for any pair of molecules and could be found by solving the Schrödinger equation. In practice, this is virtually impossible, and quantum-mechanical calculations have been made only for the very simplest molecules. In the case of interactions between neutral, nonpolar, spherical molecules, e.g., noble-gas atoms, the quantum-theoretical interaction energy can be approximately decomposed into several parts, of which the two most important are the *dispersion energy* and the *valence repulsion energy*. The former corresponds to the van der Waals attraction and the latter to the van der Waals repulsion. The dispersion energy varies inversely with the sixth power of the distance. The valence-repulsion energy takes account of the short-range repulsion that sets in when the electron distributions of the two molecules begin to overlap, and it is associated with the Pauli exclusion principle. There is no simple, general form for the dependence of the valence repulsion potential on the distance: it is often empirically represented by Ae^{-ar} or by μr^{-n} where $n = 12$ is commonly used. In the case of molecules that possess permanent electric dipole or quadrupole moments, there are additional contributions to the van der Waals attraction but these are usually less important than the dispersion energy (H_2O is an exception).

In the absence of a complete quantum-mechanical expression for the intermolecular potential, it is necessary to approximate the potential by a semi-empirical formula, containing one or more adjustable constants, which is chosen on the grounds of physical plausibility and mathematical convenience. The semi-empirical force law is then used to calculate macroscopic properties that are known from experiment, and the parameters in the force law are adjusted to give the best agreement with experiment. Given the form of the intermolecular potential, it is possible to calculate not only the virial coefficients in the equation of state but also the kinetic-theory transport coefficients (i.e., the viscosity coefficient, the thermal conductivity, and the various diffusion coefficients of the gas) and the density, compressibility, and sublimation energy of the solid. A particular functional representation of the intermolecular potential can be considered satisfactory only if it is possible to secure agreement with all experimental data involving a particular pair of molecules with a single choice of the parameters that appear in the law of force.

The semiempirical law that is most frequently used to represent the interaction between nonpolar molecules is the *Lennard-Jones* (12, 6) *potential:*

$$u(r) = 4\epsilon[(\sigma/r)^{12} - (\sigma/r)^6] \qquad (7)$$

where ϵ and σ are parameters characterizing the particular pair of molecules. This simple two-parameter function, when inserted in Eq. (5), predicts a temperature variation of the second virial coefficient in good agreement with experiment. The same potential with slightly different values of ϵ and σ also explains the temperature variation of the viscosity coefficient over a substantial temperature range. Third virial coefficients calculated from Eq. (6) do not agree with experiment at low temperatures near the critical point. The large discrepancies have been attributed to three-body forces which invalidate the assumption of pairwise additivity. Calculations of virial coefficients and transport coefficients of gases and of equilibrium properties of the crystal lattices have also been made for other semiempirical potential functions, but the results are not very different from those found with the (12, 6) potential. Nevertheless, there is accumulating evidence both from experiment, e.g., atomic beam scattering, and from theory, e.g., quantum-mechanical calculations of the dispersion energy, that the (12, 6) potential has serious defects, and it has been replaced in recent work by more complicated multiparameter potential functions.

Further advances in this field will come, on the theoretical side, from a more detailed knowledge of the intermolecular forces, and on the experimental side, from more accurate ways of extracting virial coefficients from thermodynamic data. Current values of $C(T)$ are not only subject to experimental errors in the p, V, T measurements but also to substantial uncertainties incurred in fitting the data with polynomials in the density.

Dense Gases High-density gases cannot be conveniently represented by the virial equation of state because of the slow convergence of the virial series. Furthermore, the theoretical evaluation of the higher virial coefficients on the basis of any plausible molecular model would meet with great computational difficulties. Other approaches are therefore needed, e.g., the empirical equations of state already mentioned and the principle of corresponding states. In the latter method, one introduces the reduced, dimensionless variables: $p_r = p/p_c$, $V_r = V/V_c$, and $T_r = T/T_c$ where the subscript c refers to the critical point. The principle of corresponding states then asserts that all substances obey the same equation of state in terms of the reduced variables. The variables may also be reduced in terms of intermolecular potential parameters.

A promising theoretical approach to the equation of state of a dense gas or liquid is provided by the method of the radial distribution function $g(r, n, T)$. Because of intermolecular forces, the actual density at a small distance r from a given molecule is different from the bulk density n and is represented by $ng(r, n, T)$. Thus the radial distribution function measures the effect of intermolecular forces on the probability of finding two molecules close together. While it is difficult to determine $g(r, n, T)$ theoretically, it can be found experimentally from the diffraction pattern observed when x-rays are scattered by the fluid.

GASES: THERMODYNAMIC PROPERTIES

Fundamental Principles The thermodynamic properties of a substance may be classified as either reference properties, energy functions, or derived properties.[1] The reference properties of a single-component system with their symbols and units are pressure, p, Pa or Nm^{-2}; volume, V, m^3; temperature, T, K; and entropy, S, JK^{-1} mol^{-1}. For a specific amount of a pure gas, it is necessary to specify only two of these reference properties to fix the state of the system and its properties. For mixtures of gases, the composition must also be specified to fix the system completely. The energy functions with their symbols and units are internal energy, U, J mol^{-1}; enthalpy, H, J mol^{-1}; Helmholtz energy, A, J mol^{-1}; and Gibbs energy, G, J mol^{-1}. These functions represent the energy available for performing useful work under various process conditions. Derived properties with their symbols and units include heat capacity, C, JK^{-1} mol^{-1}; fugacity, f, Pa or Nm^{-2}; compression factor, Z, unitless; and the Joule-Thomson coefficient, μ, K Pa^{-1} or Km^2 N^{-1}.

Properties are termed intensive if they are independent of the amount of the material. Examples are pressure and temperature. Properties such as volume and entropy, which are dependent on the amount of material, are termed extensive.

Absolute values may be determined for the reference properties, but the energy functions must be determined relative to an arbitrary zero reference point. The internal energy, U_0°, of the ideal gas at the absolute zero of temperature is generally taken as the zero reference point of the enthalpy and free energy functions. Other reference points include a zero value for the enthalpy of the ideal gas at the ice point, $H_{273.15}^\circ$, and another in which the sensible enthalpies are combined with chemical energies.[2] In the latter base, the value of $H_{298.15}^\circ$ is zero for the assigned reference elements so that the values of $H_{298.15}^\circ$ for the various compounds are equal to their heats of formation from the assigned reference elements.

Thermodynamic properties of gases are calculated for both the ideal gas state and the real gas state. A gas is defined to be ideal if it follows the simple equation of state, $pV = RT$, for 1 mole of gas. Gases behave in this manner only at very low pressure, but the ideal gas state is a convenient reference state for the calculation of the thermodynamic properties. Thus, the thermodynamic standard state[3] is defined as the ideal gas at 1 atmosphere (= 101 325 Pa) pressure at each temperature, and it is denoted by a superscript degree mark as in H° and S°. The ideal gas properties have been calculated for many substances, but the real gas properties are known for relatively few substances.

Thermodynamic properties are used in the calculation of energy balances, reaction compositions at chemical equilibrium, reaction temperatures, and the work involved in the compression or expansion of gases in various systems.

Ideal Gas Properties The thermodynamic properties of an ideal gas such as heat capacity at constant pressure, C_p°, enthalpy function, $(H^\circ - H_0^\circ)/T$, entropy, S°, and Gibbs energy function, $(G^\circ - G_0^\circ)/T$, in units of JK^{-1}mol^{-1}, are calculated from theoretical equations and from an analysis of spectroscopic and molecular structure data.[4-7] These complex calculations are based upon the contributions from all of the energy states available to the molecule, such as translational, electronic, vibrational, and rotational. Contributions from excited electronic states are important for diatomic molecules at higher temperatures but are entirely negligible for most polyatomic molecules. Vibrational energy levels are obtained from an analysis of infrared and Raman spectroscopic data by applying the principles of wave mechanics and group theory.[4,7,8] The interpretation of the spectra includes the assumption of a model for the molecule with parameters such as bond lengths, bond angles, and force constants. The parameters are varied within certain limits until the best agreement with observed spectra is obtained. Rotational energy levels are observed in infrared, Raman, and microwave spectra. The rotational energy includes not only the rotation of the molecule as a whole but also internal rotations by groups of atoms within the molecule and a pseudorotation in some ring molecules.[9]

For higher orders of accuracy in the calculation of the thermodynamic properties, additional contributions may be determined that are caused by the interaction between vibrational and rotational motions, centrifugal distortion of the molecule during rotation, and anharmonicity of the vibrations. Another contribution due to nuclear spin can be, and generally is, neglected for all molecules except H_2 and D_2 since it causes a detectable effect on measurable quantities only at very low temperatures. Adjustments are made for the presence of isotopes in some diatomic and polyatomic molecules.

The calculation of the thermodynamic properties of an ideal gas is based not only on theory but also on accurate experimental vapor heat capacity, heat of vaporization, and low-temperature calorimetric data.[9] The ideal gas heat capacity C_p° and entropy S° are derived from these data and are compared to theoretical values. When differences are found, the theoretical calculations are revised until there is good agreement. In this manner, new information is gained about the conformation of the molecule, its frequencies of vibration, etc. Thus, experimental data provide a firm base to test theoretical calculations and improve the calculation of all of the thermodynamic properties.

Theoretical calculations become increasingly complex as the molecular size increases. Thus, a method of increments has been devised to calculate the thermodynamic properties of large molecules based on an "anchor compound" for a given homologous series.[1,10]

Real Gas Properties The thermodynamic properties of real gases are determined primarily from experimental compressibility (pressure-volume-temperature) measurements (see COMPRESSIBILITY, GAS). All other properties are calculated either from equations of state or from a correlation of the individual experimental data points. In addition, the properties may be estimated from generalized correlations of the compression factor ($Z = pV/RT$). Here and in the equations that follow, V denotes molar volume in $m^3 \text{ mol}^{-1}$ and R denotes the molar gas constant, in $JK^{-1} \text{ mol}^{-1}$.

Experimental compressibility measurements have been made by a variety of methods[11,12] such as constant volume cells (Eucken and Meyer), variable volume cells (Beattie and Douslin, Michels, and Sage and Lacey), expansion systems with variable sample mass (Burnett), and differential systems (Whytlaw-Gray). The apparatus of Beattie and Douslin is used to measure both isometrics and isotherms up to 350°C and 400 atmospheres. The Michels apparatus may be used up to 3000 atmospheres but is limited to a temperature of 150°C. Sage and Lacey have made extensive measurements on both gas and liquid systems up to 240°C and 670 atmospheres.

Equations of state have been derived from compressibility data to represent the behavior of a gas over wide ranges of temperature and pressure.[11,13-14] Numerous equations have been published but one of the most important is the virial equation,

$$pV = RT(1 + B/V + C/V^2 + D/V^3 + \cdots) \tag{1}$$

It is quite important because the parameters B, C, D, etc., are related to the interactions between molecules according to the intermolecular potential energy theory. Other equations having wide applications are those of Beattie and Bridgeman and of Benedict, Webb, and Rubin (see GAS LAWS).

The energy functions, entropy, and heat capacity of a real gas are calculated as the sum of the ideal gas properties and a correction for the nonideality of the gas. The corrections for the nonideality of the gas are called difference or departure functions. For example, $S\text{-}S°$ is the entropy of the gas in the real state less that of the gas in the standard state at the same temperature. Theoretical equations needed for the computation of the thermodynamic properties have been derived in terms of pressure, volume, temperature, and the first derivatives $(\partial V/\partial T)_p$ or $(\partial p/\partial T)_v$.[13]

For example:

$$H - H° = \int_v^\infty [p - T(\partial p/\partial T)_v]\, dV + pV - RT \tag{2}$$

The heat capacity differences $C_p - C_p^\circ$ and $C_v - C_v^\circ$ are functions also of the second derivatives $(\partial^2 V/\partial T^2)_p$ or $(\partial^2 p/\partial T^2)_v$ depending upon whether the equations are written in terms of p and T, or V and T. The quantities appearing in Eq. (2) are usually evaluated from equations of state. However, the most accurate properties are those which are calculated from an analysis of isometric and isothermal p-V-T data.[15] The slopes of the isometrics $(\partial p/\partial T)_v$ are found by analytical, residual, and graphical techniques. The integrals as in Eq. (2) are integrated graphically or numerically.

Extensive correlations of data have been made to develop methods for estimating the properties of gases.[1,13] One method based on the theory of corresponding states presents the thermodynamic properties as a function of reduced temperature ($T_r = T/T_c$), reduced pressure ($p_r = p/p_c$), and the compressibility factor, Z_c. The subscript c refers to the critical state.

Gas Mixtures The thermodynamic properties of a mixture of gases may be calculated, but the procedures are only approximate unless compressibility data are available for the particular mixture.[11-13] Since few data for mixtures are available, the properties must be estimated from: (a) the equations of state of the pure gases assuming either additive volumes or additive pressures, (b) an equation of state for the mixture, or (c) generalized correlations of the compressibility factor based on pseudoreduced conditions.[1]

GAUGE THEORIES

The principle of gauge invariance in classical electromagnetism expresses the postulate that electric and magnetic field strengths are measurable, and thus have objective meaning, while the scalar and vector potentials (from which the fields are usually derived) are neither measurable nor uniquely defined. For example, a static electric field is the negative gradient of a scalar potential function whose value is undefined up to a constant. Similarly, the magnetic field **B** is the curl of a vector potential, to which may be added any gradient of a scalar function without changing **B**, because the curl of a gradient vanishes identically. The importance of gauge invariance was first pointed out by Hermann Weyl in 1922. Its quantum mechanical significance was emphasized by Fritz London in 1927, namely: Gauge invariance fixes the form of the electromagnetic interaction and guarantees the atomicity of electric charge (without, however, fixing its value). Its application to relativistic field theories of elementary particles was made by Wolfgang Pauli and others.[1]

Quantum electrodynamics (QED) is the quantum theory of the electromagnetic field. It is the prototype of important quantum field theories that many believe describe all known fundamental interactions except gravitation; the theories of this type are called ***gauge theories***. They are characterized by a principle that is a generalization of the gauge invariance principle of electromagnetism, namely: Gauge theories describe relativistic quantum fields that are invariant under a set of local symmetry transformations, i.e., operations of a continuous group (Lie group), whose elements are denoted by parameters that are functions of space and time. QED itself is a highly successful gauge theory, whose gauge group is Abelian, i.e., it has only mutually commuting elements.

A non-Abelian generalization of QED is the "standard" electroweak theory, which is a gauge theory that unifies the electromagnetic with the weak nuclear interactions that are responsible, e.g., for nuclear beta decay. Another non-Abelian gauge theory is quantum chromodynamics (QCD), designed to explain the binding of unobserved elementary particles called ***quarks*** into observed strongly interacting particles called ***hadrons*** (e.g., proton, neutron, pion). It postulates the exchange between quarks of eight massless "color gluons," analogous to the ordinary photon of electromagnetism, in order to account for the total confinement of quarks (whose nonintegral electric charges may not be observed) and to account for the strong nuclear force.[2] Non-Abelian gauge theories have also been proposed that unify all three of the above interactions (i.e., all fundamental interactions except gravity); they are called grand unification theories (GUTS).[3]

QED is formulated in terms of a relativistic four-vector field A^μ ($\mu = 0, 1, 2, 3$), which is the quantum generalization of the electromagnetic four-potential. The principle of gauge invariance states that A^μ can be replaced by $A^\mu + \partial\Lambda/\partial x_\mu$, where Λ is any (relativistic) scalar function of space and time, without affecting any of the consequences of the theory. Among these consequences are:

- The appearance of massless photons (at all frequencies, spanning the entire electromagnetic spectrum)
- A unique form of electromagnetic interaction with charged particles
- The conservation of electric charge.

The last property follows from gauge invariance alone.

QED, proposed by P. A. M. Dirac in 1927, was plagued for two decades by so-called *divergences*, i.e., infinite values predicted for physical quantities that are actually finite. In the late 1940s, it was found that this problem could be circumvented by an ingenious calculational procedure called *renormalization*. Thus far, among quantum field theories applicable to elementary particles, only gauge theories have been found to be renormalizable.

The first gauge theory other than QED was formulated in 1954 by C. N. Yang and R. L. Mills. Among their motivations were:

- To find the consequences of assuming a law of conservation of *isotopic spin* (which was thought to be the strong-interaction analogue of electric charge)
- To have a principle that would select, from many possibilities, a unique form for the strong nuclear interaction.

The isotopic spin is a quantum-mechanical concept, having no classical analogue; it is represented by a vector operator whose components have the same commutation relations as the quantum mechanical angular momentum, hence the term *spin*. These operator components are the generators of a non-Abelian Lie group. In order to ensure that the strong-interaction Lagrangian be invariant under this local isospin group, a four-vector field $\mathbf{b}_\mu$ is seen to be necessary, having three components, and bearing the same relation to the isospin that the electromagnetic field bears to the electric charge. The field $\mathbf{b}_\mu$ (because of non-Abelian isospin gauge invariance) turns out to obey a nonlinear equation of motion.

In the case of electromagnetism, the interaction with an electric charge, described by a wave function $\psi(x)$, where $x = (\mathbf{x}, t)$, is obtained by replacing any gradient acting upon $\psi(x)$, by the so-called *covariant derivative* D^μ; that is,

$$\partial^\mu \rightarrow D^\mu = \partial^\mu - ie\, A^\mu,$$

where $\partial^\mu \equiv \partial/\partial x_\mu$ and A^μ is the electromagnetic four-potential. It follows from quantum mechanics that an arbitrary phase is allowed the complex wave function $\psi(x)$. That is, the theory is invariant under the replacement

$$\psi(x) \rightarrow e^{i\alpha(x)}\, \psi(x).$$

To insure invariance under this transformation, terms in the Lagrangian must contain derivatives in the form D^μ, *not* ∂^μ, for only then:

$$D^\mu \left\{e^{i\alpha(x)}\, \psi(x)\right\} = e^{i\alpha(x)} D'^\mu\, \psi(x)$$

where

$$D'^\mu = \partial^\mu + i\partial^\mu \alpha(x) - ie\, A^\mu(x).$$

D'^μ is equivalent to D^μ because of the gauge invariance of $A^\mu(x)$, which allows the addition of the gradient of an arbitrary scalar function, i.e., $\partial^\mu \alpha(x)$.

Like the A^μ of QED, the isotopic spin invariant $\mathbf{b}_\mu$ field of Yang and Mills, whose gauge group is $SU(2)$, consists of massless "photons." However, since $SU(2)$ has three generators, while the Abelian group of electromagnetism has only one, there are three kinds of "photons." Similarly QCD, based upon the $SU(3)$ group that has eight generators, has eight kinds of "photons," called *gluons*. In all three cases (QED, Yang-Mills, and QCD) we deal with an "unbroken" gauge symmetry, characterized by a vacuum state which is itself gauge symmetric.

It is possible, however, to have a nonsymmetric vacuum state, leaving open the possibility that the quanta of the field (the "photons") are massive. This occurs as a result of a phenomenon known as *spontaneous symmetry breaking*. An example of such a field is the electroweak field theory of Weinberg, Salam, and Glashow.

GEODESY

Geodesy comprises the determination of the earth's external form and gravitational field, and the location of points with respect to earth-fixed reference systems. The earth's external form is customarily defined by the geoid: the equipotential of the earth's gravity field which most closely approximates the mean sea level.

The geoid is irregular in form, so that the mathematical representation thereof is necessarily an approximation. The most important approximation is an oblate ellipsoid of revolution, which is conventionally defined by its equatorial radius, a, and the flattening, f, equal to $(a - b)/a$, where b is the polar semidiameter. Location is conventionally expressed in coordinates referred to such an ellipsoid, in terms of the latitude ϕ, the angle between the normal to the ellipsoid and the equator; the longitude λ from the reference meridian, Greenwich; and altitude h above or below the ellipsoid.

If the ellipsoid is considered to be rotating with rate ω, and to be an equipotential for the combined effects (called gravity) of centrifugal and gravitational acceleration, additional parameters customarily required are γ_e, the acceleration of gravity at the equator; and m, the ratio of the centrifugal acceleration at the equator,

$\omega^2 a$, to γ_e. γ_e and m are connected to the total mass M contained in the ellipsoid by:

$$GM = a^2 \gamma_e [1 - f + 3m/2 - 15mf/14 + O(f^3)] \quad (1)$$

where G is the constant of GRAVITATION ($6.67 \times 10^{-8} \text{cm}^3 \text{g}^{-1} \text{sec}^{-2}$). The customary formula for the acceleration of gravity γ at geodetic latitude ϕ is:

$$\gamma = \gamma_e [1 + (5m/2 - f - 17mf/14) \sin^2 \phi + (f^2/8 - 5mf/8) \sin^2 2\phi + O(f^3)] \quad (2)$$

The customary formula for the gravitational potential external to the ellipsoid is:

$$V = \frac{GM}{r} \left[1 - J_2 \left(\frac{a}{r} \right)^2 P_2(\sin \phi) - J_4 \left(\frac{a}{r} \right)^4 P_4(\sin \phi) - O(f^3) \right] \quad (3)$$

In Eq. (3), V is written as positive, which is the convention of astronomy and geodesy, contrary to that of physics. In Eq. (3), P_2 and P_4 are Legendre polynomials, and

$$J_2 = 2f(1 - f/2)/3 - m(1 - 3m/2 - 2f/7)/3 + O(f^3) \quad (4)$$

while J_4 is usually taken as a quantity determined observationally from satellite orbits.

The discrepancies in location of the actual geoid and a well-fitting ellipsoid are nearly always 10^{-5} or less of the radius vector, while the discrepancies in intensity of the gravitational acceleration from that of the standard ellipsoid are nearly always 10^{-4} or less of the total intensity. The mathematical representation of these discrepancies may either be in the form of spherical harmonic coefficients or in the form of mean values for areas; the former being preferable for effects on satellites in orbit, and the latter for use of terrestrial data. The potential theory dealing with the relationship between variations in the location of the geoid and the intensity of gravitational acceleration is known in geodesy as Stokes' theorem.

There are five principal categories of measurement in geodesy.

(1) Horizontal control comprises the determination of the horizontal components of position—latitude and longitude—starting from fixed values for a certain point. It includes measurement of distances over the ground by metal tapes or by pulsing or modulating radio or light signals, and measurement of angles about a vertical axis by theodolites. Over the land, the relative horizontal position of points is obtained either by triangulation—a system of overlapping triangles with nearly all angles measured, but only occasional distances measured; or by traverse—a series of measured distances at measured angles with respect to each other; or by trilateration—a system of overlapping triangles with all sides measured. Much of the land area of the world is covered by triangulation, which gives the difference in latitude and longitude between points in the same network with a relative error of about 10^{-5}.

(2) Vertical control comprises the determination of heights, which is performed separately from horizontal control because of irregularities in atmospheric refraction. The most accurate method, leveling, measures successive differences of elevation on vertical staffs by horizontal lines of sight taken at intermediate points over short distances (less than 150 meters) balanced so as to minimize differential refraction effect. The datum to which vertical control refers is mean sea level as determined by tide gages. The accuracy is such that the error in difference of elevation between points on the same principal network should be a few tens of centimeters or less. Current research emphasis in horizontal and vertical control is on the determination of temporal changes in areas of earthquake potential.

(3) Geodetic astronomy comprises the determination of the direction of the gravity vector and the direction of the north pole at a point on the ground. Astronomic longitude is the angle between the meridian of the gravity vector and the Greenwich meridian and is determined by measuring the time of intersection of a line of sight by a star. Astronomic latitude is the angle between the gravity vector and the equatorial plane, and is determined by measuring the maximum altitude attained by a star. In these types of astronomic observation, several stars are normally observed which are selected so as to minimize error due to atmospheric refraction. Astronomic azimuth is determined by the measurement of the horizontal angle between a target and Polaris or other reference star.

(4) Gravimetry comprises the determination of intensity of gravitational acceleration. Most gravimetric observations are made differentially, by determining the change, with change in location, of the tension on a spring supporting a constant mass. These measurements are connected through a system of reference stations to a few laboratory determinations of absolute acceleration of gravity. The relative accuracy of gravimetry is about ±.001 cm/sec^2 on land and ±.005 cm/sec^2 at sea. The principal difficulty in its geodetic application is irregular distribution of observations.

(5) Satellite tracking comprises the determination of the directions, ranges, or range rates of earth satellites (including the moon) from ground stations or other satellites, plus altitudes above the sea surface. These observations will be affected both by errors in positions of the station with respect to the earth's

TABLE 1. GEODETIC PARAMETERS.

Parameter	Current Estimate and Standard Deviation
Mean sidereal rotation rate, ω	$0.7292115085 \times 10^{-4}$ sec^{-1}
Gravitational constant × mass, GM	$39860047(\pm 5) \times 10^{7}$ m^3/sec^2
Equatorial radius, a	6378137 ± 2 meters
Oblateness, J_2	$108263(\pm 0.5) \times 10^{-8}$

center of mass and by perturbations of the orbit by the earth's gravitational field; hence, in conjunction with a dynamical integration of the orbit, they are used to determine the position of tracking stations and the variations of the gravitational field. Radar altimetry from satellites is accurate to ±10 cm, and hence affected by oceanic temperature, salinity, and dynamics, as well as geoidal height and orbital perturbation. Satellites can also be used as elevated targets by simultaneous observations from several ground stations.

The principal practical application of geodesy is to provide a distribution of accurately measured points to which to refer mapping, navigation aids, engineering surveys, geophysical surveys, etc. The principal scientific interests in geodesy are the indications of the earth's internal structure from the variations of the gravity field and surface motions.

Numerical values of the leading geodetic parameters are given in Table 1.

GEOPHYSICS

Geophysics is the physics of the earth and the space immediately surrounding it and the interactions between the earth and extraterrestrial forces and phenomena. It consists of a number of interlocking sciences dealing with physical properties, its interior, its atmosphere, oceans, glaciated areas, its age, motions and paroxysms, and the practical applications of the acquired knowledge. All of these sciences use the methods of physics for measurements and analysis. From observational material, often of an indirect nature, attempts are made to derive abstract models of states and processes through advanced mathematical concepts, but in many cases through statistical relations.

Geophysics is an ancient science. In its early stages it was developed by the Greeks who attempted to determine the shape and size of the earth (Eratosthenes, 275–194 B.C.). Among its most illustrious contributors have been Galileo Galilei (1564–1642), Sir Isaac Newton (1642–1727) who dealt with the motions of the earth and its gravitational field, Alexander von Humboldt (1769–1859) and Karl Friedrich Gauss (1777–1855) who observed and developed theories of the geomagnetic field; and Vilhelm Bjerknes (1862–1951) who laid the foundation for the hydrodynamic theories of the atmosphere and the oceans. During the current century its roster of distinguished scientists includes: L. Vegard (polar aurora), Sidney Chapman (aeronomy), Sir Harold Jeffreys and F. A. Vening-Meinesz (structure of the earth); Emil Wiechert, Boris Galitzin, Beno Gutenberg and J. B. Macelwane (seismology); H. U. Sverdrup (oceanography); C. G. Rossby and T. Bergeron (meteorology); A. Wegner, H. Hess and J. T. Wilson (tectonophysics).

Geophysics is the outstanding example of organized international scientific cooperation. In the 19th Century the International Polar Year (1882) served coordinated observations of the geophysical mysteries of the polar regions. Major milestone's in the development of the science were the International Geophysical Year (IGY) and the period of International Geophysical Cooperation (1957–1959), when 8000 scientists from 66 nations tackled a host of physical mysteries of our planet. The IGY started man's most spectacular ventures to date: The launching of artificial earth satellites and other space probes. It started the conquest of the icy wastes of the Antarctic continent where many geophysical secrets are locked, and through the Antarctic Treaty created the only weapon-free area in the world solely devoted to scientific research. The IGY took place in an interval of high solar activity. It was followed by the year of the quiet sun (IQSY, 1964–65) to cover the range of solar influences on the earth (see SOLAR-TERRESTRIAL PHYSICS PROGRAM). The Global Atmospheric Research Program (GARP) started with a number of observational experiments covering monsoons, tropical circulations, and a coordinated complete global coverage of weather phenomena (FIGI, 1980).

A brief survey of various subfields of geophysics follows.

Geochronology is study of the age of the earth and its various geological formations. Inadequate earlier methods of sedimentology have been replaced by the use of radioactive decay constants and isotope ratios. This has made it possible to date approximately all major geological eras. For the oldest rocks, the decay of ^{238}U to ^{206}Pb has led to ages of around 3×10^9 years.

Geodesy deals with the size and shape of the earth and its gravitational field. Because of the rotation of the earth, its lack of absolute rigidity, crustal mass distribution, and tidal forces, the shape is not quite spherical. The largest deviation from sphericity is the flattening at the poles. Historically this polar flattening has been determined by surface measurements and lunar observations, but since 1957 the most accurate determinations have been made by observations of the motions of artificial satellites. The current estimate of the flattening is 1:298.257. The sea-level surface of the earth, which is irregular, is referred to as the *geoid*, which represents an equipotential surface. The undulations of the geoid have been determined by surface gravity measurements and by utilization of data from artificial satellites. The value of gravity depends mainly on latitude because of the flattening and the variation of centrifugal force from pole to equator. The normal value of gravity at the earth's surface, in centimeters per second per second is represented by

$$\gamma = 978.0327(1 + 0.0053024 \sin^2 \varphi - 0.0000058 \sin^2 2\varphi),$$

where φ is latitude. This formula is based on the Geodetic Reference System 1980, representing geodetic constants officially approved by the International Union of Geodesy and Geophysics in 1979.

Gravity measurements have shown that, in spite of large mass differences at the surface, the earth is nearly in isostatic equilibrium. Various crustal blocks act as if they floated in a dense subcrustal material. The undulations of the geoid do not exceed 100 meters. Approximate dimensional figures for the earth are: surface area 510×10^6 km^2; volume 1.083×10^9 km^3; average density 5.516 g/cm^3; mass 5.974×10^{27} grams; equatorial radius 6,378.137 km.

The deformations of the solid earth by tidal forces are an additional consideration. The twice daily occurring tides are observed by deflections of the vertical or variations of gravity. For the lunar tides the variations amount to 0.165 milligal, for the sun to 0.076 milligal (one milligal equals 10 micrometers per sec per sec). The maximal elevation of the geoid is 35.7 cm, the largest depression 17.8 cm, for the lunar effect; the total solar tide can reach 24.6 cm. The combined total at new and full moon is 78.1 cm.

Geomagnetism deals with one of the most important physical characteristics of the earth. Its magnetic field can be represented by a centered dipole, which at present is inclined at an angle of about 11° to the axis of rotation. Its field strength at the earth's surface is about 0.3 gauss at the equator and 0.6 gauss near the poles. There are small slow secular changes both in ionosphere direction and strength of the field. About $\frac{9}{10}$ of the field strength, designated as the main field, is assumed to be caused by internal forces, principally by differential rotation between the earth's core and its mantle. About $\frac{1}{10}$ of the field is externally produced by a ring current in the ionosphere. That part is often disturbed by electron and proton invasions from solar eruptions. Major flares cause magnetic storms lasting from a few minutes to several hours. In the polar zones these are often accompanied by auroras. In those regions field disturbances of 0.035 gauss have been observed. Small, short disturbances of the field are common. The earth's magnetic field, the *magnetosphere*, extends far beyond the atmosphere, especially on the side away from the sun, where the distance of the magnetopause is about 10 earth radii. The force of the magnetic field in the space surrounding the earth has created two zones where solar protons and electrons are trapped, the van Allen belts.

The magnetic field distribution at the earth's surface has been mapped, showing not only the total intensity but also inclination and declination. The latter is of importance for direction finding with magnetic compasses. The elements of the earth's magnetic field undergo slow secular changes and in geologic time intervals even reversals of polarity of the field have been observed. Paleomagnetisms, determined from the remanent magnetization from the time of formation of iron-bearing rocks, not only show rotations of the field but divergent motions of the continents.

Seismology deals with study of earthquakes. Most of them can be attributed to breaks in the earth's crust. A few may be subcrustal and caused by phase transformations. Some minor ones are associated with collapse of cavities and volcanic eruptions. All of them are characterized by the sudden release of elastic waves. These are longitudinal, transverse, Rayleigh or Love (surface) waves. They are recorded at seismographic stations, now often consisting of arrays of digitally recording sensors responding to various frequencies. Through analysis of the travel times of various wave groups from the point of origin and their amplitudes, the hypocenter and epicenter of an earthquake as well as its magnitude can be determined. Like other waves, earthquake waves can be reflected and refracted upon entering a different medium. The internal constitution of the earth has been derived primarily from seismic evidence. This reveals an upper and a lower crust, an upper and lower mantle, an outer and an inner core. The boundary between crust and mantle was first discovered by A. Mohorovičić in 1909. Its depth varies from about 5 km in some oceanic areas to 60 km in some continental regions. Seismic wave analysis also permits some statements on the strength of materials in the earth. The crust and upper mantle are rigid (lithosphere) with a more plastic layer below (asthenosphere). Present interpretations assume that the inner core (1370 km thick) is solid and the outer core (2100 km thick) is liquid. The scattering properties of various rock types in the crust reveal many inhomogeneities and seismic procedures, and are widely used in geophysical prospecting for mineral resources.

Careful records kept during the 20th Century, together with historical records, have yielded a fair picture of magnitude and distribution in time and space of earthquakes. Such seismicity studies permit risk estimates and hazard mitigation. The effort devoted to earthquake prediction has not yielded much in the way of progress toward that elusive goal. The principal approaches are geodetic observations of ground motions, interpretation of foreshocks, changes in wells, radon exhalations, and even animal behavior. Earthquakes under the oceans often result in seismic sea waves (tsunamis). A warning system for endangered coastal areas has been quite successful because of the slow travel times of these waves.

Geodynamics deals with the slow motions of crustal material. In 1912 Alfred Wegener presented a hypothesis of continental drift. This was fiercely contested until the 1960s. By then suboceanic cores had shown ocean-floor spreading and satellite geodetic observations yielded drifts of continental plates of several centimeters per year. This has led to the plate tectonics model which postulates the motion of lithospheric and upper mantle layers (100 km thick) over the less viscous asthenosphere, driven by convective subcrustal thermal circulations. There is evidence for different and separate convective systems under the continents and oceans. At the edges of the various plates form mountain systems, volcanic arcs, and earthquake zones. Extrusions of material from lower layers take place and some of the plates seem at their edges to submerge under others. Although problems and contradictions still remain with this model much research in this area promises clarifying discoveries.

Volcanology deals with some of the most spectacular phenomena in geophysics. They include explosive eruptions, lava flows, gaseous exhalations, magma intrusions, geysers, and hot springs. Since the last ice age it is estimated that about 1300 volcanoes have been active with over 5500 dated eruptions. Duration of eruptive activity and amounts of ejecta vary widely. In historical times the 7–12 April 1815 eruption of Tambora (Indonesia) was the greatest, with an estimate of 100 km^3 of tephra ejected. The 26–27 August 1883 eruption of Krakatoa (Indonesia) which killed 36,000 persons, threw an estimated 10^7 tons of dust into the air. This caused spectacular sunsets. The dust veil stayed in the stratosphere for several years. Some hypotheses of climatic fluctuations have been based on such veils. The dust from the much smaller eruption of Mt. St. Helens (Oregon) on May 18, 1980, after 123 years of dormancy, caused observable reduction in local maximum temperatures. Prediction of volcanic eruptions remains an uncertain art. It is based on precursory seismic activity, gaseous exhalations, and lava movements in or near the craters. Areas of present or ancient volcanic activity show abnormal geothermal gradients and are in some areas being tapped for electric energy production.

Meteorology and *aeronomy* are concerned with the physical state and the motions of the atmosphere, which is divided into a number of layers. The lowest is the *troposphere* with an average thickness of 7 to 8 km in polar regions and 13 km in the equatorial zone. Temperatures decrease to an interface, called the *tropopause*, where polar temperatures are about 218 K, at the equator about 193 K. The next higher layer is the *stratosphere*, where temperatures stay nearly isothermal in the first few kilometers and then increase again above about 20 km to a maximum of 270 K at 50 km where, above the stratopause, the *mesosphere* begins. The warming in the stratosphere is produced by absorption of the short wavelengths of solar radiation by photochemically produced ozone (O_3). The anthropogenic threat to the ozone layer by oxides of nitrogen and halomethanes has become a major environmental concern. In the mesosphere temperatures again decrease to 180 K at about 80 km, where notable dissociation of the permanent constituents of the atmosphere occurs. This is the region of rare noctilucent clouds; above this region lies the *thermosphere*. Here by vigorous interaction with the solar wind and cosmic rays many of the atmospheric constituents are in excited atomic states and ionized. There are several temporarily or permanently ionized layers in the thermosphere, often designated as *ionosphere:* The *D*-layer below 90 km, the *E*-layer between 90 and 180 km, and the *F*-layer above 160 km. The ionization undergoes a diurnal variation and large changes in response to the solar activity rhythms.

Most manifestations of weather take place in the troposphere. They are governed by the general atmospheric circulation, which is stimulated by the differential heating between tropical and polar zones. The resulting motions in the air are subject to the laws of fluid dynamics on a rotating sphere with friction. They are characterized by turbulence of varying time and space scale. Evaporation of water from the ocean and its transformation through the vapor state to droplets and ice crystals are important symptoms of the weather producing forces (see METEOROLOGY).

Hydrology studies the water cycle on the earth in detail. It includes the runoff from precipitation, the surface courses of water and their floods, the deposited forms of water as snow and ice, and the return of water to storage underground or the ocean. The study of ice caps, sea ice, and glaciers (cryosphere) is an important phase of this field and contributes to the understanding of the earth's heat balance. Stream flow has been successfully mathematically modelled but flash floods still present a major problem.

Oceanography has a broad overlap with both meteorology and hydrology. It includes the study of wind-driven waves and currents, and the storage of heat and its release to the atmosphere. Ocean currents are an important mechanism for the equalization of the temperature differences between low and high latitudes. Near some coast lines, wind-induced upwelling of highly nutrient deep ocean water is of major importance for the fishing industry. Temperature and salinity differences are additional causes for the dynamics of the ocean but most exchanges take place in a shallow mixed surficial layer, only about 100 meters thick, but occasionally reaching to 500 meters depth. Below that is a thermocline with high density cold water to the bottom. Exchange time of this abyssal water with higher layers is measured in centuries.

The tidal motions and their dependence upon configuration of ocean basins and coastal lines were among the earliest geophysical phenomena observed and analyzed by man. They were also the first to be predicted by computer. These predictions are now quite precise in timing and amplitude and are of great importance for ships with ever increasing draft.

Exploration geophysics uses physical methods derived from the study of earthquakes and magnetic and gravitational fields. These, using highly sensitive instruments, permit the discovery and mapping of the structure and inhomogeneities in the upper geological layers. These result in local anomalies and permit inferences about potential mineral resources. Magnetic anomalies, often associated with ore bodies, can be rapidly mapped by sensitive airborne magnetometers. Seismic techniques, using small explosions and a multiple array of sensors coupled to a computer use reflection and refraction of wave energy to map geological structures three-dimensionally. This technique is extensively used for petroleum exploration. It can be readily applied also for mapping of off-shore stratigraphy. Radioactivity and geochemical procedures are auxiliary methods, often used in boreholes. Distortions of artificially created electric fields in the ground can indicate the presence of shallow ore bodies but are now more extensively employed for groundwater exploration.

GRAND UNIFIED THEORIES

Introduction Much of our progress in understanding the basic interactions of matter has involved the development of unified theories, in which two or more apparently unrelated forces are realized to be different manifestations of a more fundamental underlying force. The first modern example was the unification of the electric and magnetic forces into the electromagnetic interaction by Maxwell and others in the 19th Century. Maxwell's equations not only reveal the intimate relation of the electric and magnetic fields, but also predict the existence of electromagnetic waves that can be emitted or absorbed by charged particles. We now know that the quanta of these waves are massless photons (γ) carrying an internal spin of one unit of Planck's constant $\hbar$. They are therefore referred to as *spin* -1 or *vector* (or *gauge*) *bosons*.

The next successful unification combined the electromagnetic force not with gravity (as had been unsuccessfully attempted by Einstein during much of his life) but rather with the weak force responsible for β decay. This electroweak theory of Glashow, Weinberg, and Salam (GWS), which reached its fruition in the early 1970s, combined the intermediate vector boson model of the weak interactions (Fig. 1a, b), in which the weak interactions are mediated by the exchange of massive electrically- charged vector bosons W^+ and W^-, with quantum electrodynamics, in which the electromagnetic force is mediated by the exchange of photons (see Fig. 1c). The result was a mathematically and physically consistent quantum field theory. Furthermore, the electroweak unification predicted the existence of a new electrically-neutral vector boson (the Z). The subsequent discovery of the weak neutral current interaction, mediated by the Z (Fig. 1d) along with the discovery of the charm quark (needed to correctly describe strongly interacting particles in the model) provided a dramatic verification of the electroweak unification.

Grand unified theories (GUTs), which are so far untested, go one step further and unify the electroweak interactions with the nuclear or strong force. (The strong interactions are thought to be due to the exchange of massless vector gluons (G) between quarks, which are believed to be the constituents of the proton, neutron, pion, and other strongly interacting particles. See Fig. 1e). In addition to unifying three of the four known interactions, GUTs have the attractive feature of regarding the quarks and the non-strongly interacting particles or leptons (electron, muon, tau, and neutrinos) as fundamentally similar.

Just as the electroweak unification predicted the existence of the Z boson, grand unified theories predict the existence of new, extremely massive vector bosons. In most GUTs, these new bosons can mediate the decay of the proton into lighter particles, such as a positron and neutron pion, as shown in Fig. 2. This is a remarkable prediction because it has generally been believed that the proton is absolutely stable. It is known experimentally that if the proton does decay, its average lifetime must be longer than 10^{30} yr, which corresponds to fewer than one decay per ton of matter per year! The strength of the new interactions can be predicted from the observed strength of the strong and electroweak interactions. Within the simplest grand unified theories, the proton lifetime is predicted to be $\tau_p \simeq 10^{29\pm2}$ yr, precisely the range that may be observable in new, dedicated experiments!

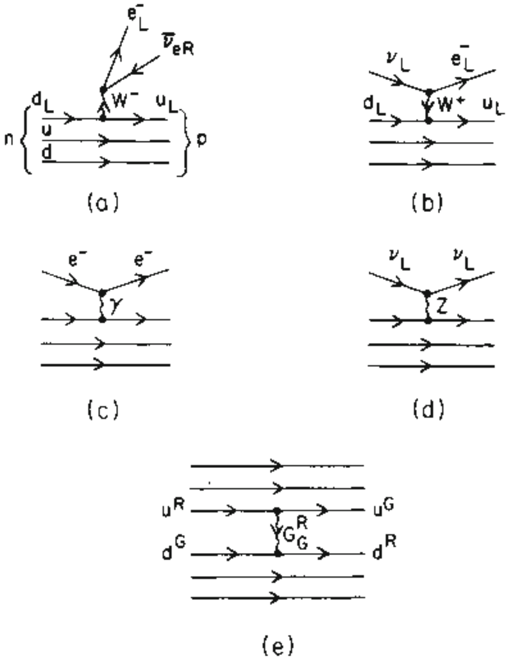

FIG. 1. (a) Beta decay $n \to pe^-\bar{\nu}$. (b) $\nu N \to e^-X$, where N is a nucleon (proton or neutron) and X represents any strongly interacting final state (e.g., $X = N, N\pi, N\pi\pi$). (a) and (b) occur via the exchange of charged weak bosons $W^\pm$. (c) The electromagnetic process $e^-N \to e^-X$. (d) The weak neutral current process $\nu N \to \nu X$. In (a)–(d), the quark color quantum number is not changed, but the flavor (u, d, etc.) is changed in charged current processes. (e) A strong interaction between quarks via the exchange of a gluon. Quark color (but not flavor) is changed in the transition.

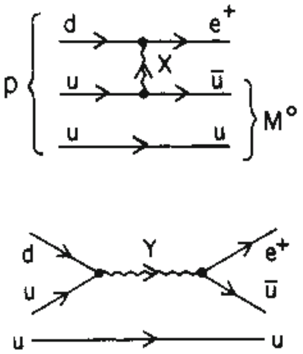

FIG. 2. Typical diagrams in which proton decay is mediated by the exchange of superheavy bosons carrying both flavor and color quantum numbers.

The same new interactions that lead to the instability of the proton may explain the longstanding puzzle of the apparent excess of matter over antimatter in the universe. Instead of having to postulate this excess as an asymmetric initial condition on the big bang, it is possible that it was generated dynamically by the new interactions in the first 10^{-35} seconds after the big bang when the universe was incredibly hot and dense! Of course, all matter will ultimately decay into a gas of electrons, positrons, neutrinos, and photons in a time $\gtrsim 10^{30}$ yr. if the universe does not collapse first!

In addition to their theoretical elegance and their fascinating predictions about the creation and decay of matter, grand unified theories yield explanations of the relative electric charges of quarks and leptons and of the value of the weak interaction angle, and they predict the existence of superheavy magnetic monopoles. These as well as difficulties of GUTs are detailed below. Particle physicists eagerly await the confirmation or refutation of GUTs in proton decay experiments.

The Standard Model There now exists a renormalizable (i.e. free from unmanageable divergences) field theory of the elementary particles and their interactions that is compatible with all known experimental facts. In this standard model the electroweak and strong interactions are gauge invariant, which means that the forms of the equations of motion are left invariant under a group of transformations of the fields into each other, which can be performed independently at different space-time points. Gauge invariance requires the existence of N vector or gauge bosons A_i, one for each of the N generators of the symmetry group. The amplitude for a fermion (lepton or quark) k to emit or absorb boson i and be transformed into fermion j is $gL^i{}_{jk}$, where g is the strength parameter or coupling constant of the theory and $L^i{}_{jk}$ is the jk element of the ith group generator (Fig. 3a). The forms of the self-interactions between the gauge bosons are also prescribed by the gauge symmetry (Fig. 3b).

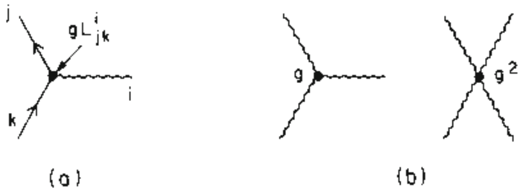

FIG. 3. (a) Vertex for fermion k to be transformed into fermion j upon emission or absorption of boson i. (b) Self-interactions between three or four bosons.

For example, the GWS electroweak theory is based on the gauge group $SU_2 \otimes U_1$. The SU_2 group implies three gauge bosons W^+, W^-, and W^0, with gauge coupling g, while the U_1 group involves one neutral boson B with coupling g'. The charged bosons W^+ and W^-, with masses $m_{W^\pm} \simeq 83$ GeV/c^2, mediate the ordinary charged-current weak interactions, the neutral boson $Z = W^0 \cos\theta_W - B \sin\theta_W$, with $m_Z \simeq$ 94 GeV/c^2, is exchanged in neutral current processes, and the massless photon $\gamma = W^0 \sin\theta_W + B \cos\theta_W$ is responsible for electromagnetism. The weak angle is $\theta_W \equiv \tan^{-1} g'/g$ and the electric charge is $e = g \sin\theta_W$. Parity nonconservation in the weak interactions is introduced by assigning the left- and right-handed fermions to different representations of the $SU_2 \otimes U_1$ group. The left-handed up and down quarks (u_L, d_L) and the left-handed neutrino and electron (ν_{eL}, e_L) transform as doublets, which means that they are related by the symmetry operators and can be transformed into each other upon the emission or absorption of a W^+ or W^-. (The color quantum number is unchanged in these processes). The more massive left-handed particles (c_L, s_L), (t_L, b_L), ($\nu_{\mu L}$, μ_L^-) and ($\nu_{\tau L}$, τ_L^-) also transform as doublets. The right-handed fermions are unaffected by SU_2 transformations and do not couple to $W^\pm$ bosons (they do couple to the Z and γ).

The basic equations of gauge theories do not allow mass terms for the gauge bosons. The W^+, W^-, and Z masses are introduced by spontaneous symmetry breaking. This can occur if the ground state contains a nonzero expectation value of spin-0 Higgs fields (essentially a Bose condensation). The $W^\pm$ and Z bosons (but not the photon) couple to the Higgs field and develop a nonzero effective mass.

The strong interactions are described by quantum chromodynamics (QCD), which is a gauge theory based on the gauge group SU_3 with gauge coupling g_s. There are eight massless gauge bosons or gluons in QCD. Quarks are transformed from one color state (R = red, G = green, B = blue) into another upon emission or absorption of gluons, with the flavor quantum number (u, d, c, s, etc.) unchanged. The QCD couplings of left-and right-handed quarks are equal (parity is conserved), and there are no direct couplings of gluons to the SU_3 invariant leptons, which therefore do not participate in the strong interactions.

Despite the many successes of the standard model, most physicists believe that it is too arbitrary and complicated to be taken seriously as the fundamental theory of elementary particles. For example, the standard model involves the direct product of three different gauge groups with three distinct coupling constants ($\alpha_s = g_s^2/4\pi \simeq 0.25$, $\alpha_g \equiv g^2/4\pi \simeq 0.03$, $\alpha = e^2/4\pi \simeq 0.007$ when measured at laboratory energies). There is no fundamental explanation for the pattern of spontaneous symmetry breaking, for the breaking of parity in the weak but not the strong interactions, for the existence of repeated fermion families, or for the relation between the electric charges of the quarks and leptons. There are many arbitrary parameters, such as coupling constants, fermion masses, and weak mixing angles (19 in all if the neutrinos are massless). Finally, gravity is not incorporated in the theory.

Grand Unified Theories Grand unified theories constrain some of the arbitrary features of the standard $SU_3 \otimes SU_2 \otimes U_1$ model by embedding it in a simple (i.e., not a direct product) group G with a single coupling constant g_G. The simplest example is the SU_5 model of Georgi and Glashow. SU_5 implies 24 gauge bosons, of which 12 are those of the standard model. The other 12 are supermassive ($m > 10^{14}$ GeV/c^2) and carry both flavor and color quantum numbers. They are the X and Y bosons, with electric charges $\frac{4}{3}\,e$ and $\frac{1}{3}\,e$, each of which comes in three color states, and their antiparticles. Quarks, antiquarks, leptons, and antileptons are related by SU_5 transformations and are fundamentally similar. The left-handed fields (ν_{eL}, e_L^-, $\bar{d}_{\alpha L}$, $\alpha = R, G, B$) form a five-dimensional representation 5*, which means that they can be transformed into each other upon emission or absorption of gauge bosons. Similarly, the fields (e_L^+, u_L^α, d_L^α, and $\bar{u}_{\alpha L}$) form a 10-dimensional representation (the right-handed fields are related by CPT). The heavier fermion families are assigned to additional 5* and 10-dimensional representations.

Other grand unified theories are based on still larger groups, such as SO_{10} or E_6. They involve additional supermassive bosons emitted in transitions between the 5* and 10, between different families, or between the ordinary and hypothetical new fermions.

Implications of Grand Unification (a) There is basically only one interaction. The complicated structure of interactions observed at low energies is due to the pattern of spontaneous symmetry breaking (gauge boson masses). Similarly, the quarks (q) and leptons (l) are closely related. This explains the simple relation $\frac{1}{2}\,q_u = -q_d = -\frac{1}{3}\,q_e = \frac{1}{3}\,e$ between quark and lepton charges (charge quantization).

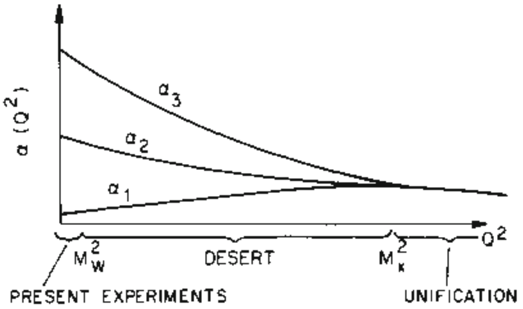

FIG. 4. Variation of the effective couplings $\alpha_3 = \alpha_s = g_s^2/4\pi$, $\alpha_2 = \alpha_g = g^2/4\pi$, and $\alpha_1 = \frac{5}{3}\,\alpha' = \frac{5}{3}\,g'^2/4\pi$ with momentum.

(b) Because of vacuum polarization and other higher order corrections, measured gauge couplings actually depend logarithmically on the typical squared momentum Q^2 in an experiment. The observed low energy couplings are predicted to approach a common value (up to known normalization factors) $\alpha_G = g_G^2/4\pi$ at momenta $Q^2 \gtrsim M_X^2$ for which spontaneous symmetry breaking can be ignored, as in Fig. 4. From the observed ratio of α_s/α at low energy and the theoretical Q^2 dependence, one can predict: (i) $M_X \simeq M_Y \simeq 2.4 \times 10^{14 \pm 0.5}$ GeV/c^2, which is twelve orders of magnitude larger than M_W and M_Z! (The threshold-free region between M_W and M_X is referred to as *the desert.*) (ii) The requirement that all three couplings meet at M_X yields the additional prediction: $\sin^2\ \theta_W = \alpha/\alpha_g = 0.214 \pm 0.005$, which is in remarkable agreement with the experimental value 0.215 ± 0.012 obtained from neutral current reactions. Predictions (i) and (ii) hold for essentially all grand unified theories with no new mass scales in the desert and no exotic fermions or weak interactions.

(c) The X and Y bosons can mediate proton decay through diagrams such as those in Fig. 2. The average proton lifetime in years in the SU_5 model is predicted to be $\tau_p \simeq \lambda M_X^4/(\alpha_G^2\, m_p^5) \simeq (0.8 - 13) \times 10^{29}\ (M_X/2.4 \times 10^{14}\ \text{GeV}/c^2)^4 \simeq 3 \times 10^{29 \pm 2}$ yr, where the coefficient λ has been estimated using several phenomenological models of the proton and meson wave functions. This extremely long lifetime is due to the very short range ($R_X \sim \hbar/M_X c \simeq 10^{-28}$ cm) of the interaction. The predicted lifetime is comparable to current experimental limits $\tau_p{}^{\exp} \gtrsim 10^{30}$–$10^{31}$ yr and is within the sensitivity of several dedicated experiments now under construction. Most other theories give similar predictions for τ_p, although models with supersymmetry or large mixing effects can lead to longer lifetimes.

The dominant decay modes are $p \rightarrow e^+ M^0$ and $p \rightarrow \bar{\nu} M^+$, where M^0 represents neutral mesons (π^0, ρ^0, η, ω, $\pi^+\pi^-$, . . .) and $M^+ = \pi^+, \rho^+, \pi^+\pi^0$, ... Bound neutrons can decay into $\bar{\nu} M^0$

and e^+M^-. Different gauge groups (SU_5, SO_{10}, etc.) can be distinguished by their predictions for the ratio of e^+M^0 to $\bar{\nu}M^+$ decays. All models with a desert between M_W and 10^{14} GeV/c^2 imply the selection rule $\Delta B = \Delta L$, where B and L are baryon and lepton number. ($B = +1$ or -1 for nucleons (p or n) or antinucleons, respectively. $L = +1$ for leptons (e^-, ν) and -1 for antileptons.) Theories with lower mass scales (which are disfavored by the $\sin^2 \theta_W$ test) can predict baryon number violating processes with different selection rules. For example, some models with particles with mass $\simeq 10^6$ GeV/c^2 predict that free neutrons can oscillate into antineutrons in a time scale $\tau_{n\bar{n}} \gtrsim 10^7$ sec and that two nucleons in a nucleus can annihilate in a time $\tau_{\text{nuc}} \gtrsim 10^{30}$ years.

(d) The baryon-number-violating interactions would have been very important in the first 10^{-35} sec after the big bang when the temperature kT was comparable to $M_X c^2$. Relics of that first instant may be observable today.

For example, grand unified theories may explain the baryon (matter-antimatter) asymmetry $n_B/n_\gamma \simeq 10^{-10\pm1}$, $n_{\bar{B}}/n_B \simeq 0$, observed in our part of the universe, where n_B, $n_{\bar{B}}$, and n_γ are the number densities of baryons (p, n), antibaryons ($\bar{p}$, $\bar{n}$), and blackbody photons. If baryon number were absolutely conserved and there is no large scale separation of baryons and antibaryons in the universe (no plausible separation mechanism has been found) then the net baryon number would have to be postulated as an asymmetric initial condition on the big bang. Alternatively, $n_B - n_{\bar{B}}$ may be generated dynamically in GUTs. The ingredients needed are (i) B violation (this alone is sufficient to erase or dilute any initial net baryon number), (ii) nonequilibrium of the $\Delta B \neq 0$ interactions, (otherwise $n_B = n_{\bar{B}}$), and (iii) CP and C violation (to distinguish baryons from antibaryons).

A possible specific mechanism is that superheavy spin-0 Higgs bosons and antibosons drop out of equilibrium at $kT \lesssim M_X c^2$. Their CP-violating decays into qq, $\bar{q}\bar{q}$, $\bar{q}l$, and ql can create a slight excess of quarks over antiquarks. These eventually form nucleons after most $q\bar{q}$ pairs annihilate. Detailed estimates are difficult, but the ratio $n_B/n_\gamma \simeq 10^{-10}$ appears quite plausible.

Grand unified theories also predict the existence of superheavy ($m \simeq 10^{16}$ GeV/c^2) magnetic monopoles, which would have been produced prolifically in the big bang. The monopole density depends sensitively on the nature and sequence of phase transitions (in the ground state spontaneous symmetry breaking pattern) in the early universe. Second-order transitions probably imply many orders of magnitude more monopoles than are allowed by limits on the total mass density of the present universe. Strongly first-order transitions may sufficiently suppress monopole production and may lead to a period of exponential expansion of the universe that could solve the cosmological horizon and flatness problems. However, it is not clear that this expansion would terminate in an acceptable manner. Phase transitions and other aspects of GUTs may also be of relevance for galaxy formation.

(e) Almost all GUTs (with the exception of the SU_5 model) predict nonzero masses for the neutrinos. Estimates are very model dependent, typically ranging from $m_\nu = 10^{-9}$ eV/c^2 to 10^{+2} eV/c^2. Neutrino oscillations associated with mass $> 10^{-5}$ eV/c^2 could explain the missing solar neutrinos. Neutrinos in the 10–100 eV/c^2 range could account for the missing mass in galactic clusters and would dominate the mass density of the universe.

Some of the simpler GUTs, such as the simplest SU_5 model, correctly predict the ratio of the b quark and τ lepton masses.

Outstanding Problems Despite their attractive features and successful predictions, grand unified theories have several serious problems and shortcomings. (a) Perhaps the most severe is the gauge hierarchy problem, which refers to the incredibly tiny ratio $(M_W/M_X)^2 \simeq 10^{-24}$. This quantity is not a natural feature of GUTs: in the usual models it must be put into the theory by hand by fine tuning parameters. Theories with composite Higgs bosons and models with an approximate low energy symmetry between bosons and fermions (supersymmetry) are promising approaches to this problem, but neither has been completely successful.

(b) Another problem is that GUTs have not shed much light on the fermion mass spectrum and mixings, the reason for heavy fermion families, or the origin of CP violation.

(c) Superheavy magnetic monopoles are a serious problem. Much work remains to be done on the dynamics of phase transitions in the early universe and on possible monopole suppression mechanisms.

(d) Finally, gravity has so far resisted all attempts at unification. Supergravity theories, in which spin-$\frac{3}{2}$ fermions are related to spin-2 gravitons, appear to be a promising direction.

GRAVITATION

Gravitation is the phenomenon characterized by the mutual attraction of any two physical bodies. This universal character of the gravitational force was first recognized by Sir Issac Newton who also gave its quantitative expression. For point masses or spherical bodies a simple expression results:

$$F = \frac{GM_1M_2}{R^2} \qquad (1)$$

In addition to the masses M_1, M_2 of the two bodies and their distance apart R, the force depends only on a constant $G = 6.670 \times 10^{-8}$ dyne cm^2 which is independent of all properties of the particular bodies involved. The same force law describes the motion of the planets around the sun, of the moon around the earth, as well as the falling of an apple to the earth. A body moving under an inverse square law as given in Eq. (1) satisfies the three laws established by Kepler for the motion of the planets around the sun:

(1) The planets move in elliptical orbits with the sun at one focus (the general orbit is a conic section) (Fig. 1).

(2) The radius vector sweeps out equal areas in equal times.

(3) The square of the period of revolution is proportional to the cube of the semimajor axis: $a^3 = (2\pi)^{-2}GM_\odot T^2$. Here $M_\odot$ is the mass of the sun and T is the period of the planet. These results together with a detailed analysis of anomalies in the motion of the moon established the correctness of the Newtonian theory of gravitation (see KEPLER'S LAWS).

Recently, careful calculations have been carried out to determine the orbits of the artificial satellites which have been launched by the United States and the Soviet Union. These have required modifications in the force law Eq. (1) to take into account the deviation of the earth's figure from a sphere and the anistropy of the earth's density as well as the atmospheric drag. The success of the space program to date is an additional tribute to Newton's genius. Other calculations study powered space flight in order to examine possible orbits for exploration of the solar system. There is every reason to believe that Newton's gravitational theory is sufficiently accurate for this purpose. Einstein's modification of the theory, to be described below, will probably have little effect on our space program for some time to come.

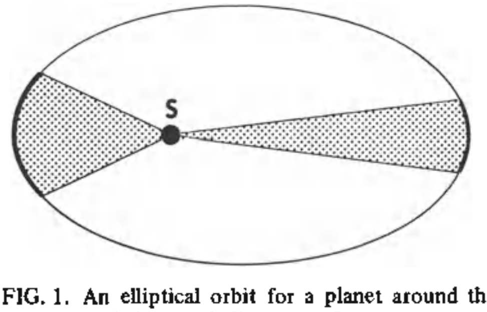

FIG. 1. An elliptical orbit for a planet around the sun. The shaded areas indicate equal areas swept out in equal times at different parts of the orbit. Clearly, the speed of the planet varies with its position in its orbit.

The weight of a body of mass M on the earth is the force with which it is attracted to the center of the earth. On the surface of the earth the weight is given by

$$W = Mg$$

where the acceleration due to gravity is obtained from Eq. (1):

$$g = \frac{GM_E}{R_E{}^2} = 980 \text{ cm/sec}^2 = 32 \text{ ft/sec}^2$$

All freely falling bodies near the surface of the earth are accelerated at the same rate g. It is for this reason that Galileo found that both light and heavy objects take the same time to reach the ground when dropped from the Leaning Tower of Pisa.

An astronaut is said to be in a state of weightlessness when he is in orbit. Strictly speaking, he still has weight, for the earth's gravity still acts on him. Otherwise he would fly off into outer space. However, when in free fall, the local effects of the gravitational field are eliminated for the astronaut. Objects which are released fall together with him and hence remain in his vicinity, unlike the situation on the ground. Therefore, the organs of the body respond as though the gravitational field were absent and this gives the sensation of weightlessness. Conversely, we sense the earth's gravity and feel weight because we are supported by the earth's surface.

Gravitational Field According to Newtonian theory, the sun exerts the gravitational force directly on the earth without an intervening medium for transmitting that force. The behavior of such forces is called "action at a distance." To overcome the conceptual difficulty of a force acting directly over large distances, one assumes that a gravitational field fills all space. The force acting on any mass is determined by the gravitational field in its neighborhood. Thus, at the point P a distance R from the center of the earth, the gravitational field has the magnitude

$$\mathcal{G} = \frac{GM_E}{R^2}$$

and magnitude of the force on a mass M at P is simply $F = M\mathcal{G}$. Note that the field is to exist at P even in the absence of the mass M.

It is sometimes convenient to introduce the gravitational potential which determines the field through its gradient. For a spherical earth, it is defined as

$$\phi = -\frac{GM_E}{R}, \quad \mathcal{G} = -\ \mathrm{grad}\ \phi$$

In general ϕ will satisfy Poisson's equation

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} = 4\pi\rho \qquad (2)$$

ρ is the density of matter. The potential energy of a mass M, in the field is simply expressed in terms of ϕ,

$$V = M\phi$$

This is equal to the work which must be done by an outside agent if he were to move the mass M to its location in the gravitational field from infinitely far away.

A body has enough speed to escape from the earth's attraction if its total energy, kinetic plus potential, is zero or greater. From the definition of potential energy above, the *escape velocity* at a distance R from the center of the earth is given by

$$v_{es}^2 = \frac{2GM_E}{R} \qquad (3)$$

At the surface of the earth the $v_{es} = 11$ km/sec. It is interesting to note that when $R = R_s$, the Schwarzschild radius, the escape velocity is just equal to the velocity of light, $c(3 \times 10^5$ km/sec.):

$$R_s = \frac{2\,GM}{c^2} \qquad (4)$$

The subscript E has been dropped from M because the *Schwarzschild radius* R_s is defined for any mass. For the earth, $R_s = 0.9$ cm while for the sun, $R_s = 3$ km. Now, according to special relativity, the speed of light is a limiting speed for matter and cannot be exceeded by any signal. Therefore, it is fortunate that the Schwarzschild radii of the sun and the earth are interior to their surfaces. Otherwise we would receive no energy from the sun and we could not explore the solar system.

Although one can introduce the gravitational field, it is an auxiliary concept in Newtonian theory for the field has no independent dynamical behavior as is true of the electromagnetic field (e.g., electromagnetic waves). At any time, the Newtonian gravitational field is determined by the configuration of masses at that instant and does not depend on previous history or state of motion. Thus, if the sun were to vanish, the gravitational force on the earth would immediately be removed. This property may be thought of in terms of an infinite velocity of propagation for the gravitational field. Letting the velocity of light become infinite in Maxwell's equations eliminates all independent dynamical behavior for the electromagnetic field. In that case there could be no radio or television. The special theory of relativity which is based on the velocity of light in vacuum being the maximum velocity for the transmission of energy, implies that Newton's theory requires modification.

Principle of Equivalence The mass of a body may be measured either by weighing $W = Mg$ (gravitational mass) or by observing its motion under a known applied force using Newton's second law of motion $F = MA$ (inertial mass). The equality of these two differently defined masses has been measured by V. B. Braginsky and V. I. Panov of the Soviet Union to an accuracy of 2×10^{-12} improving on earlier measurements by R. H. Dicke and R. V. Eötvös. It is this equality which distinguishes the gravitational force from all other forces in giving all bodies the same acceleration. The discussion of weightlessness pointed out that local effects of the gravitational field are eliminated for an observer in free fall precisely because all bodies fall at the same rate. It follows that the gravitational field measured by an observer will depend on his state of motion. In a sense there is an equivalence between a gravitational field down and an acceleration up for the observer. However, the equivalence is not complete, for real gravitational fields converge on their sources so that two particles released at the same time will drift closer together as they fall. On the other hand, acceleration fields have no effect on the separation of particles moving on parallel paths (Fig. 2). In a curved space, initially parallel geodesics—the "straight lines"—do not maintain a constant separation (e.g., great circles on a sphere). Thus, the gravitational field may have its explanation in the geometry of a curved space-time.

Red Shift According to the quantum theory, a photon of frequency ν has an energy $h\nu$ (h is Planck's constant), and by the relation $E = mc^2$,

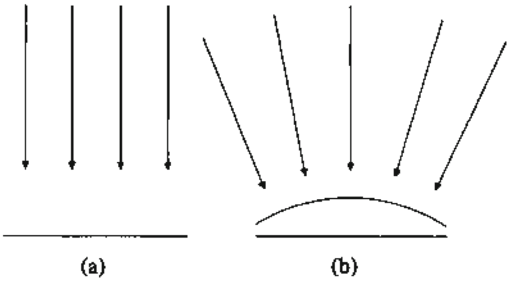

FIG. 2. The paths of particles released in: (a) an acceleration field (the acceleration is up, the apparent force is down); (b) a gravitational field showing convergence toward the source.

this quantum has a mass $m = h\nu/c^2$. To lift a mass m a height H requires expenditure of the energy mgH. Therefore, a photon emitted at the surface of the earth arrives at the height H with the energy

$$h\nu - (h\nu/c^2)\,gH = h\nu\left(1 - \frac{gH}{c^2}\right) = h\nu'$$

At the surface of the earth, the frequency shift amounts to

$$\frac{\Delta\nu}{\nu} = 1.1 \times 10^{-16}\ H (H \text{ in meters})$$

This shift was measured by Pound and Rebka, using the Mössbauer effect, in good agreement with the prediction. As standard clocks are determined by atomic transitions in freely falling atoms, it follows that if the same photon were emitted at the height H, it would be measured to have the frequency ν not ν'. Therefore, an observer at H must conclude that clocks at H run fast compared with the identical clocks on the ground in the ratio (ν/ν') (Fig. 3).

Einstein's Theory of Gravitation Albert Einstein assumed that gravitation is a physical effect produced by the curvature of a four-dimensional space-time. The generalization of Newton's gravitational potential is the metric tensor $g_{\rho\sigma}$ in terms of which the four-dimensional distance, and hence the geometry of space-time, is determined:

$$ds^2 = \sum_{\rho,\sigma=1}^{4} g_{\rho\sigma}\, dx^\rho\, dx^\sigma$$

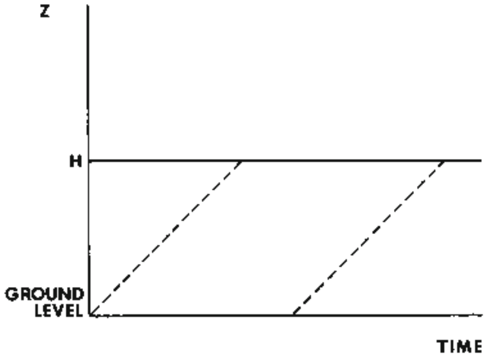

FIG. 3. Photons are emitted on the ground and are received at the height H. Between the two dotted lines representing the beginning and end of a pulse, the same number of oscillations, n, are received at H as are emitted at the ground level. Because of the red shift, the interval t' between oscillations at H is greater than the interval t between oscillations on the ground. Therefore, the time measured at H for the reception of the n oscillations is greater than the time required for their emission on the ground: $nt' > nt$. This result implies that clocks run faster at H than on the ground.

The curvature of space-time is defined in terms of a four-index tensor $R_{\nu\rho\sigma}{}^{\mu}$, the curvature tensor. The vanishing of the curvature tensor means that no real gravitational field is present. The field equations are ten linear combinations of the curvature components which are of the second order in the derivatives of the metric tensor and are a generalization of Poisson's equation [Eq. (2)]. Symbolically these equations are written

$$G^{\rho\sigma} = 8\pi\kappa\, T^{\rho\sigma}$$

where $T^{\rho\sigma}$ is a symmetric tensor which describes the distribution of matter and energy throughout space-time and $\kappa = G/c^2$. In a weak-field static approximation, these equations contain Newton's theory of gravitation with the Newtonian gravitational potential given by $2\phi/c^2 = g_{44} - 1$.

The metric tensor outside a static spherically symmetric mass distribution is given by the Schwarzschild solution:

$$ds^2 = \left(1 - \frac{2\kappa m}{r}\right)dt^2 - \left(1 - \frac{2\kappa m}{r}\right)^{-1} dr^2 - r^2 d\theta^2 - r^2 \sin^2\theta\, d\varphi^2$$

This geometry exhibits the red shift described above and in addition shows three other effects:

(1) The bending of a ray of light passing near the sun's edge by

$$\delta\theta = 1.75''.$$

(2) The precession of the perihelion of Mercury by

$$\delta\phi = 43''.03/\text{century}.$$

(3) The retardation of signals passing near the sun. For a radar pulse reflected from Mercury, this amounts to a maximum time delay

$$\Delta t = 1.6 \times 10^{-4} \text{ sec.}$$

Observations and experiments to check these predictions are still in progress.

Since one can see stars near the sun's edge only during an eclipse, the optical data on the bending of light have been slow and difficult to obtain and such measurements have poor reliability—about 10 to 25 per cent. However, using radio frequency measurements, a group including I. I. Shapiro has observed the angular positions of two sources, 3C279 and 3C273 which have an angular separation of about 10°. The latter source acts as the reference as 3C279 is occulted by the sun each year on October 8. Their results are in agreement with Einstein theory within 6 per cent. E. Fomalont and R. Sramek have carried out similar observation of three radio sources, the central one being occulted by the sun on April 11 of each year, which gives agreement within 2 per cent. Improvements in these observations are expected in coming years.

Shapiro has also reevaluated the optical data with regard to the solar system and has also taken new data using radar ranging. In both cases he finds agreement with the predicted value for the perihelion precession of Mercury within 3 per cent. If he combines the data, he reduces the error to 1 per cent.

As a new test of Einstein's theory of general relativity, Shapiro suggested measuring the retardation of radar echo signals from Mercury when the planet moves into a position of superior conjunction. The gravitational field of the sun, as represented by the Schwarzschild solution, not only produces a bending of the ray, but also affects the time of flight of the signal. Therefore, the time delay between the transmission of a radar pulse to Mercury and the reception of the reflected signal will depend not only on the relative positions of the earth and Mercury in their respective orbits, but also on whether the radar signals pass near the sun (Fig. 4). Current measurements give agreement within 2 per cent.

C. H. Brans and R. H. Dicke have proposed a "scalar-tensor" theory of gravitation in which the added scalar function determines the strength of the gravitational interaction. In this theory the gravitational constant G is no longer a universal constant, but depends on location and time. This effect has not been verified, but the theory also introduces small changes in the above predictions of the Einstein theory. Unfortunately, the experimental errors in the observations are such that one cannot distinguish between the Brans-Dicke and the Einstein theories. Nonetheless, the seeming arbitrariness of the scalar interaction makes the simpler Einstein theory preferable at the present time.

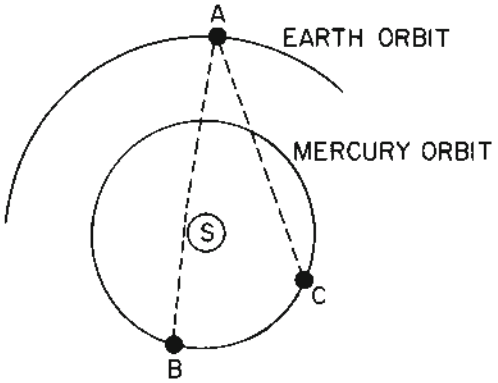

FIG. 4. There will be very little time delay, due to the sun's gravitational field, in the reception of the reflected radar signal when the earth-Mercury position is as in A-C compared to that when their position is as in A-B.

Gravitational Lens Effect A consequence of the bending of light by a massive object is that a distant galaxy may behave like a lens by bending light and other electromagnetic signals from even more distant objects.

Two quasars, labeled by their astronomical coordinates 0957 + 561 A, B, were observed to have identical red shifts, identical spectra, and very similar shapes. Further analysis indicated that they are two images of the same object produced by an intervening galaxy which acts as a gravitational lens. Qualitatively, if the earth, a galaxy, and a distant quasar are lined up, one can expect that signals passing near or through the outer limbs of the galaxy would give us two images displaced from the center while a central image might also be formed. Thus one may expect to see three images plus a central galaxy which might obscure the central image. As the galaxy moves off the earth-quasar line of sight, two of the images would move closer together, coalesce, and eventually would not be refocused to the earth if the galaxy is too far off the line of sight. Since, in fact, only two images are observed one infers that two of the images have merged and, indeed, it appears that the image of the galaxy itself is obscured by one of the images (see Fig. 5).

Gravitational Collapse. The gravitational force between any two masses is attractive. Therefore, given a quantity of matter, under action of gravity alone it will become as compact as possible. In the planets the compaction process is stopped by the electrical forces which act between atoms and molecules in close range. The pressure in the sun, however, is much too great to be supported by such solid body forces. This tremendous pressure is balanced primarily by the counter pressure of electromagnetic radiation which is produced by the nuclear processes at the sun's center. Stars in which the nuclear processes have ended undergo a further contraction which is stopped by the pressure of free electrons at the densities associated with white dwarfs. This pressure, which occurs because electrons obey the Pauli exclusion principle, is capable of supporting up to 1.4 solar masses within a volume of 10^{-4} to 10^{-8} of the solar volume. Objects which are more massive continue the crush. Neutrons become the most stable particles in the interior and the contraction is stopped by repulsive nuclear forces when a neutron occupies only about 10^{-39} cm^3, the nuclear volume. If the resulting neutron star is one solar mass, its radius is just 10 km and its volume 10^{-15} the sun's volume. Objects with more than about 1.2 solar masses cannot be stable as neutron stars. They continue to contract. Beyond this point the situation is confused by the abundance of exotic elementary particles, but there is no theoretical evidence that the contraction can be stopped.

One might have hoped that Einstein's theory of gravitation would contain a short-range re-

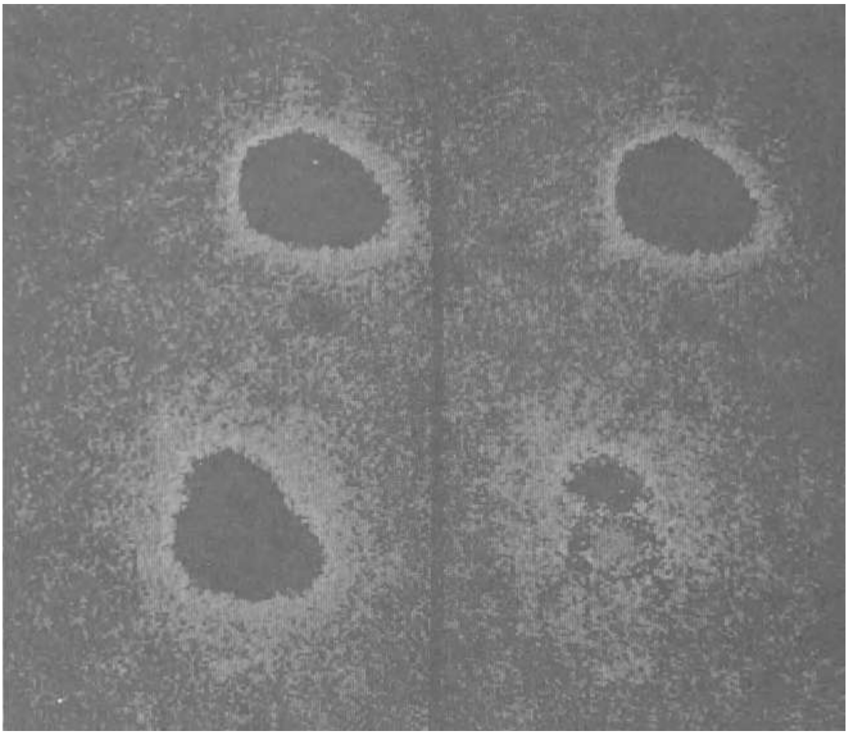

FIG. 5. This is a black and white print of a false color photograph. The display at the left was generated by a computer program that summed and color-coded many images of the twins. Elongation of both the northern twin and the southern one in the direction of four o'clock is an artifact of imperfect alignment of the telescope optics. The northern image was adjusted so that it had the same brightness as the southern one. Display at the right was made by subtracting the adjusted northern image (top) from the unadjusted one (bottom). What remains is an image of the galaxy one arc second north of the southern twin. (Courtesy of the Institute for Astronomy and Planetary Geoscience Data Processing Facility, University of Hawaii.)

pulsion which would stop this endless contraction. However, the opposite is the case. First of all, all forms of energy contribute to the attractive mass in general relativity, and secondly, the fact that matter determines the geometry means that there should be peculiarities in the space when an object is highly collapsed. There are several general theorems, particularly by R. Penrose and S. Hawking, whose general conclusion seems to be that as long as the energy density remains everywhere positive, collapse is inevitable. This does not mean that collapse actually occurs in nature. As a very massive star proceeds through the various stages indicated in the above paragraph, it may become unstable and throw off enough mass through an explosive process, such as a supernova, that it may settle down at a planetary size, or as a white dwarf, or as a neutron star. We have observational evidence for the existence of these objects. (A pulsar is thought to be a rapidly rotating neutron star.) So, not everything continues to collapse. But, there are many very massive stars and in the absence of more information it is unreasonable to rule out the possibility that some will indeed go through an indefinite collapse or that some may have already done so.

What physical effects result from the collapse? It was pointed out above, Eq. (4), that at the Schwarzschild radius the escape velocity from a point mass is the velocity of light. Thus, no signal can escape from a body which has collapsed below R_S. This result can in fact, be deduced from the Schwarzschild solution of the Einstein equations which is given above. As a result, our knowledge of events is limited at the Schwarzschild radius; the surface $r = R_S$ is an *absolute event horizon*. (Because we can receive no light or other signal from a source which has collapsed below its Schwarzschild radius, we call such objects *black holes*.)

Note that a neutron star of one solar mass has a radius of 10 km while $R_s = 3$ km; a neutron star of 10 solar masses will have a radius of 30 km and $R_s = 30$ km. Thus, we have observational evidence for the existence of objects which are very nearly black holes. There is at present an active search for peculiar stellar motions which might indicate the presence of a black hole. On the other hand, if there should be a collapsed object in the nucleus of a galaxy, the very high concentration of stars near the black hole would produce a cusp in the surface brightness. So far there is no positive evidence, but the existence of black holes in the center of galaxies or as collapsed individual stars has not been ruled out.

Gravitational Waves Einstein's field equations require that the gravitational field have a finite velocity of propagation—the same as that for light. Therefore, the gravitational field has independent dynamical degrees of freedom which permit gravitational waves to exist in two states of polarization. These states are wholly transverse. That is, the waves act on matter only in planes which are orthogonal to the direction of propagation. In passing through matter, one state produces oscillations such that there is a compression followed by elongation along one axis and a corresponding elongation followed by compression along the perpendicular axis (Fig. 6). For a periodic wave this process repeats at the frequency of the wave. The other state of polarization has the same effect along axes rotated by 45°. This character for the modes is caused by the tensor nature of the potentials $g_{\rho\sigma}$ which limits the lowest order of gravitational waves to quadrupole radiation. A crude estimate of the energy radiated by the earth-sun system per year amounts to 10^{16} ergs (about 10^6 kWh). Radiating at this rate, the earth has lost about 10^{-15} of its available mechanical energy since its formation 5×10^9 years ago. Presumably there are stronger sources of gravitational waves available in the universe.

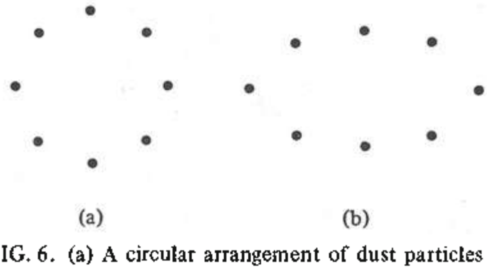

FIG. 6. (a) A circular arrangement of dust particles before a gravitational wave arrives. (b) The same particles after a passage of a wave consisting of one state of polarization. The second state of polarization would produce the same effect, rotated at 45°.

Experiments to detect gravitational radiation were begun in 1958 by J. Weber. For a detector he used an aluminum cylinder which is suspended in the earth's gravitational field. An incident gravitational wave sets up transverse oscillations in the cylinder. These oscillations are transformed into electrical signals by piezoelectric crystals which are bonded to the surface of the cylinder (Fig. 7). However, the observations are made at room temperature and the thermal fluctuations produce displacement of the end faces of about 10^{-14} cm—an amount which, although only one-tenth the diameter of a nucleus, interferes with the expected gravitational effect. The gravity wave signal must be separated out from this background noise. To eliminate fluctuations due to earth tremors, trucks, or people dropping hammers, the whole apparatus is acoustically insulated from the ground.

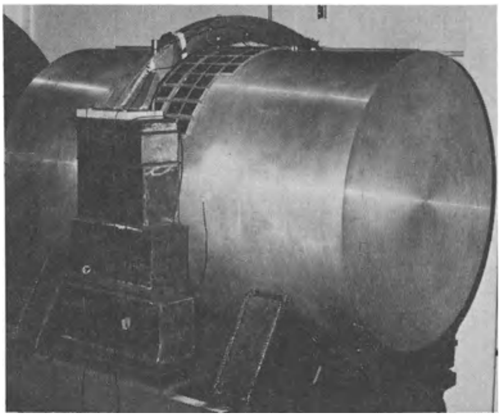

FIG. 7. One of the aluminum cylinders used by Professor Joseph Weber as a detector of gravitational waves. (Courtesy of Professor Weber.)

The initial detection program used principally two identical cylinders, 153 cm long and 66 cm in diameter. One is located at the University of Maryland and the other at Argonne National Laboratory, 1000 km away. The electronic recording system is narrowly tuned to 1660 Hz which has an acoustic half-wavelength of 153 cm in aluminum. Thermal oscillations are randomly generated and one does not expect correlation between the outputs of two detectors, particularly if they are 1000 km apart. Therefore, Weber looks for coincidences in the output signals of the two detectors. The observation technique is to record each signal separately at its own location and at the same time to transmit the Argonne signal to Maryland where it can be compared directly with the Maryland signal. Coincidences of a certain pulse height are then marked (Fig. 8). A careful statistical analysis compares the coincidence rate due to random fluctuations with the observed rate. Weber concludes that there is a "significant coincidence rate of about one every two days."

Unfortunately other centers which have con-

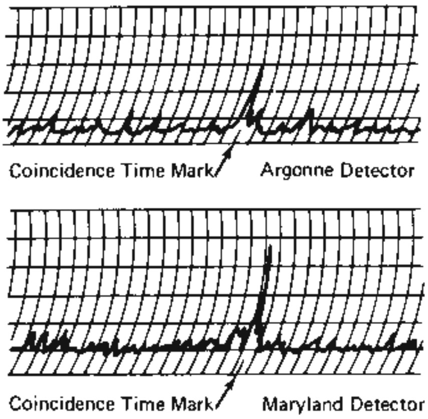

FIG. 8. Argonne National Laboratory and University of Maryland coincidence. (Courtesy of Professor Weber and *Physical Review Letters*.)

structed detectors for gravitational waves have been unable to corroborate Weber's observations. Therefore, at this time there is general agreement, among most workers in the field, that Weber's results cannot be accepted as evidence for the existence of gravitational waves. However, his claims have stimulated many other people to begin the search for gravitational radiation. Many improvements in the design of detectors have been proposed. The more obvious is to cool the detector with liquid helium to reduce thermal oscillations which mask the change in dimensions produced by an impinging gravitational wave. Several ingenious ideas have been proposed which could improve the sensitivity by as much as a factor of 10^5. Among these is the use of very large (several kilograms), carefully grown and annealed sapphire crystals instead of aluminum bars. Another is the use of a carefully designed microwave cavity whose frequency would shift by a very small amount when a wave impinges on it. A third design would use the shifting interference fringes of laser light when the distance between mirrors changes because a gravity wave is incident. Progress is slow because the technological problems are difficult. But there is confidence that in about ten years we will be monitoring the arrival of gravitational radiation inaugurating gravitational astronomy. When radio astronomy began, one did not know or understand the origin of the radiation. Now, in fact, radio observations rival and in some cases exceed the resolution of optical observations. These have shown structures which can not be seen optically. The same problems will arise with gravitational radiation; the interpretation of the observations will be much more difficult. But we may learn much about the universe which can not be discovered otherwise.

Although scientists are still waiting for the observation of gravitational waves, a stellar system has been observed which appears to exhibit the dynamical effect resulting from its emission of gravitational waves. A pulsar has been observed which is part of a double star system. The pulsar, identified as PSR 1913 + 16, has a precise spin rate of 16.94 revolutions per second. It is an object of 1.4 solar masses and has a diameter of about 20 kilometers. Its companion is about the same size, but there is no searchlight to indicate that it is also a pulsar.

Using equations of motion derived from Einstein's theory, the parameters describing the orbit have been determined. This is possible with high accuracy because the precise spin rate can be used as a clock. One found that the orbit is tilted 45° from the perpendicular plane to the line of sight, the separation of the two companions varies from 1.1 to 4.5 solar diameters, and that the periastron advances 4.2 degrees per year. Even more remarkable, however, the period of periastron passage is decreasing (Fig. 9). Over the six years of observation the period has decreased by 1 second. This means that the bodies have moved a little closer together, which indicates a loss of energy. This loss has been calculated to be that expected if the system PSE 1913 + 16 is radiating gravitationally in accordance with the Einstein theory.

Quantum Theory The gravitational interaction among the elementary particles is down by a factor of 10^{-40} from the electromagentic or strong nuclear interactions. Therefore, one cannot expect to observe quantum effects at the level of today's experiments. Nonetheless, because the gravitational field has two independent modes, the quantum field formalism requires that the gravitational field operators exist and satisfy appropriate commutation relations. However, the gravitational field equations are complicated by being nonlinear and by their covariance under arbitrary coordinate transformations. From its linear approximation, one expects that the quantized field will be a spin 2 boson field. However, the linear approximation may be deceptive because the gravitational field determines the geometry of space-time. Quantization of the geometry may have the effect of undermining our current description of particle properties. Therefore, the labels we use to distinguish particle properties may be lost. Indeed, one can show that a black hole is characterized completely by its mass, angular momentum, and electric charge. Thus, when elementary particles are absorbed by a black hole, all of their characteristics, e.g., baryon number, flavor, and color, disappear. In this way, the gravitational field may be a link among all particles and all interactions.

As a result, a number of novel developments have occurred. One is an attempt by Roger Penrose to smear out space-time points by identifying them with the intersections of light rays. The light rays themselves are to be described by new mathematical objects called *twistors*. (Twistors have a similar relation to the con-

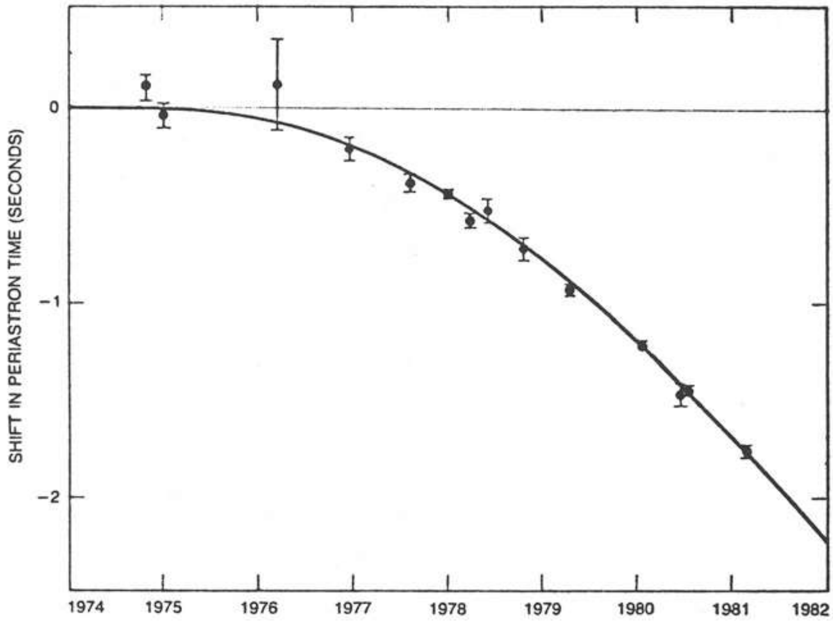

FIG. 9. Emission of gravitational radiation by PSR 1913 + 6 leads to an increasing deviation in the time of periastron passage compared with a hypothetical system whose orbital period remains constant. The solid curve corresponds to the deviation predicted by the general theory of relativity while the dots represent the measured deviation. The pulsar now reaches periastron more than a second earlier than it would if its period had remained constant since 1974. The data provide the strongest evidence now available for the existence of gravitational radiation. (Courtesy of J. H. Taylor, J. M. Weisberg, and *The Astrophysical Journal*.)

formal group in four dimensions as spinors have to the Lorentz transformations.) If one can construct a quantum theory of twistor fields, then space-time and its geometry would likewise be quantized. Another interesting suggestion is that through quantum gravity the distinction between Fermi-Dirac particles (half-odd-integral spin) and Bose-Einstein particles (intgral spin) can be broken down. This work comes under the heading of "supergravity." While many interesting results have been obtained from studies of both of these new ideas, the results are still too preliminary to suggest that either is in the right direction.

On the other hand, Stephen Hawking has produced a striking result in a semiclassical treatment. He considers a quantized scalar field in a classical background metric—that of the Schwarzschild metric which has an absolute event horizon. Hawking assumes that in the infinite past the scalar field is in its lowest energy state—the vacuum state. He then shows that in the infinite future the scalar field is in a state corresponding to a black body temperature of

$$T_b = \frac{\hbar c^3}{8\pi GMk} \simeq 10^{-6}\,\frac{M_\odot}{M}.$$

An intiutive understanding of this process can be given as follows. The fluctuations of a quantized field produce particle-antiparticle pairs. If one particle of a pair should be produced with momentum toward the horizon, the other will be produced with momentum away from the horizon. There is a finite probability that one particle will fall across the horizon while its antiparticle moves away from the horizon and is observed. The net result is that black holes are unstable because of quantum fluctuations of the various quantized fields. However, the decay of black holes is a very slow process, the temperature of a $1M_\odot$ black hole being $T_\odot = 10^{-6}$ °K. It is estimated that any black hole created in the initial big bang smaller than 10^{15} grams would have radiated away all of its mass-energy by this time.

Cosmology One expects the gross structure of the universe to depend on global geometrical properties and the mean distribution of matter more than on the details of particle interactions. Among the various cosmological solutions of Einstein's equations are those models based on a homogeneous and isotropic matter distribution in which matter is streaming away from every point with a velocity dependent on its distance from that point. Such models agree with observations made by Hubble on the red shift in the spectra of distant galaxies. He interpreted this red shift as a Doppler effect due to a recessional velocity of the galaxy which is proportional to its distance:

$$v = Hr$$

with $H = 30$ km/sec/10^6 light-years and r measured in millions of light-years. This value of H leads to an age for the universe of about 10^{10} years.

The models based on Einstein's equations are evolutionary. This means that the rate of expansion of the universe, hence Hubble's constant H, depends on time. Bondi and his coworkers have suggested that the universe is in a steady state and that H is in fact independent of time. The steady-state theory says that the distribution of galaxies and the density of matter remain the same on the average. New matter is created in order to fill in the thinning density of matter as the universe maintains its expansion. One attempts to distinguish between the steady-state theories and the evolutionary models by counting the number of galaxies and the number of radio sources as a function of distance. These observations, though not definitive, suggest that the evolutionary models are correct.

There are two other observations which strengthen this conclusion. One of these is the recognition of the QSO (quasi-stellar objects) as extra-galactic objects. The QSO are very small, very luminous objects, and with very large red shifts. The simplest and most satisfactory interpretation of the observed red shifts is that it is the cosmological Doppler shift. With this interpretation, 3C273, the nearest, most luminous, and the first identified QSO, is at a distance of 1.6×10^9 light-years. This distance is so great that it is possible that an early state in the development of galaxies is being observed. On the other hand, the amount of energy being released is so great (~10^{49} ergs/sec) that a nuclear source for the energy is ruled out, and it is sug-

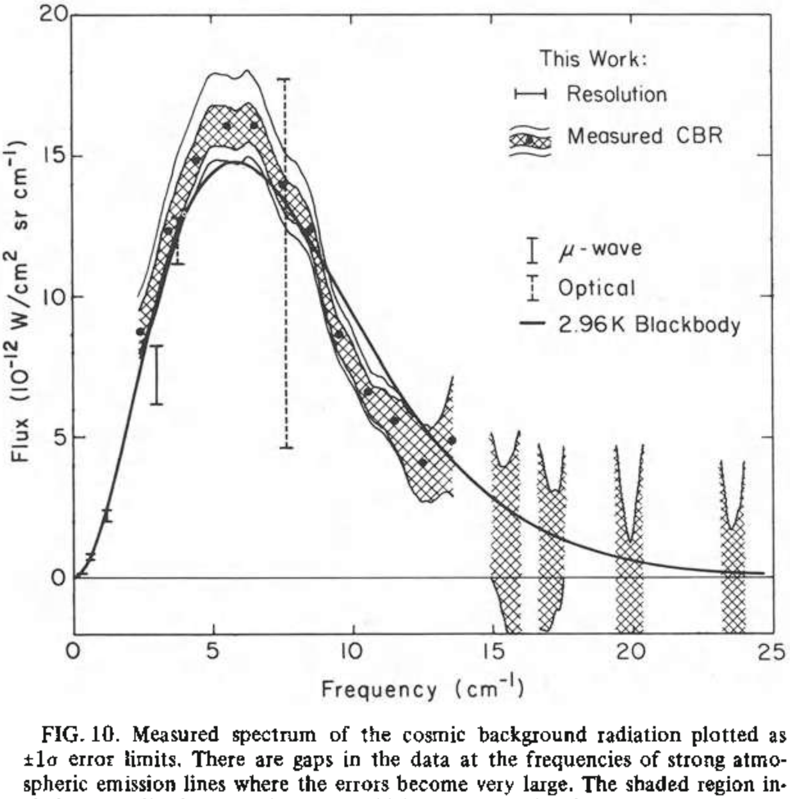

FIG. 10. Measured spectrum of the cosmic background radiation plotted as ±1σ error limits. There are gaps in the data at the frequencies of strong atmospheric emission lines where the errors become very large. The shaded region includes contributions to the error which are uncorrelated across the spectrum. Additional solid lines are shown to represent the effect of changing the frequency-independent scale factor by ±1σ. The shaded region can be scaled up or down within these limits. The spectrum of the 2.96°K blackbody, which has the same integrated flux as the measured spectrum, and selected microwave and optical measurements of the CMB are also shown for comparison. (Courtesy of David P. Woody and Paul L. Richards and *The Astrophysical Journal*.)

gested that the energy comes from the gravitational contraction of 10^{10} $M_\odot$ down to its Schwarzschild radius of about 10^{10} km. However, it is equally possible that the QSO represent the opposite effect, the exploding of matter from a highly compacted state which is being thrust out. At present the models giving the energy through collapse seem to fit the observations. From the point of view of the steady-state cosmology, the QSO create serious problems. They are far away and there seems to be an overabundance of them at very large distances, hence a long time ago.

In 1949, George Gamow and his co-workers suggested that at an early stage in an evolutionary expanding universe, matter and radiation interacted very strongly and were in thermal equilibrium. As the universe expanded, the opportunity for interaction decreased, the radiation and matter were effectively decoupled. Matter cooled more rapidly and condensed into the galaxies and stars. The radiation maintained its thermal equilibrium distribution, its *blackbody* distribution, behaving like a gas which is undergoing an adiabatic expansion. Gamow estimated the temperature of this remnant of the primeval fireball at about 25°K. Fifteen years later, Dicke came to a comparable conclusion independently and set about to observe this radiation. In the meantime, Penzias and Wilson, while tracking down residual noise in a sensitive microwave radiometer, discovered an isotropic background radiation at a wavelength of 7.4 cm whose intensity corresponded to the emission of a blackbody at a temperature of 3.5°K. Subsequent measurements by many observers have verified the existence of this background radiation, but have reduced the temperature to 2.7°K.

The use of microwave radiometers from the ground was very successful in mapping the low frequency region. Unfortunately, because of atmospheric absorption and interference from local sources, this method of measurement could not be carried over the peak of the curve for black body radiation at 2.7 °K. However, recent measurements by Woody and Richards used a balloon-based spectrophotometer to measure the cosmic background radiation from the low frequency side well over the peak into the high frequency side of the black body curve. Within the errors of their measurements the total flux in the frequency range 2.4 - 13.5 cm^{-1} (λ^{-1}) agrees with the flux from a black body at a temperature of 2.96 °K with lower and upper limits of 2.88 and 3.09 °K respectively. These results together with those from earlier measurements are shown in Fig. 10.

The prediction and observation of the blackbody radiation and its interpretation as evidence of a primeval fireball give very strong support to the concept of an evolutionary universe, a universe which has expanded from a compact volume to its present size. However, it does not select a particular cosmological model from the many which are allowed by Einstein's gravitational theory, those permitted by the Brans-Dicke modification, or other possibilities which have not yet been constructed.

GYROSCOPE*

The gyroscope consists of a flywheel or a sphere that is spinning (usually at high speed) about an axis. If this axis is free in space (such freedom may be provided by gimbals, by floating the spinning mass on a column of gas or fluid, or by suspension in a magnetic or an electrostatic field), the axis will remain parallel to its original position even though the gyroscope is mounted on a vehicle that translates and rotates in three dimensions. This property of the "free gyro" often referred to as "spatial memory" was used as an artificial horizon as early as 1744 by Serson. This permitted a ship's navigator to take readings with a sextant (measurement of the angular elevation of a star with respect to the horizon) when the horizon was obscured by darkness, fog, mist, etc. This early instrument has led to the modern vertical gyro.

In 1852, Leon Foucault built one of the first precise gyropscopes. Utilizing a flywheel 80 millimeters in diameter supported in near-frictionless gimbals, this instrument was sensitive

*Illustrations and text excerpted from Refs. 1 and 2.

enough to detect the rotation of the earth. This free gyro maintained a fixed orientation in space as the earth turned. The relative motion was observed through a microscope.

In 1896, the gyroscope saw its first application for guidance when Obry used it in a self-propelled torpedo. An *un*guided torpedo, under the influence of winds, currents, and ocean waves would *not* follow a prescribed course. The gyroscope, on the other hand, was pointed at the target before launching the torpedo, and by means of linkages connected to the spin axis support, it actuated the rudder of the torpedo, steering it along a straight course.

When the gyroscope is *not* free, that is, when the spin axis is forced to turn in space, the gyroscope develops a torque about an axis that is perpendicular to the plane containing the spin axis and the axis about which turning takes place. This property was utilized to find north by continually reorienting the spin axis until the gyroscope could *not* detect the *rotation* of the earth. This instrument, called the gyrocompass, was perfected in 1908 by Anschütz of Germany and by Elmer Sperry (1911) of the United States. This instrument used a wheel 0.1 to 0.2 meters in diameter, and was suspended in such a way that it tended to remain vertical. Since the vertical turned with the earth, the gyroscope following it produced a torque. This torque, in turn, was used to provide self-turning of the spin axis in a direction that would reduce the torque. In the final equilibrium position, the instrument pointed north. The gyrocompass is still widely used today.

The gyroscopic torque is also used to stabilize ships. Due to the motion of waves, the *un*stabilized ship rolls considerably. It is impractical to shift huge masses fast enough to counteract the irregular motion. On the other hand, a gyroscope develops torque instantly and with much less effort. This led to the development of the gyroscopic ship stabilizer. Utilizing a wheel 3 to 6 meters in diameter, and a hydraulic turning mechanism, angular rates are applied to the spin axis support producing tremendous gyroscopic torques upon the ship. In moderately rough seas, the gyro stabilizer can eliminate 70 to 80 per cent of the roll motion. The control signal to the turning mechanism is provided by a small "vertical gyro" which is very much like Serson's artificial horizon gyro. This essentially is a guidance system (like Obry's) using a small guidance gyro to provide the vertical and a large gyro to provide the "muscle."

If the motion of the gyro is free, and if a torque is applied to the structure containing the spinning mass, it will turn or precess about an axis that is perpendicular to the plane containing the torque axis and the spin axis. This is the converse of the gyroscopic torque phenomenon. By adjusting the amount of torque, the gyroscope provides a controlled rate. This property is utilized in an autopilot during a constant rate of turn. The principle is also used for platform stabilization where the platform carries instruments which must bear specific orientations with respect to the earth. By carefully regulating the torque, the gyroscope and platform rotate with the earth without being in contact with the earth.

Gyroscopic Torque If the gyro is not free, but is forced tor turn, its spin axis is forced to change its orientation. Refer to Fig. 1(a). Let the initial position of the spin axis be represented by the vector ω_1 and the position after time Δt be the vector ω_2. The vector $\Delta\omega$ represents the change in angular velocity. It has a magnitude

$$\Delta\omega = \omega\Delta\phi \tag{1}$$

where $\Delta\phi$ is the angle turned during time Δt.

Likewise, the angular momentum vector $\mathbf{H}$ may be shown initially and after time Δt, as indicated in Fig. 1(b).

$$\mathbf{H} = I\omega \tag{2}$$

where I = mass moment of inertia of wheel about the spin axis
ω = angular velocity of wheel.

The change in magnitude of angular momentum is

$$\Delta H = I\Delta\omega \tag{3}$$

The torque required to change the angular momentum is T_i, and the equal and opposite torque T felt by the structure is

$$T = \frac{\Delta H}{\Delta t} \tag{4}$$

Apply Eqs. (1)-(3) to Eq. (4):

$$T = H\,\frac{\Delta\phi}{\Delta t} \tag{5}$$

In the limit, $\Delta\phi/\Delta t$ approaches $\dot{\phi}$. If the turn rate vector $\dot{\boldsymbol{\phi}}$ makes an angle ψ with the plane containing the vectors $\mathbf{H}_1$ and $\mathbf{H}_2$, then the perpendicular component is

$$\dot{\phi}\sin\psi.$$

Applying the above concepts to Eq. (5), we have

$$T = H\dot{\phi}\sin\psi \tag{6}$$

as the magnitude of the torque. In vector notation, this becomes

$$\mathbf{T} = \mathbf{H} \times \dot{\boldsymbol{\phi}}. \tag{7}$$

In order to determine the sense of the torque vector $\mathbf{T}$, rotate the angular momentum vector $\mathbf{H}$ toward the input rate vector $\dot{\boldsymbol{\phi}}$ and apply the right-hand rule.

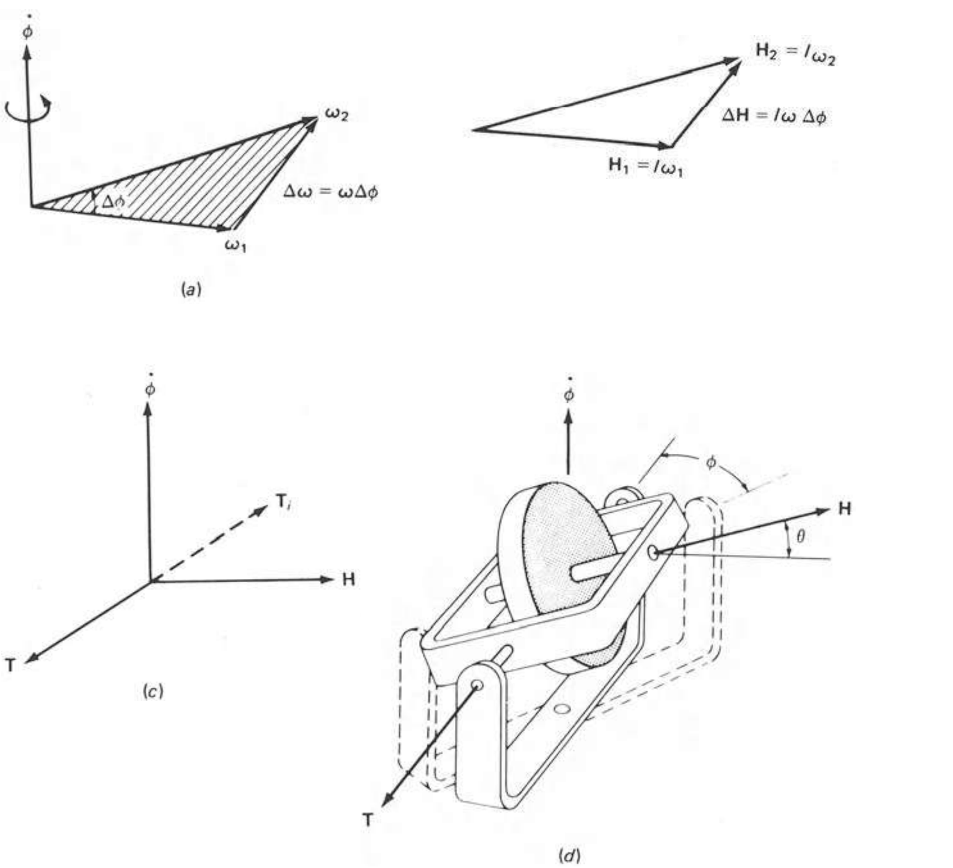

FIG. 1. Gyroscopic torque.

Gyro Drift The free gyro maintains its orientation in space, provided that there are no disturbances to the gyro. However, the presence of small torques produces a precession or *gyro drift*. Usually the magnitude and direction of the torque are unknown. Hence, gyro drift is usually unknown, and thus, constitutes an error.

One common source of this unknown or uncertain torque is the axial shift of the spin axis bearings. In a vertical gravity or acceleration field g, the torque T_d is given by

$$T_d = Mgb \tag{8}$$

where M = mass of gyro wheel
g = acceleration along the ϕ axis
b = axial shift.

The resulting gyro drift rate $\dot{\theta}_d$ is given by

$$\dot{\theta}_d = \frac{T_d}{H} = \frac{Mgb}{H}. \tag{9}$$

If the gyro wheel has most of its mass concentrated in its rim, then the angular momentum is approximately,

$$H = MR^2\omega. \tag{10}$$

Then the gyro drift is given approximately by

$$\dot{\theta}_d = \frac{Mgb}{MR^2\omega} = \frac{gb/R}{R\omega}. \tag{11}$$

In superprecise gyroscopes, the axial shift b is of the order of one millionth of the wheel radius, the wheel speed ω = 25,000 rpm = 2510 rad/sec, and the wheel radius R = 25 mm = 0.025 meters. Then,

$$\dot{\theta}_d = \frac{(9.8\ \mathrm{m/s^2})\ 10^{-6}}{(0.025\ \mathrm{m})\ (2510\ \mathrm{rad/s})}$$

$$= 0.156 \times 10^{-6}\ \mathrm{rad/s}$$

$$= 0.0322°/\mathrm{hr}.$$

A tolerance of one part in a million may seem extraordinary. However, as extreme as this seems, it is not good enough for typical applications in inertial guidance systems, where a drift rate of 0.01°/hr is required. For such applications, exceptional accuracy is demanded—possible only in ultrasophisticated instruments. One such device is the "ring laser gyro," which consists of three lasers (each about 0.1 meter long) arranged in a triangle. This instrument makes use of the linear momentum of a beam.

H

HALL EFFECT AND RELATED PHENOMENA

If a current of particles bearing charges of a single sign and constrained to move in a given direction is subjected to a transverse magnetic field, a potential gradient will exist in a direction perpendicular to both the current and the magnetic field. This phenomenon is called the Hall effect, after E. H. Hall who discovered it in a metal in 1879. To commemorate the 100th anniversary of Hall's discovery, a symposium was held on November 13, 1979 at The Johns Hopkins University. It was at this university, while a graduate student under Henry Rowland in the Physics Department, that Edwin Herbert Hall did the experiments which led to his discovery of what is now universally known as the Hall effect. The published proceedings of the centennial symposium, entitled "The Hall Effect and Its Applications," occupy a total of 550 pages and illustrate the wealth of activity which has evolved from Hall's work. For example, studies of the Hall effect provide extremely useful techniques for obtaining information about the electronic properties of solids. As will be discussed in more detail, Hall data can be used to obtain concentrations and numerous other properties of the charge carriers. In addition, the Hall effect is the basis of a variety of specialized devices, in which the fundamental unit (referred to as a *Hall element* or, sometimes, as a *Hall generator*) is made of a material in which the voltage or, depending upon the application, the power produced by the Hall effect is especially large. More specific details are given later in the section entitled "Hall Effect Applications." Broadly stated, the utilization of the Hall effect yields a variety of miniature, light-weight, highly reliable devices which can efficiently be used in a number of applications such as: (1) replacement of the troublesome contacts commonly found in conventional circuitry; (2) measurement of position or velocity of rotating elements; (3) measurement of magnetic fields or magnetic field gradients by means of a simple probe and associated circuitry. The above applications are of especial importance in the guidance and sensor systems of satellites. Finally, Hall phenomena play an important role in plasmas in magnetic fields and in magnetohydrodynamics. For example, it was pointed out in a paper given at the symposium mentioned above that the Hall currents in the aurora can be as large as one million amperes. In magnetohydrodynamic technology, Hall phenomena enter into the design of MHD electrical power generators.

Principles Involved The Hall effect is a manifestation of the force, usually known as the Lorentz force, which is exerted on a charged particle moving perpendicular to a magnetic field. The direction of the force is perpendicular to both the magnetic field and the velocity of the charge. If this sidewise thrust is not counteracted, the charged particle undergoes a deflection. The result of such motion is to create a charge unbalance and to produce a transverse electric field component, known as the *Hall field*. The force on the charged particle due to this Hall field tends to oppose the force resulting from the magnetic field. Mathematically, the forces and fields in question are represented by the following vector equation:

$$\mathbf{F} = e[\mathbf{E} + (1/c)\mathbf{v} \times \mathbf{H}] \qquad (1)$$

where **F** is the force, *e* the charge, and **v** the velocity of the particle, **E** is the electric field, and **H** is the magnetic field. A permeability of unity is assumed, and for the Gaussian system of units, *c* is the speed of light and **F** is in dynes. The use of the symbol **H** in the above equation, when more precisely the magnetic induction **B** is meant, is perhaps unfortunate. However, this notation was used almost universally in the early literature on Hall phenomena. In the Gaussian system the values of **B** and **H** are the same in nonmagnetic materials (a permeability of unity). As the equation indicates, the total force on the particle of charge *e* is the vector sum of that due to the electric field **E** and that resulting from the magnetic field. The latter enters via the *vector cross product* **v** × **H**, which represents a vector perpendicular to both **v** and **H** and in the direction indicated by the right hand rule as **v** is rotated into **H**. The magnitude of the vector **v** × **H** is equal to the product of the individual magnitudes of **v** and **H** times the sine of the angle between them. Hence, only the component of **v** perpendicular to **H** contributes to the sidewise force.

The physics involved in the Hall effect is con-

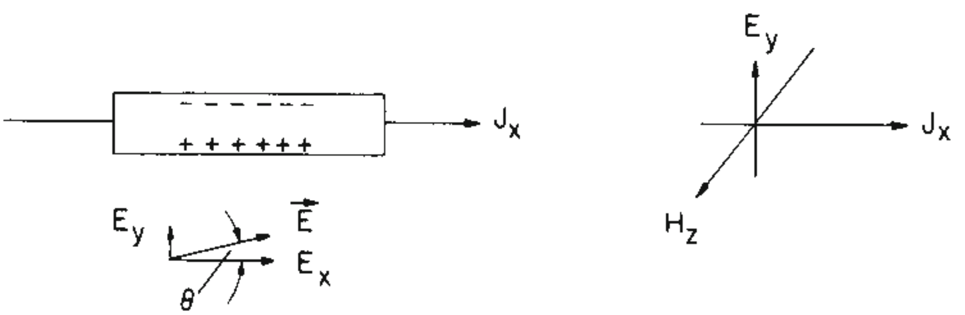

FIG. 1. Hall field due to action of magnetic field on positive charge carriers. For example shown, e, J_x, and H_z are positive and, therefore, v_x, E_x, and E_y are also. The resultant electric field and the Hall angle are shown at lower left. In the case of electrons, the Hall field is reversed for positive J_x, both v_x and e now being negative.

viently illustrated by considering a confined stream of free particles, each having a charge e and an initial velocity v_x. A magnetic field in the z direction produces initially a deflection of charges along the y direction. This charge unbalance creates an electric field E_y, and the process continues until the force on a moving charge due to the Hall field E_y counter-balances that due to the magnetic field so that further particles of the same velocity and charge* are no longer deflected. A pictorial representation of this is shown in Fig. 1. The magnitude of the Hall field follows at once from Eq. (1), with F = 0 at steady state, namely

$$E_y = (1/c)v_x H_z = J_x H_z/nec \text{ (Gaussian}^\dagger \text{ units)} \tag{2}$$

In obtaining the last equality, the electric current density J_x was expressed in terms of the density of charge carriers n by the product nev_x. For *electronic* (i.e., as opposed to *ionic*) conduction in solids, the magnitude of e is the electronic charge (4.8×10^{-10} esu in Gaussian units; 1.6×10^{-19} coulomb in practical units), and its sign is negative for transport by electrons and positive for transport by holes (deficit electrons). The *Hall coefficient* is defined by the ratio $E_y/J_x H_z$, namely

$$R_\text{H} \equiv E_y/J_x H_z = 1/nec \text{ (Gaussian units)} \tag{3}$$

Thus a very simple relation exists in the free-particle example between the Hall coefficient and the charge-carrier density. It is also seen that R_H is negative for conduction by electrons, positive for conduction by holes. Now the electric current density J_x exists by virtue of an applied electric field E_x. With the Hall field present, the *resultant* electric field in a solid‡ lies at some angle θ to the x axis. This angle is called the Hall angle, namely

$$\theta \equiv \tan^{-1} E_y/E_x \tag{4}$$

Thus the Hall effect may be described as a rotation of the electric field. At zero Hall field, the equipotential lines are perpendicular to **J**, but when the Hall field appears, they are oblique, so that a Hall voltage exists across the specimen in a direction normal to the current. The rotation aspect is also brought out by considering the components of the *conductivity tensor*, which relate electric current densities and fields. For the boundary condition that $J_z = 0$, we may write

$$\begin{aligned} J_x &= \sigma_{xx}E_x + \sigma_{xy}E_y \\ & \qquad\qquad J_z = 0, H = H_z \quad (5) \\ J_y &= -\sigma_{xy}E_x + \sigma_{xx}E_y \end{aligned}$$

Equations (5) hold for media of sufficient symmetry§ that $\sigma_{xx} = \sigma_{yy}$, $\sigma_{yx} = -\sigma_{xy}$, and $\sigma_{xz} = \sigma_{yz} = \sigma_{zx} = \sigma_{zy} = 0$. The latter insures that E_z

*If the particles have a *distribution* of velocities, then it is only those particles having a certain "average" velocity, which are undeflected. This point is expanded later.

†In the Gaussian system, mechanical quantities are in cgs units, electrical quantities in esu, and magnetic fields in gauss or oersteds. In the *practical* system, mechanical quantities are in cgs units, electrical quantities in volts and coulombs, and magnetic fields in gauss or oersteds. In all equations in this article, except for Eq. (1), conversion from the Gaussian system to the practical system is effected by replacing c by unity and replacing H by $H/10^8$, where these quantities explicitly occur. The practical units for R_H are cm^3/coulomb; those for mobility are cm^2/volt-sec. The corresponding units in the Gaussian system are cm^2-sec/esu and cm^2/statvolt-sec. If practical units are to be used in Eq. (1), to obtain the force in dynes it is necessary not only to make the changes specified above but also to include a factor of 10^7 on the right-hand side. This results from the additional procedure of converting charge in coulombs to esu and the field terms in volts/cm to statvolts/cm.

‡Although the Hall effect can be discussed for any constrained electron gas, we shall, for simplicity, talk about a solid conductor.

§Isotropic media, e.g., or cubic systems with coordinate axes along cube axes.

vanish when J_z is zero. Since the boundary conditions for Hall effect require that J_y vanish, Eqs. (4) and (5) yield the following result for the off-diagonal elements σ_{xy}:

$$\sigma_{xy} = \sigma_{xx} \tan\theta \qquad (6)$$

The inverse of the conductivity tensor is the *resistivity* tensor, which relates **E** to **J**. A general definition of the Hall effect involves relating it to the antisymmetric* components of the resistivity tensor. This leads to the vector equation for the Hall field, namely

$$\mathbf{E}_\mathrm{H} = R_\mathrm{H} \mathbf{H} \times \mathbf{J} \text{ (Gaussian units)} \qquad (7)$$

The identity in the first part of Eq. (3) is recognized as a special case of Eq. (7)

Application to Real Solids In a real solid the idealized free particle treatment no longer applies and must be replaced by a theory that takes into account the distribution of velocities and the interactions of the charge carriers with impurities, defects, and lattice thermal vibrations of the solid (i.e., the *scattering*), as well as the *band structure* of the solid. The latter consideration relates to the fact that the charge carriers in the solid are not free but exist in a potential energy field having the periodicity of the lattice. As a result of these constraints, only certain energy states, or *bands*, are allowed for the charge carriers. In addition, the relationship between the energy and velocity of the carriers is not the simple $\frac{1}{2}mv^2$ of the free electron, but is more complex. As an approximation, one frequently characterizes the charge carriers by an *effective* mass, m^*. Taking into account most of the complexities mentioned above, one still obtains an expression similar to Eq. (3), namely

$$R_\mathrm{H} = r/nec \text{ (Gaussian units)} \qquad (8)$$

The *Hall coefficient factor*, r, actually depends on the nature of the scattering, the band structure, the magnetic field strength, and on the statistics characterizing the distribution of velocities of the carriers. Fortunately it depends weakly on these factors, and its value is usually within, say, 50 per cent of unity.

An important attribute of charge carriers is their mobility, i.e., their drift velocity per unit electric field. The conductivity mobility μ is related to the conductivity σ by

$$\mu = \sigma/ne \qquad (9)$$

It is also customary to define a *Hall mobility* μ_H for conduction by a single type of charge carrier by the relation .

$$\mu_\mathrm{H} H/c = \tan\theta, \text{ or } \mu_\mathrm{H} = R_\mathrm{H}\sigma c \text{ (Gaussian units)} \qquad (10)$$

With the use of Eqs. (8) and (9), it can be seen that the ratio of Hall and conductivity mobilities is precisely the Hall coefficient factor. It follows that the Hall angle is proportional to μ and H.

When transport by two or more kinds of charge carriers occurs, Eq. (8) is not applicable, and one must return to the general relations of Eq. (5). For conduction by electrons and holes (of respective densities n, p), the *weak-field* Hall coefficient can be written in the form

$$R_0 = -(r_\mathrm{e}\mu_\mathrm{e}{}^2 n - r_\mathrm{h}\mu_\mathrm{h}{}^2 p)/ [|e|c(\mu_\mathrm{e} n + \mu_\mathrm{h} p)^2] \qquad (11)$$

where $|e|$, μ_e, etc., are positive. We note that the charge-carrier densities are now weighted by the mobilities μ_e, μ_h. There are also Hall coefficient factors for each carrier. For arbitrary H, the terms involve field-dependent factors.

Analysis of Hall-effect data is one of the most widely used techniques for studying conduction mechanisms in solids, especially semiconductors. For the single-carrier case, one readily obtains carrier concentrations and mobilities, and it is usually of interest to study these as functions of temperature. This can supply information on the predominant charge-carrier scattering mechanisms and on activation energies, i.e., the energies necessary to excite carriers from impurity levels into the conduction band. Where two or more carriers are present, the analysis is more complicated [cf. Eq. (11)], but much information can be obtained from studies of the temperature and magnetic field dependencies.

Unlike, for example, the magnetoresistance, the Hall effect is a first-order phenomenon. At weak magnetic fields it depends linearly on H, and it does not vanish in isotropic solids if all the carriers have essentially the same velocity or if the scattering is characterized by a relaxation time which is independent of the carrier energy. The Hall effect forms the basis of a number of devices used in isolating circuits, transducers, multipliers, converters, rectifiers, and gaussmeters (for measurement of magnetic fields). As mentioned earlier, the fundamental component of such devices is a slab of material (called a "Hall element" or a "Hall generator") possessing favorable Hall characteristics. Additional devices are mentioned in the last section.

Experimental Determination A number of techniques are available, the most direct being to measure, by means of a potentiometer or other high-impedance device, the Hall voltage V_H across a parallelepiped in a direction normal to both **H** and **J**. The Hall coefficient follows from Eq. (3) or (7), with attention to the footnote to Eq. (2):

$$R_\mathrm{H} = 10^8 \; V_\mathrm{H} t/IH, \text{ (practical units)} \qquad (12)$$

*These components are defined by the condition that $\rho_{ik} = -\rho_{ki}$, where the ρ_{ik} [cf. Eq. (5)] are defined by $E_l = \sum_{k=1}^{3} \rho_{ik} J_k$, $1 \equiv x$, $2 \equiv y$, $3 \equiv z$.

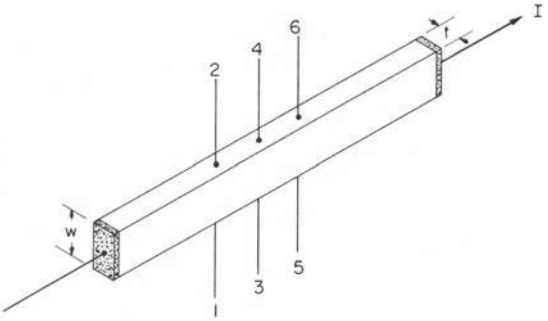

FIG. 2. Arrangement of contacts for measurement of Hall coefficient and related effects. Hall probes are 3 and 4. Probes 2 and 6 are for resistivity and magnetoresistance. Probes 1 and 5 allow a check of the uniformity of the specimen. For Hall effect and transverse magnetoresistance, the magnetic field is in the direction of the thickness t; for longitudinal magnetoresistance, it is along I. To avoid disturbances due to contact shorting, all probes should be at a distance of at least $2w$ from the end contacts.

where t is the thickness of the specimen and I is the total current. The arrangement is shown in Fig. 2. Since V_H may be the order of microvolts, extreme care must be taken to avoid extraneous voltages. An example is the misalignment voltage, caused by probes 3 and 4 not being on an equipotential plane when $H = 0$. This may be eliminated by taking measurements for opposite directions of H and taking half the difference, inasmuch as $V_H(H)$ is odd in H. Alternatively, one can adjust the position of the Hall probes for a null reading with $H = 0$. Other techniques involve use of resistances with sliding contacts suitably attached to the specimen. Other spurious voltages can arise from temperature gradients and resulting thermoelectric or thermomagnetic emf's (see following section). Some of these can be eliminated by taking appropriate averages among measurements for reversed polarities of I and direction of H. It is usually desirable to maintain good thermal contact between all points of the specimen and a constant-temperature bath. Although it is possible to analyze *adiabatic* Hall data (no heat flow to or from the specimen during measurement), *isothermal* data are preferred because of the simplicity of the equations. All of the relations in this article are for isothermal conditions. Errors in measurement can also result from a shorting of the Hall voltage, especially by the end contacts. With regard to the latter, the error is essentially negligible if the length-to-width ratio of the specimen is about 4 or more, and the Hall probes are near the center.

Related Effects A widely-studied galvanomagnetic effect is *transverse magnetoresistance*, usually written $\Delta\rho/\rho_0$. This phenomenon can be illustrated by the pictorial scheme in Fig. 1. If a charge carrier is deflected by the Lorentz force so as to traverse a longer path, it will contribute less to the conductivity, and there will be a positive magnetoresistance. It was noted, however, that if all charge carriers have the same velocity, none will be deflected since the Hall field cancels the $\mathbf{v} \times \mathbf{H}$ force. This is the case in an isotropic metal, where the velocity of all the electrons is essentially the Fermi velocity. It is also true for electron scattering mechanisms described by a relaxation time which does not depend on energy. In these cases—assuming, of course, a single type of carrier—there is no magnetoresistance. If, however, there is a distribution of electron velocities—as in a semiconductor—then it is clear that only those electrons of a certain "average" velocity will be undeflected. The remaining carriers, having velocities either larger or smaller than the "average" will be deflected and will traverse longer paths, thus increasing the resistance of the conductor. A similar situation obtains if more than one type of carrier is present. It is also apparent that any mechanism which shorts out the Hall voltage—e.g., special geometry, shorting contacts, inhomogeneities in the specimen—will increase the magnetoresistance.

For the reasons discussed and the fact that $\Delta\rho/\rho_0$ varies as H^2 in weak fields, magnetoresistance is a second-order effect. It tends to saturate in strong magnetic fields, unless there is a disturbance of the Hall field as mentioned above. Magnetoresistance is even in H, and it is related to the *symmetric* components of the resistivity tensor, i.e., those for which $\rho_{ik} = \rho_{ki}$ [cf. footnote on p. 401]. It can be measured with the geometry shown in Fig. 2 by maintaining the current constant and determining the potential difference between probes 1 and 5 or 2 and 6 as a function of magnetic field. Magnetoresistance data can supply information on charge-carrier scattering and band structure. In the latter case, if anisotropy exists, it is useful to obtain data for different crystallographic directions. There is also a *longitudinal* magnetoresistance, measured when **H** is parallel to **J**. This effect vanishes in isotropic solids, and its presence indicates anisotropy in scattering or band structure, or inhomogeneities in the specimen.

By shorting the Hall field or by choosing a disk geometry so that such a field does not exist, one obtains a "magnetoresistance" (more strictly, a *magnetoconductivity*) which does not saturate. This is called the Corbino magnetoresistance or Corbino effect, after O. M. Corbino who studied circulating secondary currents in a "Corbino" disk carrying a primary radial electric current in a magnetic field.

There are a number of thermal effects in a magnetic field, which can produce transverse voltages or temperature gradients. These result from the velocity separation of charge carriers by the Lorentz force—the energetic ones going to one side, the slower ones going to the other. Temperature gradients are produced, and also electric fields. In the Righi-Leduc effect, a longitudinal temperature gradient produces a transverse temperature gradient (thermal analog of the Hall effect); in the Nernst effect, it produces a transverse electric field. In the Ettingshausen effect, a longitudinal electric current produces a transverse temperature gradient. This latter effect, if large, can lead to complications in the measurement of the Hall field since the potential probes and leads are seldom made of the same material as the specimen. Therefore the Ettingshausen temperature gradient can produce a thermoelectric voltage which adds to the Hall voltage.

Hall Effect Applications* The Hall effect finds application in many practical devices. These include a variety of contactless switches such as solid-state keyboards, plunger-operated switches, proximity switches, and vane switches. Other device applications include tachometers and various other counting systems, and the control of automobile ignition. For space application, such Hall effect devices as sensors, gaussmeters, magnetometers, brushless DC motors, and uses in connection with satellite magnetic-hysteresis damping and gravity-gradient stabilization at synchronous altitude are extremely important. Inasmuch as Hall elements can be made of silicon, their processing is compatible with silicon integrated-circuit technology and a number of devices utilizing Hall effect in conjunction with IC functions are now produced on silicon chips.

HEALTH PHYSICS

Health physics is the profession that is concerned solely with the protection of man from the damaging effects of radiation.† It attempts to understand the action of radiation on man and his environment, to establish appropriate limits for exposure to radiation, and to devise appropriate methods for detection, measurement and control of radiation exposure. Although this profession is relatively new, man's awareness and concern for the harmful effects of ionizing radiation are not of recent origin. Perhaps the earliest record of damage to man

*The information presented in this section can be found in the centennial symposium proceedings "The Hall Effect and Its Applications."

†The Health Physics Society in 1971 extended the scope of health physics to include also non-ionizing electromagnetic radiations.

from ionizing radiation dates back to about 1500 when the high incidence of lung diseases was recognized among the Schneeberg miners of Saxony and the Joachimsthal miners of Bohemia. In 1879 Herting and Hess performed the first autopsies on these miners and reported malignant growths in the lungs; however, the cause of these malignancies was not understood until after 1896 when Roentgen first announced his discovery of x-rays and Becquerel reported the discovery of radiation due to uranium. Even during the first year following the discovery of x- and γ-radiation, many things were learned about both the harmful and useful characteristics of this new source of energy. Grubbé, a manufacturer of Crookes tubes in Chicago, Illinois, was using his equipment to study the fluorescence of chemicals even before the public press on January 4, 1896, heralded Roentgen's discovery of x-rays. During January, 1896, he first noticed an erythema on the back of his hand and later the formation of a blister with skin desquamation and epilation. His hand was sufficiently painful that he sought medical aid on January 27, 1896. Realizing from first-hand experience the destructive power of x-rays Grubbé on January 29, 1896, treated a patient for carcinoma of the breast with his Crookes tube. Not only was this treatment significant because it was one of the earliest—if not the first—therapeutic uses of ionizing radiation, but it is noteworthy that he acted as one of the first health physicists when he used lead as a shield to protect the rest of the body of the patient. Even Becquerel and Madame Curie learned from first-hand experience the need for radiation protection when they received skin burns from the careless handling of radium (see RADIOACTIVITY).

S. Russ in 1915 made a comprehensive series of recommendations for radiation protection to the British Roentgen Society, and if these recommendations had been heeded, many of the early radiation fatalities might have been averted. It was not until 1928, when the International Commission on Radiological Protection was formed and published the first set of recommendations for radiation protection, that there began to be widespread interest and concern for this problem. In the following year the National Council on Radiation Protection was formed and it has set the standards in the United States.

Beginning at the time of the First World War and continuing until about 1930, there were many unfortunate exposures to radium. Some of these were the result of therapeutic injections of radium, the drinking of radium and radiothorium water, and occupational exposures of radium chemists. During this period, radium was considered to be a useful therapeutic agent, and as a result it was administered by physicians in the United States to hundreds of patients. In some cases it was taken as a general tonic, and in others it was given as a curative agent for hypertension, anemia, arthritis, and many other human ailments—even for insanity.

By far the most serious exposures were to young women engaged in the radium dial painting industry. Some of these women ingested relatively large quantities of radium as a consequence of tipping brushes with their lips as they applied radium paint on the dials of clocks and watches. The total number of radium dial painters and others who took radium by mouth or injection and, as a result, died with readily detectable symptoms of radiation damage is not known. The first recorded fatality due to radium-induced cancer, resulting from exposure in the radium dial industry, was in 1925, and since that time histories of over 1000 Ra cases have been recorded and studied in the United States.

In 1942–43 there was begun at the University of Chicago a program to explore the possibility of assembling a critical mass of natural uranium in such a way that a "pile" or NUCLEAR REACTOR could be operated for the production of the new element plutonium to be used in atomic weapons. A. H. Compton, the director, and his associates debated the wisdom of proceeding with this project because they realized that in a single large reactor there would be produced ionizing radiation equivalent to that from thousands of tons of radium. Yet all the radium that had been available to man throughout the world only amounted to about two pounds, and these men were acutely aware of the extensive suffering and death that had resulted from its misuse. They decided to call together a rather unique group of scientists to evaluate these health problems, to develop new instruments, equipment, and techniques and to establish radiation standards for the protection of nuclear energy workers. The group assembled was concerned with the *health* of the workers and consisted mostly of *physicists*; hence, they were called *health physicists*. E. O. Wollan was the leader and the other senior members were H. M. Parker, C. C. Gamertsfelder, K. Z. Morgan, R. R. Coveyou, J. C. Hart, L. A. Pardue, and O. G. Landsverk. Thus in 1942–43 health physics had its beginning at the University of Chicago. Although prior to this time many early pioneers such as S. Russ (England), L. S. Taylor (United States), G. Failla (United States), A. Mutscheller (Germany) and R. Sievert (Sweden)—to name only a few—had devoted considerable attention to the radiation protection problem, it was not until the advent of health physics that a professional group was organized with this as its sole objective.

As the nuclear energy programs expanded, large laboratories were established to carry on the program at Oak Ridge, Los Alamos, Hanford, Berkeley, Brookhaven, Savannah River, etc., and as the need for health physicists was recognized beyond nuclear energy programs and in private industry, hospitals, military organizations, utility power companies, state and federal agencies of public health, and colleges and universities, the profession of health physics grew and expanded very rapidly so that today (1982) it is estimated there are about 14 000 health physicists in the world. In 1956 the Health Physics Society was organized which now has a membership of about 5000. This society publishes the journal, *Health Physics.* In 1959 the American Board of Health Physics was formed for the certification of persons whose technical competence and judgment qualify them to be responsible for handling major problems of radiation exposure and/or contamination control. The International Radiation Protection Association was organized at the First International Congress on Radiation Protection in Rome on September 7, 1966, with K. Z. Morgan as its first president. In 1982 it included 28 affiliated societies with 10 000 members living in 70 countries.

There are three principal areas in which health physicists are employed—education and training, applied activities, and research—and these three areas will be discussed below.

In the early period, health physicists were scientists who had to develop their own competence during employment on the various atomic energy programs. In 1948 AEC Health Physics Fellowship programs were established at Oak Ridge National Laboratory in cooperation with Vanderbilt University and the University of Rochester and later with other national laboratories and universities. This program, over a twenty-five-year period in the U.S., became the principal source of senior health physicists. Unfortunately, during the period 1973–1976 the programs, which had expanded into some twenty universities, were phased out. Although most of the early health physicists began as physicists, there is today a need for health physicists with many different backgrounds, e.g., physics, biology, chemistry, mathematics, engineering. In the AEC Health Physics Fellowship program the student satisfied the usual Ph.D. requirements of courses, research, and thesis in one of these major departments, and at the same time, he met additional requirements such as special courses and summer work at one of the National Laboratories where he was given practical experience in health physics. Likewise, some of the graduate programs of the U.S. Public Health Service during this same period provided training in health physics. In spite of the various opportunities for education and training in health physics, the supply has not kept pace with the demand because of the expanding nuclear industry and the increasing uses of radiation in hospitals.

In addition to the above-mentioned graduate programs in health physics, there are education and training programs at all operating levels. The on-the-job programs are important because the success of health physics can be measured, to a considerable degree, in terms of how well plant managers, supervisors, scientists, engineers, technicians and operations personnel are made to realize their responsibility for protecting themselves and their associates from radiation damage. They must be ever aware that to some degree all radiation exposure is harmful and no unnecessary exposure may be permitted unless it can be balanced by benefits of equal value. At the same time they must be made to respect ionizing radiation—not fear it.

The duties of the health physicist in applied operations are very diverse and differ considerably from place to place, depending upon the size and nature of the operation. For example, the health physicist in a reactor operation would have duties quite different from those of the health physicist associated with an accelerator program or the health physicist connected with a state public health organization charged with the survey of medical x-ray equipment. A few typical applied health physics activities may be summarized as follows:

(1) Aid in the selection of suitable locations for buildings in which radioactive materials are to be produced or used, and conduct preoperation background surveys.

(2) Offer advice in the design of laboratories, hoods, remote control equipment, radiation shields, etc.

(3) Provide personnel monitoring meters for radiation dosimetry to all persons subject to radiation exposure and read these meters frequently; make thyroid counts, breath measurements, urine and feces analyses; check body with scanners and total body counters and conduct other tests to aid in estimating how much (if any) radioactive material is fixed in the body; and maintain accurate records of the accumulated dose from each type of ionizing radiation received by each individual for his protection and for the protection of the employer.

(4) Make frequent surveys of all accessible reactor areas, radioactive sources, x-ray equipment, high voltage accelerators, chemistry and physics laboratories, metallurgical shops, and other working areas where radiation exposure is possible.

(5) Advise scientists, supervisors and research directors of all radiation exposure hazards, of permissible working time in a given area, and of radiation protection measures and techniques (e.g., protective clothing, shields, remote control equipment) and aid supervision in the solution of new radiation problems as they develop.

(6) Make frequent surveys of all radioactive waste discharged beyond the area of immediate control, maintain accurate records of the level of this radioactivity in the air, water, soil, vegetation, milk, etc., and advise management of remedial measures as they are needed.

(7) Aid in all emergency operations where there are associated radiation hazards.

(8) Purchase and maintain in working order and in proper calibration suitable health physics survey and monitoring instruments which are used as aids in the protection of personnel from radiation damage.

(9) Prepare operations manuals on "Rules and Procedures Governing Radiation Exposure" and assist in preparation of Environmental Impact Statements required of nuclear power plants.

(10) Assist in radiation protection problems

related to civil defense, emergency planning, weapons fallout, space radiation, nuclear power plants, etc.

(11) Interface with members of the public in helping them to understand the risks of low level exposure and the desirability of keeping all exposures as low as reasonably achievable.

(12) Many health physicists work as consultants assisting radiation workers, atomic veterans, medical patients, etc. by litigation to receive compensation for alleged radiation damage.

Health physics research ranges from the applied and engineering programs to very basic studies. It is a working together of scientists of many disciplines—physicists, chemists, biologists, engineers, geologists, mathematicians—all studying the effects of ionizing radiation on man and on his environment. In these studies, they are working at all levels—nuclear, atomic, molecular, plasma, gas, solid, liquid, cell, animal, and the ecosystem. In this research program, radiation ecologists are studying the effects of low levels of radiation exposure on the environment. Some essential organisms in the environment are known to concentrate radioactive waste by a factor of 100 000 or more, and the health physicist must determine the importance of the indirect damage of ionizing radiation to man's environment as well as its direct effects. Internal dose studies are under way by researchers in health physics, studies which have led to the publication of the official handbooks on maximum permissible concentration of the various radionuclides in food, water, and air. These handbooks are issued by the National Council on Radiation Protection and the International Commission on Radiological Protection. They are under constant revision by the health physicist as more reliable and detailed information becomes available. Biologists in health physics are studying the uptake distribution and elimination of radionuclides which are taken into animals and man by the several modes of intake —ingestion, inhalation and skin penetration. Engineers in health physics are exploring and demonstrating new methods for the disposal of radioactive waste in deep wells thousands of feet below the earth's surface in salt mines and in a number of other geological formations. They are studying the seepage rates of radionuclides into various soil formations, its slow dissipation from packages of radioactive waste deposited on the ocean floor, and the dilution of airborne radioactive waste as it is discharged from stack of nuclear power plants under varying meterological conditions. The physicists in health physics are making basic studies of the various energy exchanges that take place in matter when it is exposed to ionizing radiation. This information aids in the development of better radiation detection systems and leads to an understanding of the true meaning and consequence of radiation exposure. When high energy radiation (in the MeV or keV region) strikes living matter, there are innumerable, complex energy exchanges that take place as the ENTROPY of the system increases. An understanding of the many low energy transitions is basic to a proper interpretation of the effects of ionizing radiation on man. Health physicists are working toward the ultimate goal of developing a coherent theory of radiation damage. Only when such a theory is available can they have complete understanding and confidence in the many extrapolations to man of the effects of ionizing radiation on animals. Such information is essential in developing reliable radiation protection standards and measures that are enforced by the applied health physicist. Many health physicists are working on programs to reduce unnecessary medical diagnostic exposure, which at present accounts for over 90 percent of exposure of the United States population.

The units used in health physics often result in some confusion. In the early period units such as the threshold erythema dose, roentgen, and rep were used, but they have been phased out and replaced by the rad and the rem, and in some cases these two units are now being replaced by the gray and the sievert. The rad corresponds to the absorption of 100 ergs per gram of medium and is the unit of absorbed dose. The rem is the unit of dose equivalent. We have the following relation:

Dose Equivalent (rem) = Absorbed Dose (rad) $\times Q \times N$ in which Q is a qualtiy factor that corrects for LET (linear energy transfer) or the density of ionization along the tracks of ionizing particles. Thus we have $Q = 1$ for x-, gamma, and beta radiations and $Q = 20$ for alpha radiation, recoil ions, and fast neutrons. The N is a biological correction factor which attempts to correct for such things as nonuniform distribution of radionuclide deposition in body organs, the radiosensitivity of the irradiated tissue and its essentialness to proper body function. It is common to set N equal to:

1 for x- and gamma radiation
1 for external exposure (radionuclide not inside body)
1 for radium when it is the parent radionuclide
1 for all tissue except bone
5 for bone if internally deposited radionuclide is not radium and the radiation is not x- or gamma.

The gray corresponds simply to 100 rads and the sievert to 100 rem.

The curie corresponds to an amount of a radionuclide which disintegrates at the rate of 3.7×10^{10} disintegrations per second. The becquerel has been introduced to replace the curie. It corresponds to a quantity of radionuclide which disintegrates at the rate of 1 disintegration per second. There is considerable opposition to the gray, sievert, and becquerel units—especially in the U.S., where they are seldom used.

There are many so-called maximum permissible dose levels, but the one most commonly used is the limit of 5 rem per year to the total body of a radiation worker. The present limits for internal dose in the U.S., upon which the present U.S. levels of maximum permissible body burden of radionuclides and their maximum permissible concentration in our water, air, and food are based, are set at 5 rem per year to total body, gonads, and red bone marrow; 30 rem per year to bone, thyroid, and skin; and 15 rem per year to all other body tissue. Various maximum permissible dose levels are in use for exposure to members of the public, but perhaps the most generally applied levels are those of the Environmental Protection Agency of the U.S. in reference to the uranium fuel cycle (i.e., nuclear power plants, reprocessing plants, etc.). These limits are 75 mrem per year to the thyroid and 25 mrem per year to all other body organs and the whole body.

The health physicist makes use of many types of instruments to determine the dose of ionizing radiation. For area survey measurements he uses geiger counters, ion chambers, proportional counters, and scintillation counters. Sometimes the instruments have sliding windows so that they can respond preferentially to alpha, beta, gamma, and low-energy x-rays. Neutron doses are measured with proportional counters, BF-3 counters, and threshold detectors (i.e., activation of radionuclides of indium, Pu-239, U-238, Np-237, S-32, etc.) The Ge-Li detectors (lithium drifted germanium detectors) are widely used to determine the energy of radionuclide emissions and thus identify them. When the radioactive material is contained inside the body, the body burden is determined by analyses of urine and feces and by total body and scan-counting, using large scintillators or Ge-Li detectors. Personnel monitoring used to be done by the use of pocket ion chambers and film badges. Today the pocket ion chambers are often replaced by direct-reading fiber dosimeters or small G-M counters which display the dose rate and the integrated dose. The film badges have for the most part been replaced by TLD's (thermoluminescent dosimeters) for beta, gamma, and x-ray monitoring. In the past, neutron personnel monitoring was done mostly by the use of thick nuclear emulsion photographic films. However, these are being replaced by polycarbonate foils which are read with optical instruments. This foil technique is a big improvement over the photographic film, in which fading of the tracks is a serious problem (the half-life of the tracks ranges from 3 weeks to 6 months depending on the type of emulsion and the relative humidity). For polycarbonate foils, track fading is almost nil and fast neutron detection sensitivity is about 1,000 times higher than that of photographic emulsions.

Only a relatively few health physicists are engaged in work with nonionizing radiations (UV, visible, microwave, rf, infrared, sonic, ultrasonic, and infrasonic), but here many new problems are being faced and there are uncertainties. For example, the maximum permissible occupational exposure limit of rf and microwave radiation is 1000 times higher in the U.S. than in the USSR (10 mW/cm^2 in the U.S. and 10 μW/cm^2 in the USSR).

There is disagreement and strong debate[3] among health physicists regarding the cancer risk from low-level exposure to ionizing radiation. The common estimates of general cancer risk range between 1×10^{-4} to about 8×10^{-3} lethal cancers per person rem. This author[4] believes one should not use a value smaller than 10^{-3} lethal cancers per person rem, or twice this value for total cancer incidence, until some important questions can be answered and some of the biases in the present studies can be evaluated.

Health physics continues to grow as a most interesting and challenging profession for scientists of many backgrounds. The success of these programs is attested by the fact that ionizing radiation with unparalleled potential for radiation hazards has expanded in its use and applications into almost every area of human endeavor and yet the nuclear energy industry has become one of the safest of all industries.

HEARING

The role of the sense organ of hearing is to code acoustic disturbances into neural signals suitable for transmission to the brain. The study of this process necessarily involves anatomy and physiology of the ear, the nature of auditory pathways and central nervous system activity in hearing, properties of acoustic signals that elicit auditory responses, and observed phenomena of auditory behavior. These aspects serve to define and delineate areas for investigations of hearing and are the topics of discussion for this article.

In this approach to hearing, questions are asked about the structure of the system, how the system functions, and the relationships between inputs and outputs of the system. These three kinds of data–morphological, physiological, and psychological–need to be compared and correlated for a full understanding of hearing. It is important, however, that these three frames of reference be kept separate and not be confused. Although physiological functions may correspond in a general way to anatomical sequences, several physiological functions may occur in the same anatomical structure or a single function may require several anatomical units. In a similar manner, psychological functions cannot usually be identified with specific physiological functions, and it is recognized that the central nervous system, as well as the auditory system, is involved in any auditory response. The correlations between and knowledge about structure and functions are best developed for peripheral, rather than central, parts of the auditory system because the ear is more accessible for examination and study than are the more central parts of the auditory system.

Traditional theories of hearing have been largely concerned with pitch perception. A comprehensive theory does not exist that can account for the complexities of the processing of speech or music by the auditory system. However, there are a number of excellent models that depict various physiological, sensory, and perceptual functions of hearing. Much research is concerned with empirical testing of these models, with results that are in the direction of a more coherent understanding of hearing. Investigators often endeavor to relate many phenomena of hearing to a particular model. An example is the critical-band model, a concept of a filterlike mechanism early in the auditory system that affects various auditory functions in a similar manner. Frequency analysis, masking, pattern perception, and changes in hearing with aging are but a few of the features of hearing that can be related to a critical-band filter model.

When the structure of the ear is examined, it is convenient to consider the external, middle, and inner ear separately. A cutaway drawing of the ear is shown in Fig. 1. From a functional point of view, the ear may be divided into an outer and inner part. The outer is concerned with the transformation of acoustic energy into mechanical energy and the inner with the transduction of mechanical energy into neural impulses. The auricle and external auditory meatus constitute the external ear. The meatus is an irregularly shaped tube approximately 27 mm long with a diameter of about 7 mm, terminated by the tympanic membrane. The outer ear serves as an acoustic resonator to produce a gain in acoustic energy of about 10 to 15 decibels in the frequency range from 2000 to 5000 Hz. This is a combined effect of the concha (the area at the entrance to the ear canal) and of the ear canal itself, each having a separate resonance. The

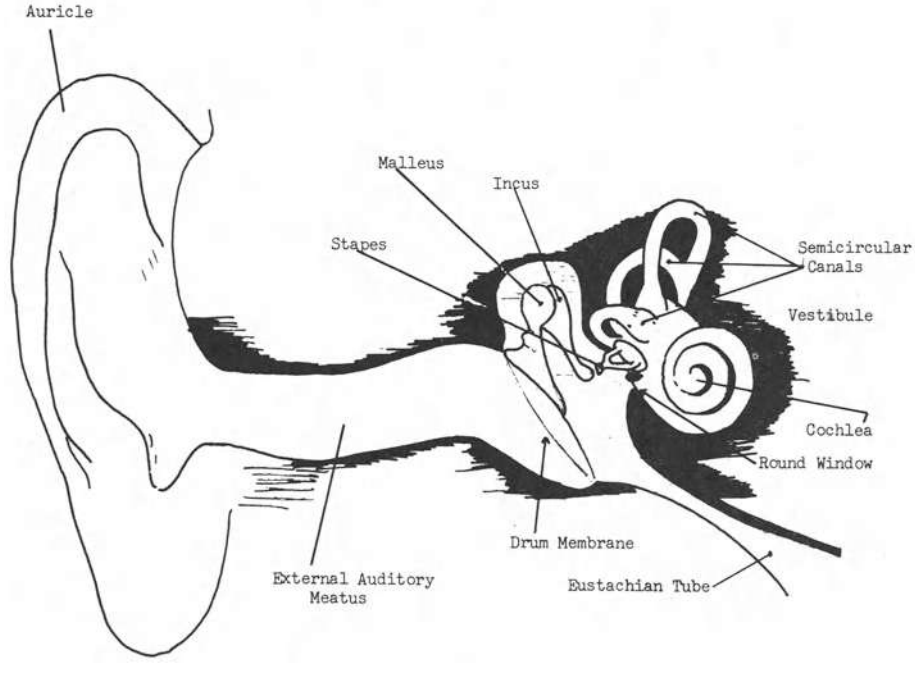

FIG. 1. A cutaway drawing of the ear.

former has a resonance at about 5000 Hz, the latter a resonance at slightly above 200 Hz. The ear drum is in a protected position at the end of the canal, and humidity and temperature conditions at the drum are relatively independent of those external to the ear.

The middle ear is an irregular, air-filled space in the petrous portion of the temporal bone. The three ossicles of the middle ear—the malleus, the incus, and the stapes—provide mechanical linkage between the tympanic membrane and the fenestra vestuli, an opening in the vestibule of the inner ear commonly known as the oval window. The handle of the malleus attaches to the tympanic membrane, and the footplate of the stapes attaches to the oval window. The important function of the middle ear is impedance matching and transformation of energy of air vibrations in the ear canal to fluid in the cochlea. This efficiency of sound transmission from one medium to another is accomplished primarily because the area of the tympanic membrane responding to vibrations of air is considerably larger than the area of the footplate of the stapes at the oval window to the inner ear. The lever action of the ossicles contributes to the efficiency of this transformation to a lesser extent than the area ratios of the two membranes. The amplification gain due to the middle ear is approximately 30 dB. The effectiveness of the middle ear action in increasing hearing sensitivity is evidenced in middle ear pathologies where the ossicular chain is disrupted. A hearing loss on the order of 25-40 dB occurs. The second function of the middle ear, that of protecting the inner ear from loud sounds, is accomplished by reflex action of the middle ear musculature, the stapedius, and the tensor tympani. The action of the muscles is to draw the stapes away from the oval window, retract the ear drum, and change ossicle vibrations in such a way as to decrease the transmitted pressure. The stapedius may be more responsive to accoustic stimulation than the tensor tympani. Latency of muscle contraction and possible muscle fatigue limit protection of the inner ear by these mechanisms. Middle ear air pressure is equalized by virtue of the eustachian tube which connects the middle ear and the nasopharynx. The pressure equalization is necessary for normal ear drum movement.

The inner ear is a system of cavities in the dense petrous portion of the temporal bone. One of the cavities is the cochlea, a bony labyrinth that is approximately 35 mm in length coiled around a central core for two and three-quarters turns. The spiral-shaped cochlea is divided into three ducts, two bony and one membranous. A cross section of cochlea showing the three ducts is shown in Fig. 2. The upper bony duct, the scala vestibuli and the lower bony duct, the scala tympani, are separated from each other by a membranous labyrinth, the cochlear duct. The cochlear duct is bound on top by Reissner's membrane and is bound below by the basilar membrane. The cochlear duct is filled with a viscous fluid called endolymph, and the duct is surrounded by a fluid called perilymph that has about twice the viscosity of water. The scala vestibuli and the scala tympani join at the apical end of the cochlea at a passage called the helicotrema. The scala tympani terminates at the basal end at the round window, a membrane-covered opening into the middle ear. The scala vestibuli is continuous with the vestibule; the oval window opens into the vestibule. Vibrations at the footplace of the stapes are transmitted into the fluid adjacent to the oval window. Vibration of the stapes and resultant disturbances in cochlear fluids results in movement of the basilar membrane. The cochlear duct contains the sensory receptors, specifically the organ of Corti, which lies upon the basilar membrane. There are about 12 000 hair cells; one end of each rests on the basilar membrane. The other ends of the hair cells are the cilia, very fine hairline processes, which make contact with the tectorial membrane, a membrane that overlaps the organ of Corti and that functionally behaves as if it were hinged at the cochlear wall. There are three rows of outer, and one row of inner, hair cells along most of the length of the basilar membrane. When vibrations are introduced into the inner ear and cause displacement of the basilar membrane a shearing action of the cilia occurs that results in neural activity. It is assumed that amplification occurs in the inner ear in that small pressures on the basilar membrane result in a shearing force of considerably greater magnitude that distorts the hair cells. The result is increased sensitivity of the hearing system. Physical properties of the cochlea are such that different frequencies tend to localize at different points along the basilar membrane. The basilar membrane is narrowest and stiffest at the basal end, and most lax and widest at the apical end of the cochlea. High-frequency sounds result in the greatest disturbances near the basal end, and low-frequency sounds tend to localize near the apical end. When the role

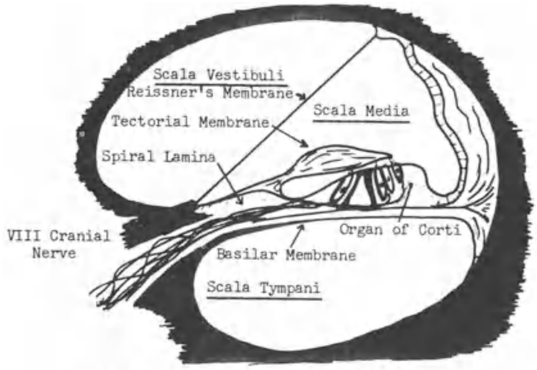

FIG. 2. Cross section of cochlea.

of the cochlea in pitch and loudness analyses is considered, it is now realized that more is involved in pitch perception than the place of localization on the basilar membrane, although the particular neural fibers involved are probably relevant. Of particular interest in this regard is the phenomenon called low pitch, where there is no energy at the frequency that corresponds to the perceived pitch. Our impression that we are hearing a fundamental pitch for a person talking over a telephone is a good example. Telephone circuits do not transmit frequencies in the fundamental pitch range so there is, in fact, no energy in this range yet an experience of pitch is experienced by the listener. Loudness is probably related to the total number of neural impulses per unit time.

The auditory pathways provide for the neural impulses from the ear to be transmitted to the cerebral centers of the auditory cortex. Processing of the neural signals probably occurs at synaptic connections as well as in the cortex. The cell bodies of the receptor neurons are located in the spiral ganglion. Neurons of the auditory nerve make synaptic connections with the hair cells of the cochlea. Nerve fibers typically innervate many hair cells, and more than one nerve fiber may make a connection with the same hair cell. There is evidence to indicate that there are also descending neural pathways as well as ascending ones. The central nervous system may thus be involved in auditory processing at the cochlea. Spiral ganglion axons make synaptic connections with cells of the central nervous system at the cochlear nucleus. At this point, there is interconnection between the pathways for the two ears. Other synaptic stations between this point and the auditory cortex include the inferior colliculus and the medial geniculate body. A schematic depicting the auditory pathways is shown in Fig. 3. It can be observed that the major projection is to the contralateral (opposite) cerebral hemisphere for each ear. That is, the right ear projects primarily to the left hemisphere and the left ear to the right hemisphere. Some evidence has been presented that for right-handed people, the left cerebral hemisphere processes speech and the right hemisphere processes non-speech signals. Evidence from pathological auditory systems is of particular interest with respect to the auditory pathways. In fact, one excellent way to understand the auditory system is to study the system when it is in a breakdown or pathological state. An impaired cochlea, for example, may result in a better than normal response to small amplitude changes in a sound. A lesion of the VIIIth Nerve is frequently manifested by a rapid decrease in the ability to respond under sustained stimulation. The ability to process speech is markedly affected when there is an involvement of the lower central nervous system. Cortical involvement does not affect usual speech or pure tone inputs.

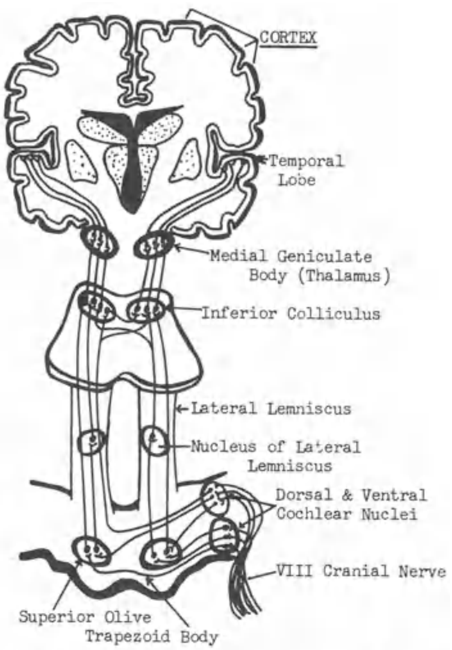

FIG. 3. Schematic depicting auditory pathways.

The stimulus for hearing is sound. Sound involves a disturbance in the air that is a forward and backward, rarefaction and compression, movement of air particles. The unit of force usually used in acoustics is the dyne. Sound pressure is frequently expressed in dynes per square centimeter. Intensities of sounds are usually measured on a decibel scale, a logarithmic ratio scale. The tremendous loudness range of the ear is exemplified by the fact that the most intense sound that can be tolerated is a million million times greater in intensity than a sound that is just audible. This is a range of approximately 120 dB. The frequency range of hearing is frequently given as 16 to 20 000 Hz. The ear is most sensitive in the middle frequency range of 1000 to 6000 Hz. In terms of discrimination of frequency and intensity, it is possible for about 1400 pitches and 280 intensity levels to be distinguished.

The truly phenomenal aspects of hearing can be observed in such behavior as localization of sounds, speech perception and particularly the understanding of one voice in the noisy environment of many, and the recognition of acoustic events that only last a few milliseconds. It is these and other behavioral phenomena that need to be accounted for in theories of hearing.

HEAT

Heat and Temperature *Heat* is (internal) energy in transit due to a decrease in temperature between the source from which the energy is coming and the sink toward which the energy is going. When heat is added to a system, the result may be either to raise the temperature or to cause a thermal transformation (e.g., melting, boiling, expansion, increase in resistance). Conversely, the removal of heat from a system may either lower the temperature or cause freezing, condensation, contraction, decrease in resistance, etc.

The concept of *temperature* begins with the physiological sensation of hotness and coldness. The hotter an object feels, the higher is the temperature, and vice versa. However, the sensation of temperature is easily influenced by the thermal condition of the skin and the thermal conductivity of the object being touched. Thus the concept of temperature must be quantified using inanimate instruments that reproducibly measure ranges of temperature over a continuous scale.

Many different types of thermometers are available, but the two most common are the colored-alcohol-in-glass and the coiled bimetallic strip. Historically the normal freezing and normal boiling points of pure water were chosen as the two fixed points of the principal temperature scales. In the English system of units the values of 32°F (F for *Fahrenheit*) and 212°F are assigned to the fixed points. In the practical metric system the values of 0°C (C for *Celsius*, previously *Centigrade*) and 100°C are assigned to the fixed points.

In the modern metric *Système International d'Unités* (abbreviated SI in all languages) temperature is measured in units of *Kelvin* (the word *degree* is dropped). The triple point of pure water is assigned the value of 273.16 K (corresponding to 0.01°C) and a temperature interval of one Kelvin is the same as one degree Celsius.

When comparing the definitions of heat and temperature, it is possible to encounter a circular argument. For example, heat may be defined to be the flow of energy due to a temperature difference; and temperature may be defined as a property of an object which determines the direction of heat flow. The circularity in reasoning will be broken later in this article when heat will be shown under certain conditions to be equivalent to work, which can be independently defined and measured.

Measurement of Heat The *calorimetric* definition of heat was established by Joseph Black (1728–1799) during the eighteenth century. Equal masses of water, initially at different temperatures, were mixed in a container called a *calorimeter*, which was insulated from its surroundings. It was observed that the final temperature of the mixture was always exactly halfway between the two initial temperatures (if the effects of the calorimeter and the thermometer were negligible). The temperature changes ΔT of the hot and cold masses of water were equal and opposite,

$$\Delta T_h = -\Delta T_c.$$

If different masses of water were mixed, the temperature changes were observed to be inversely proportional to the respective masses,

$$\frac{\Delta T_h}{\Delta T_c} = -\frac{m_c}{m_h},$$

or

$$m_h \Delta T_h = -m_c \Delta T_c. \qquad (1)$$

This experiment suggested thinking about something lost by the hot mass of water and gained in equal amount by the cold mass of water; or, in other words, that there was a transfer of *heat*. Until the middle of the 19th Century heat was assumed to be a material fluid that could be neither created nor destroyed, capable of flowing between atoms and molecules, and attracted by some materials and repelled by others. Antoine Lavoisier (1743–1794) gave the fluid principle of heat the name *caloric theory*.

Equation (1) was shown to be valid only when two samples of water were mixed at initially different temperatures, but failed to predict the correct temperature changes when water and another substance were mixed. Thus

Eq. (1) was modified to the general case:

$$C_A m_A \Delta T_A = -C_w m_w \Delta T_w, \qquad (2)$$

where A stands for a substance with a higher temperature mixed with water w, and C is a property of the material known as the *specific heat capacity* (usually shortened to *specific heat*). The left-hand term in Eq. (2) is the heat Q_A transferred to or from substance A, and the right-hand term is the corresponding amount of heat Q_w transferred from or to the water.

More accurate observations showed that the value of C for any particular substance was different and depended on the physical circumstances under which the final temperature was obtained. Gases, for example, showed a smaller value of C if the temperature changes occurred at constant volume than if the temperature changes occurred at constant pressure. Thus there needed to be a C_v for specific heat at constant volume and C_p for specific heat at constant pressure.

It was thought to be necessary to define a special unit in which calorimetric heat would be measured. Water was selected as the standard substance and C_p given the numerical value of unity. In the English system the *British thermal unit* (or Btu) is the heat needed to raise the temperature of the mass associated with one pound of water from 60°F to 61°F at one atmosphere of pressure.

In the pre-SI metric system the *calorie* was defined as the heat required to raise the temperature of a mass of one gram of water from 14.5°C to 15.5°C at one atmosphere of pressure. A large calorie or *kilocalorie* (*Calorie* written with a capital *C*) corresponds to 1000 ordinary calories and is used almost exclusively in dietetics. In the modern SI metric system there is no unique unit for heat. Instead heat is recognized as a form of energy and is measured in *joules*, as are all forms of energy.

Heat and Work The caloric theory was widely accepted toward the end of the 18th Century because of its simplicity and many successful applications. The first really conclusive evidence that heat could not be a material fluid was given by Benjamin Thompson (1753–1814), born in Woburn, Massachusetts, who left the United States because of royalist sympathies during the American Revolution and later became Count Rumford in Bavaria. In 1787, using a very delicate balance, he determined that there was no detectable difference in the weight of an object whether hot or cold, which raised doubts about the material nature of the caloric fluid.

In 1798 Rumford observed the temperature rise in brass chips produced during the boring of a cannon. The heat generated by friction between a moving boring tool and the cannon appeared to be *inexhaustible*. Obviously the caloric theory of heat could not be based on a material fluid that flowed without limitation. Rumford proposed instead that heat was a form of motion, but was unable to explain the nature of the motion.

The attack on the caloric theory continued in the 1840s, especially by the quantitative experiments of James Prescott Joule (1818–1889). In several different experiments Joule allowed falling objects to perform work on a sample of water that consequently experienced a rise in temperature. Heating one pound of water through 1°F he was able to determine that 1 Btu of heat was produced by 772 foot-pounds of work, which is sometimes called the *mechanical equivalent of heat*. In other words, energy could be converted from one form to another, an idea that would be incorporated into the formulation of the law of conservation of energy.

Recognition that heat is another form of energy means that the mechanical equivalent of heat is simply a conversion factor between different units of measurement. The currently accepted conversion factors are: 1 Btu is equivalent to 778.28 foot-pounds and 1 calorie (15°C) is equivalent to 4.1858 joules.

In order to discuss the modern definition of heat based on Joule's experiments it is necessary to specify the physical properties of the walls surrounding the system being investigated. When an *adiabatic* wall is used to separate two systems A and B, the macroscopic properties of one system are found to be unaffected by those of the other. For example, if a thick asbestos or styrofoam wall separates a gas from a wire, the properties of the gas (pressure, volume, temperature) have no influence on the properties of the wire (tension, length, resistivity). In other words, an adiabatic wall is a perfect insulator to heat.

If, however, the two systems are separated by a *diathermic* wall, such as a thin sheet of copper, the properties of the two systems will change spontaneously, until an equilibrium state of the combined system is reached, because a diathermic wall is a perfect conductor of heat. The two systems are then said to be in *thermal equilibrium*, which means they have the same temperature. Thus, temperature may also be defined as the property that determines whether or not two systems are in thermal equilibrium.

Consider next the concept of work. If there exists a macroscopic force F, undergoing a macroscopic displacement ds in a direction parallel to the force, the work dW is defined as Fds. Each simple system has its own expression for work, such as $-PdV$ for a hydrostatic system, Tdl for a wire, $\mu_0 HdM$ for a magnetic system, etc. Simple calculations show that the work in a finite process depends on the external processes (so-called *path*) used to change the system from its initial state to its final state. There is no such thing as the "work in a sys-

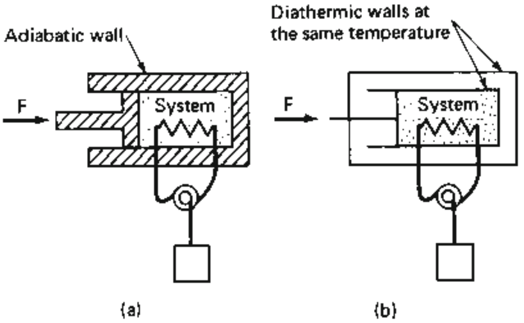

FIG. 1. The behavior of the system surrounded by adiabatic walls in (a) is the same as that whose diathermic walls and surrounding enclosure are at the same temperature in (b).

tem." The work is not a function of properties (so-called *coordinates*) of a system. In mathematical terms work is an inexact differential and the element of work may be written $\text{đ}W$.

In Fig. 1(a) there are shown two ways in which work may be performed on a system surrounded by adiabatic walls. A force may cause the piston to move some distance; and a falling object may rotate an electric generator that provides a current in a resistor embedded in the system and included as part of the system. Consider two arbitrarily chosen states of the system, i and f (initial and final). It is possible using the apparatus in Fig. 1(a) to proceed from i to f along many different paths. One process might be to move the piston in and then maintain the current until the final state is achieved. Such a process is shown by path I in Fig. 2. Another process might be to perform the electrical work first and the work of compression second, as shown by path II in Fig. 2. The *total* work in proceeding from state i to state f is the same for each path. In other words, adiabatic work W_{ad} is independent of the path and depends only on the initial and final states of a system.

Interestingly enough, it seems that experiments of this type may never have been performed. There was a rapid and universal acceptance of the law of conservation of energy following the work of Joule and especially Hermann von Helmholtz (1821-1894). It is an accepted fact, indeed a law of nature known as *the first law of thermodynamics* (in a restricted case), that adiabatic work is independent of path. This statement is established beyond any reasonable doubt, however, because all the consequences of the first law of thermodyanics have been so well verified by direct experimental evidence.

It is an experimental fact that the apparatus shown in Fig. 1(b), in which the adiabatic wall is replaced by two rigid diathermic walls, *whose temperatures are maintained equal at all times*, is in all respects equivalent to the apparatus with an adiabatic wall. This temperature equality is achieved experimentally by noting the readings of thermocouples whose junctions touch the inner wall enclosing the system and the outer wall surrounding the inner wall. When the thermocouple readings differ, energy is provided to either the inner wall or the outer wall.

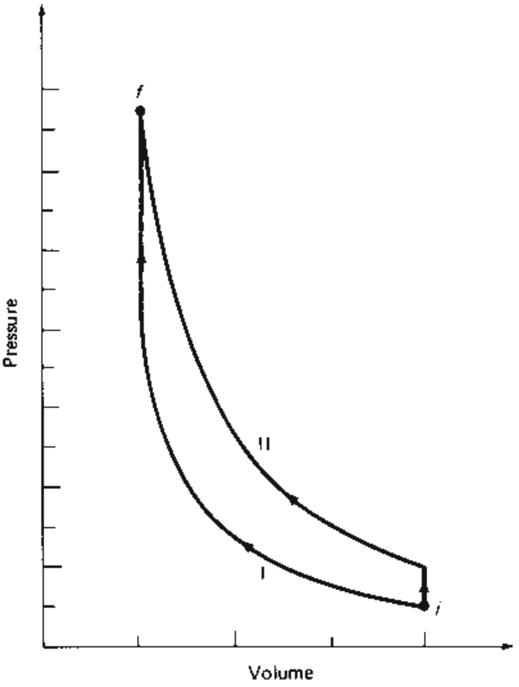

FIG. 2. The adiabatic work done on the system is the same whether going by path I or path II from the initial state i to the final state f.

Using this equipment, it is possible to measure the work W_{ad} when the system is brought from state i to state f adiabatically (by holding both diathermic walls at the same temperature). It is again observed that W_{ad} is independent of the path. The consequences of independence of path may now be derived. In mechanics the work needed to move an object slowly and without friction from one height to a higher elevation is independent of the path. Thus one is lead to the concept of gravitational potential energy. Similarly, since the adiabatic work in bringing the system in Fig. 1(b) from state i to state f is also independent of the path, then there must exist a function U of the coordinates of the system such that

$$\Delta U = U_f - U_i = W_{ad}. \tag{3}$$

The function U might justifiably be called the "adiabatic work function," but instead is called the *internal energy function*. Notice that if positive work is done on the system, its internal energy is increased, a sign convention universally used in physics. In some older discussions of the first law of thermodynamics there is a minus sign on the left in Eq. (3) and work is negative when performed on a system. The latter sign convention followed the engineering practice of defining work to be positive when a machine (the system) operates on its surroundings.

Suppose now that the inner wall of the apparatus in Fig. 1(b) is now deliberately set at a different temperature from the outer wall. While the temperature difference is maintained, the system is again brought from state i to state f and the work W is measured. This work would be found to be different from W_{ad}, that is, different from $U_f - U_i$. Since it is undesirable to give up the law of the conservation of energy, the conclusion is inescapable that the difference between W and W_{ad} (or W and $U_f - U_i$) is due to another form of energy that must have entered or left the system *by virtue of the temperature difference between the system and its surroundings*. This energy flow, which is internal energy moving between the system and its surroundings, is none other than the quantity that is called "heat."

We see that the old calorimetric definition and the modern thermodynamic definition of heat, as energy transferred by virtue of a temperature difference, are in agreement. However, any circular reasoning involving definitions of heat and temperature is now broken; heat can be independently defined by measurements in terms of work performed on a system surrounded by different walls. Denoting the heat that has entered or left the system again by the symbol Q, we get

$$Q = W_{ad} - W = U_f - U_i - W, \tag{4}$$

which is the mathematical formulation of the *first law of thermodynamics*.

Rewriting Eq. (4) in the form

$$U_f - U_i = W + Q \tag{5}$$

shows that W and Q are *methods of producing a change in internal energy*. W is the mechanical method of energy transfer, and Q is the nonmechanical or thermal method. Together they constitute the two thermodynamic methods in which U may be changed.

Work and heat are *processes* of energy transfer. When all flow is completed, the words "work' and "heat" have no longer any usefulness or meaning. It would be just as incorrect to refer to the "heat in a system," as it would be to speak of the "work in a system." The performance of work and the flow of heat are methods whereby the internal energy of a system is changed. As a result of these processes, the internal energy of the system has either increased, decreased, or remained constant. Once the processes of transferring energy are over, we can only speak of the internal energy of the system. It is impossible to subdivide the internal energy into a mechanical and a thermal part, just as it is impossible to subdivide the water in a lake into parts resulting from (1) flow from a stream, (2) rain, (3) springs, etc.

HEAT CAPACITY

The heat capacity of any thermodynamic system is

$$C = \frac{\delta q}{dT}, \tag{1}$$

where δq is the quantity of heat* required to produce the temperature increment dT. If the system consists of a single substance with definite chemical composition and physical state, C is proportional to the total quantity of matter in the system. The heat capacity of 1 gram is the specific heat, and the heat capacity of one mole is sometimes called the molar heat capacity. Commonly used units of heat capacity include cal mole^{-1} deg^{-1}, cal g^{-1} deg^{-1}, and J mole^{-1} deg^{-1}.

The heat capacity of a substance depends on the variables that determine its thermodynamic state—e.g., temperature, pressure, electric and magnetic field—and also on the constraints imposed during the absorption of heat. Here we limit consideration to a substance subject to a hydrostatic pressure P and to no other forces. In this case, the thermodynamic state is determined by two variables, usually taken to be temperature and either pressure or molar volume V. The usual conditions for which C is of interest are constant volume and constant pressure, and the symbols C_V and C_P are used for the heat capacities measured under these conditions.

The difference between C_P and C_V is related to other thermodynamic properties by the first law of thermodynamics, which, for processes of

*The symbol δ indicates a differential that is not exact, i.e., one for which a line integral is not determined by the initial and final points alone, but also depends on the path.

interest here, may be written

$$\delta q = dU + P\,dV = dH - V\,dP, \qquad (2)$$

where U is the energy and $H = U + PV$ is the enthalpy. (We write this and all subsequent expressions involving thermodynamic properties for one mole.) From Eqs. (1) and (2), we have

$$C_V = \left(\frac{\partial U}{\partial T}\right)_P \qquad (3)$$

and

$$C_P = \left(\frac{\partial U}{\partial T}\right)_P + P\left(\frac{\partial V}{\partial T}\right)_P = \left(\frac{\partial H}{\partial T}\right)_P. \qquad (4)$$

Subtraction of Eq. (3) from Eq. (4) and substitution of the mathematical relation

$$\left(\frac{\partial U}{\partial T}\right)_P = \left(\frac{\partial U}{\partial T}\right)_V + \left(\frac{\partial U}{\partial V}\right)_T\left(\frac{\partial V}{\partial T}\right)_P \qquad (5)$$

gives

$$C_P - C_V = \left\{\left(\frac{\partial U}{\partial V}\right)_T + P\right\}\left(\frac{\partial V}{\partial T}\right)_P. \qquad (6)$$

The quantity of heat required to produce a certain temperature increase dT is greater at constant pressure than at constant volume by the sum of the work of expansion in the constant pressure process, $P(\partial V/\partial T)_P\,dT$, and the increase in internal energy accompanying the expansion, $(\partial U/\partial V)_T(\partial V/\partial T)_P\,dT$.

An expression for $C_P - C_V$ that is more useful than Eq. (6) is

$$C_P - C_V = TV\alpha^2/\kappa, \qquad (7)$$

which can be obtained from Eq. (6) by introducing a relation based on the second law of thermodynamics.

$$\left(\frac{\partial U}{\partial V}\right)_T + P = T\left(\frac{\partial P}{\partial T}\right)_V,$$

the mathematical relation

$$\left(\frac{\partial P}{\partial T}\right)_V = -\left(\frac{\partial V}{\partial T}\right)_P \Big/ \left(\frac{\partial V}{\partial P}\right)_T,$$

and the definition of the coefficients of thermal expansion α and isothermal compressibility κ,

$$\alpha = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_P, \qquad (8)$$

and

$$\kappa = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T. \qquad (9)$$

The subject of the following sections is the relationship of the heat capacities of ideal gases and solids to the energies associated with different degrees of freedom of the constituent particles. The heat capacity of a liquid is more complicated and is not considered here.

Ideal Gases An ideal gas obeys the equation of state, $PV = RT = NkT$. The gas constant R is 8.314 J mole^{-1} K^{-1}, N is Avogadro's number, and $k = R/N$ is Boltzmann's constant. By Eqs. (7), (8) and (9), $C_P - C_V = R$.

In the application of statistical mechanics to the calculation of C_P or C_V it is convenient to consider first the predictions based on classical principles. The pertinent result of classical statistical mechanics is the principle of equipartition of energy: any term in the energy of a particle proportional to the square of either a coordinate or a momentum contributes an average of $\frac{1}{2}kT$ to U. Since the molecules of an ideal gas have three translational degrees of freedom, each with an associated kinetic energy proportional to the square of a momentum, the expected translational contributions to the energy and heat capacity are $U = \frac{3}{2}NkT = \frac{3}{2}RT$ and, by Eq. (3), $C_V = \frac{3}{2}R$. For monatomic gases this is the only contribution to C_V and this value is in excellent agreement with experiment.

Diatomic molecules can rotate about each of two independent axes perpendicular to the internuclear axis, and the two atoms can vibrate with respect to each other along the internuclear axis. Each of the two rotational degrees of freedom has a kinetic energy proportional to the square of a momentum, and the vibrational degree of freedom has both a kinetic energy proportional to the square of a momentum and a potential energy proportional to the square of a coordinate (the vibration is approximately harmonic). In classical statistical mechanics, C_V is therefore expected to be $\frac{7}{2}R$, but for most diatomic gases at room temperature C_V is close to $\frac{5}{2}R$. This discrepancy, one of the historically important failures of classical theory, is resolved by proper consideration of quantum effects as suggested by Einstein. The allowed energy levels of a harmonic oscillator are not continuous as in classical mechanics, but are given by

$$\epsilon_n = nh\nu, \text{ with } n = 0, 1, 2, 3, \cdots,$$

where h is Planck's constant, ν is the natural frequency of the oscillator, and the energies ϵ_n are measured from the lowest level. For the average energy of a single oscillator, quantum statistical mechanics gives

$$\bar{\epsilon} = \frac{h\nu}{e^{h\nu/kT} - 1}.$$

Instead of the classical value k, the contribution to C_V is

$$\frac{d\bar{\epsilon}}{dT} = k\,\frac{\left(\dfrac{h\nu}{kT}\right)^2 e^{k\nu/kT}}{(e^{h\nu/kT} - 1)^2}. \qquad (10)$$

This contribution to C_V is negligible for $T \leqslant 0.1\ h\nu/k$ because most of the oscillators remain in the $n = 0$ level, but it increases rapidly near $T \approx \frac{1}{4}h\nu/k$ and approaches the classical value for $T \geqslant h\nu/k$. For many diatomic molecules, $h\nu/k$ is a few thousand degrees Kelvin or more, and a room-temperature C_V of $\frac{5}{2}R$ can be understood as the sum of the translational and rotational contributions. The details of the temperature dependence predicted by Eq. (10), including the approach of C_V to $\frac{7}{2}R$ at sufficiently high temperatures, have been verified experimentally for a number of gases.

In a few cases (H_2, HD and D_2), diatomic gases exist at temperatures for which kT is comparable to the spacing of the rotational energy levels, and quantum effects can be observed in the rotational contribution to C_V. For H_2, C_V drops below $\frac{5}{2}R$ as the temperature is reduced below about 300 K, and below 50 K it becomes equal to the $\frac{3}{2}R$ that is characteristic of translation. The translational energy levels of ordinary gases are so closely spaced that quantum effects are never important in the translational heat capacity.

The heat capacity of polyatomic gases can be treated by a straightforward generalization of the foregoing discussion. A molecule with n atoms has three translational degrees of freedom and, if it is nonlinear, three rotational and $3n - 6$ vibrational degrees of freedom. If it is linear, it has two rotational and $3n - 5$ vibrational degrees of freedom.

Solids For every solid there is a lattice heat capacity associated with vibrations of the atoms. If the interatomic forces are harmonic, the N atoms in one mole of a monatomic solid have $3N$ independent vibrational modes, and the lattice heat capacity is the sum of $3N$ terms given by Eq. (10). Since the spectrum of the $3N$ frequencies of a real solid is complicated and difficult to calculate, an approximation introduced by Debye is widely used. In the Debye model, the vibrational modes are sound waves in an elastic continuum; the boundaries of the solid determine the allowed wavelengths and the sound velocities then determine the frequencies. To limit the number of frequencies to $3N$, the spectrum is cut off at a maximum frequency $k\Theta_D/h$ where Θ_D, the Debye temperature, is determined by the sound velocities and is typically a few hundred degrees Kelvin. The cutoff corresponds to the fact that in a real crystal, the vibrations have a minimum wavelength comparable to the interatomic distance. The heat capacity is

$$C_V = \frac{12}{5}\pi^4 R\left(\frac{T}{\Theta_D}\right)^3 \qquad (11)$$

for $T \leqslant \Theta_D/20$, but it increases less rapidly at higher temperatures and approaches the classical limit 3R for $T > \Theta_D$. The predicted high-temperature limit is in agreement with the empirical rule of Dulong and Petit: for most monatomic solids C_V is approximately $3R$ at room temperature. However, this value is often exceeded at very high temperatures, partly as a consequence of anharmonicity in the interatomic forces. At low temperatures, Eq. (11) is in good agreement with experiment; C_V is found to be proportional to T^3, although often only at temperatures below $\Theta_D/100$, and Θ_D is given accurately by the sound velocities. This agreement is to be expected because at low temperatures only low-frequency vibrations contribute, and these are treated accurately in the Debye model. At intermediate temperatures, the agreement with experiment is only approximate.

Occasionally the lattice heat capacity of a molecular crystal is represented by the sum of a Debye heat capacity for the vibrations of the N molecules as units and the appropriate number of terms given by Eq. (10) for the intermolecular vibrations.

In metals, there is an electronic heat capacity related to the translational motion of the conduction electrons. The small mass and high density of the electrons make quantum effects important, and Sommerfeld showed that their heat capacity should be proportional to temperature for temperatures below about 10^4 K. This contribution is usually significant below a few degrees Kelvin, where the lattice heat capacity is small, and also at high temperatures, where it contributes to deviations from the rule of Dulong and Petit.

The heat capacities of a number of solids have bumps or peaks superimposed on the smoothly varying lattice and electronic heat capacities. These are usually called anomalies and two distinct types can be recognized. A Schottky anomaly is a smooth bump that arises from a set of energy levels for a single particle. The splitting of the rotational states of magnetic ions by electric fields, and of nuclei by electric or magnetic fields, are examples for which the associated anomalies occur in the ranges 10^{-1} to 10^3 K and 10^{-3} to 10^{-1} K, respectively. Lambda anomalies are sharp peaks produced by cooperative processes involving many particles in a transition from a low-temperature ordered state to a high-temperature disordered state. Examples are: the momentum ordering of ^{4}He atoms in liquid ^{4}He at 2.18 K and of electrons in superconductors at temperatures ranging from 10^{-1} to 10 K; the magnetic ordering of ferromagnets and antiferromagnets at temperatures from 10^{-3} to 10^3 K; the spatial ordering of different atoms of an alloy on a superlattice, e.g., β-brass at 750 K; and the rotational disorder in certain molecular crystals e.g., H_2 at 1.5 K.

HEAT TRANSFER

Establishment of thermodynamic equilibrium for a system consisting of a number of media requires that the temperature be locally uniform and time-wise constant. A departure from this condition causes a transfer of energy in the form of heat from locations with high temperature to locations with low temperature. Such an energy transfer occurs very frequently and is encountered in our everyday life as well as in many engineering applications or in scientific experiments. It has, therefore, been known for a long time. The fact that quantitative predictions have become possible in the recent past only is due to the situation that several mechanisms are usually involved and interrelated in such an energy transfer process. They are generally classified as conduction, convection and radiation.

Heat transfer by conduction is that process which transports heat in a medium from one location to another without involvement of any visible movement. It is generally the only or the dominating mode of heat transfer in a solid medium; however, it occurs also in liquids and gases. In such fluids, this energy transport is often augmented when parts of the fluid are in movement and carry energy along. This mechanism of heat transfer is classified as transfer by convection. All media can also release energy in the form of photons (electromagnetic waves). This energy travels in space essentially with the velocity of light until the photons are recaptured by some other atoms, causing in this way heat transfer by radiation. An example of this energy transport is the transfer of heat from the sun to the earth. The three modes of energy transfer mentioned above will be discussed consecutively in the following sections. However, it must be realized that they often occur simultaneously, so that in some cases the total energy transport will be the sum of the contributions of the individual mechanisms. In other cases, such a summation will not lead to the correct result when the individual transport mechanisms mutually interfere.

Conduction From a microscopic standpoint, thermal conduction refers to energy being handed down from one atom or molecule to the next one. In a liquid or gas, these particles change their position continuously even without visible movement and they transport energy also in this way. From a macroscopic or continuum viewpoint, thermal conduction is quantitatively described by Fourier's equation which states that the heat flux q per unit time and unit area through an area element arbitrarily located in the medium is proportional to the drop in temperature, $-\text{grad } T$, per unit length in the direction normal to the area and to a transport property k characteristic of the medium and called thermal conductivity.

$$q = -k \text{ grad } T \qquad (1)$$

Predictions for the value of the thermal conductivity k can be made from considerations of the atomic structure. Accurate values, however, require experimentation in which the heat flux q and the temperature gradient, grad T, are measured and these values are inserted into Fourier's equation. Figure 1 presents thermal conductivity values for a number of media in a large temperature range. It can be recognized that metals have the largest conductivities and, among those, pure metals have larger values than alloys. Gases, on the other hand, have very low heat conductivity values. Electrically nonconducting solids and liquids are arranged in between. The low thermal conductivity of air is utilized in the development of thermally insulating materials. Such materials, like cork or glass fiber, consist of a solid substance with a very large number of small spaces filled by air. The thermal transport occurs then essentially through the air spaces, and the solid structure only supplies the framework which prevents convective currents. The range of thermal conductivities in Fig. 1 at ambient temperature extends through 5 powers of 10. This range is still small compared with the range for the electric conductivity of various substances where electric conductors have values which are larger by 25 powers of 10 than elec-

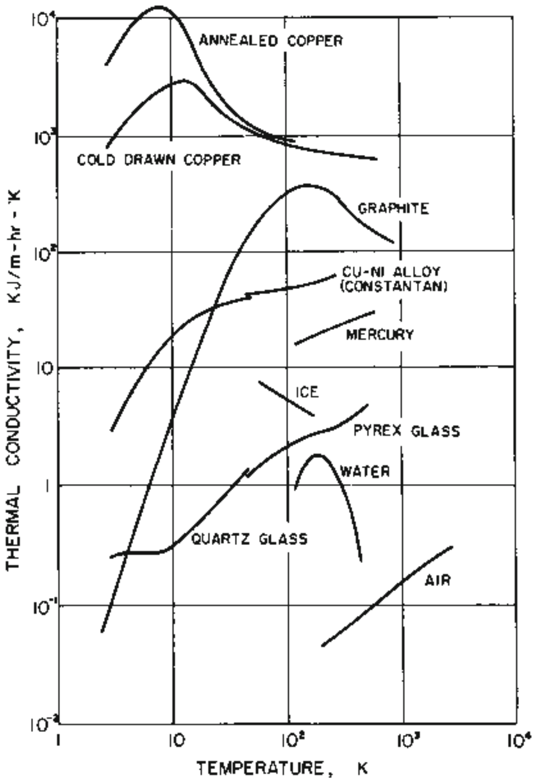

FIG. 1.

tric insulators. As a consequence of this fact, it is much easier to channel electricity along a desired path than to do so with heat, a fact which accounts for the difficulty in accurate experimentation in the field of heat transfer.

Fourier's equation can be used together with a statement on energy conservation to derive a differential equation describing the temperature field in a medium. Fourier was the first one to develop this equation and to devise means for its solution. In vector notation, this equation is

$$\rho c \frac{\partial T}{\partial t} = \nabla(k\nabla T) \tag{2}$$

where ρ is the density, c is the specific heat, t is time, ∇ is the Nabla operator. The temperature field in a substance can either change in time (unsteady state) or it can be independent of time (steady state $\partial T/\partial t = 0$). For a steady-state situation, the temperature field depends primarily on the geometry of the body involved and on the boundary conditions. The simplest case of a steady state temperature field is the one in a plane wall with temperatures which are uniform on each surface, however different at the two surfaces. The temperature in the wall then changes linearly in the direction of the surface normal as long as the variation of the thermal conductivity in the temperature range involved can be neglected. For an unsteady process, the capacity of the medium to store energy enters the energy conservation equation; correspondingly, the specific heat of the material and its density become factors for the conduction process, as well as the thermal conductivity. A combination of these properties, defined as the ratio of the thermal conductivity to the product of specific heat and density, called thermal diffusivity ($k/\rho c$), then determines how fast existing temperature differences in a medium equalize in time. It is found that metals and gases have thermal diffusivity values which are approximately equal in magnitude and considerably higher than thermal diffusivities of liquid and solid nonconductors. This means that temperature differences equalize much faster in metals and gases than in other substances.

Various other physical processes lead in their mathematical description to equations of the same form as Eq. (2), especially in its steady-state form. Such processes are, for instance, the conduction of electricity in a conductor or the shape of a thin membrane stretched over a curved boundary. This situation has led to the development of analogies (electric analogy, soap film analogy) to heat conduction processes which are useful because they often offer the advantage of simpler experimentation.

Convection It has been mentioned before that in fluids, energy is often transported by convection. In such a situation, conduction takes care of the transport of heat from one stream tube to another and is the dominating mode of transfer near solid walls. Convection transports heat along the stream lines and is dominating in the main body of the fluid where the velocities are large. In many situations, the flow is turbulent; this means that unsteady mixing motions are superimposed on the mean flow. These mixing motions contribute also to a transport of heat between stream tubes, a process which can be thought of as being described by an "effective" conductivity which often has values by several powers of ten larger than the actual conductivity of the fluid.

The movement of the fluid may be generated by means external to the heat transfer process, as by fans, blowers, or pumps. It may also be created by density differences connected with the heat transfer process itself. The first mode is called *forced convection*, the second one *natural* or *free convection*. Convective heat transfer may also be classified as heat transfer in duct flow or in external flow (over cylinders, spheres, air foils, or similar objects). In the second case, the heat transfer process is essentially concentrated in a thin fluid layer surrounding the object (boundary layer).

Of special interest in such heat transfer processes is the knowledge of the heat flux from the surface of a solid object exposed to the flow. This heat flux q_W per unit area and time is conventionally described by Newton's equation

$$q_W = h(T_W - T_f) \tag{3}$$

where T_W is the surface temperature and T_f is a characteristic temperature in the fluid. This equation defining the heat transfer coefficient h is convenient because in many situations the heat flux is at least approximately proportional to the temperature difference $T_W - T_f$. Information on the heat transfer coefficients can be obtained by a solution of the Navier-Stokes equations describing the flow of a viscous fluid and the related energy equation, or they are found by experimentation. The availability of electronic computers has tremendously increased our ability to study heat transfer analytically at least for laminar flow, whereas in turbulent flow the bulk of our information is based on experiments. Such experimentation is made difficult by the large number of parameters involved. Dimensional analysis has therefore been applied to reduce the number of influencing parameters, and relations for convective heat transfer are correspondingly presented in modern handbooks as relations between dimensionless parameters. Such an analysis demonstrates, for instance, that heat transfer in forced flow can be described by a relation of the form

$$Nu = f(Re, Pr) \tag{4}$$

in which the Nusselt number Nu is a dimensionless parameter hL/k, containing the heat transfer coefficient h; the Reynolds number $Re = \rho(VL/\mu)$ describes essentially the nature of the flow; and the Prandtl number $Pr = c_p\mu/k$ can be considered as a dimensionless transport property characterizing the fluid involved. L and V are an arbitrarily selected characteristic length and velocity, respectively, ρ denotes the density, μ the viscosity, and c_p the specific heat of the fluid at constant pressure. Occasionally the Stanton number, $St = Nu/Re\,Pr$, is used instead of the Nusselt number as a dimensionless expression of the heat transfer coefficient. Equation (4) is based on the assumption that the thermodynamic and transport properties involved in the heat transfer process can be considered as constant. Larger variations of such properties are usually accounted for by additional terms in Eq. (4) expressing the ratio of the varying transport properties or of parameters (temperature, pressure) on which they depend. Fluids occurring in nature cover a very large range of Prandtl numbers. Liquid metals, for instance, have values of order 0.001 to 0.01. Gases have values between 0.6 and 1, and oils have values up to 10 000 and more. Some heat transfer relations for forced convection are presented in Table 1. Relations for other situations can be found in the various texts mentioned at the end of this section or in corresponding handbooks. With regard to the relations in Table 1 and other similar equations, it has to be kept in mind that they are valid over a restricted range of the independent parameters only.

Heat transfer by free convection is described by relations of the form

$$Nu = f(Gr, Pr) \tag{5}$$

In this equation, the Grashof number

$$Gr = \frac{\rho^2 g\beta(T_{\mathrm{w}} - T_{\mathrm{f}})L^3}{\mu^2}$$

(where g is the gravitational constant, β is the thermal expansion coefficient, T_{f} is the fluid temperature at a distance where it is not influenced by the heated or cooled object with surface temperature T_{W}) replaces the Reynolds number. Sometimes a dimensionless parameter called Rayleigh number ($Ra = Gr\,Pr$) is used instead of the Grashof number. Equation (5) assumes again that the fluid properties involved are nearly constant. Examples for such relations are also contained in Table 1. Examples for free convection situations are the heat transfer from a heating register in the room. Free convection is also an important factor in the establishment of the temperature in the atmosphere. In the free convection relations of Table 1 and in Eq. (5), it has been assumed that the convection flows are generated by the gravitational field. Natural convection can also be created by other body forces, like centrifugal and Coriolis forces or electromagnetic forces.

TABLE 1 RELATIONS FOR CONVECTIVE HEAT TRANSFER

Forced Convection

Channel Flow

Flow through a tube:

laminar ($Re < 3000$)

$$Nu = 3.65$$

turbulent ($Re > 3000, Pr > 0.6$)

$$Nu = 0.116\,(Re^{2/3} - 125)\,Pr^{1/3}$$

$$\left(Nu = \frac{hD}{k}, Re = \frac{\bar{V}D}{\nu},\right.$$
$$\left. D = \text{diameter}, \bar{V} = \text{mean velocity}\right)$$

External Flow

Flat plate parallel to flow:

laminar ($1000 < Re < 500000, Pr > 0.6$)

$$Nu = 0.332\sqrt{Re}\,\sqrt[3]{Pr}$$

turbulent ($Re > 500000, Pr > 0.6$)

$$Nu = \frac{0.0297 Re^{4/5} Pr}{1 + 1.3 Re^{-1/10} Pr^{-1/6}(Pr - 1)}$$

$$\left(Nu = \frac{hx}{k}, Re = \frac{\rho V_s x}{\mu}, x = \text{distance from leading edge,}\right.$$
$$\left. V_s = \text{velocity outside boundary layer}\right)$$

Cylinder normal to flow: $1 < Re < 4000$

$$Nu = 0.43 + 0.48\sqrt{Re}$$

$$\left(Nu = \frac{hD}{k}, Re = \frac{\rho V_0 D}{\mu}, D = \text{diameter,}\right.$$
$$\left. V_0 = \text{upstream velocity}\right)$$

Natural Convection

Vertical flat plate:

laminar ($10^4 < Gr < 10^8$)

$$Nu = 0.508\,Gr^{1/4} Pr^{1/2}(0.952 + Pr)^{-1/4}$$

turbulent ($Gr > 10^8$)

$$Nu = 0.0295\,Gr^{2/5} Pr^{7/5}(1 + 0.494 Pr^{2/3})^{-2/5}$$

$$(Nu = \frac{hx}{k}, Gr = \frac{\rho^2 g\beta(T_{\mathrm{W}} - T_{\mathrm{f}})x^3}{\mu^2}, x = \text{distance}$$

from leading edge, T_{W} = wall temperature, T_{f} = fluid temperature at some distance from plate)

(All surfaces are assumed to have uniform temperature)

Space does not permit the discussion of other heat transfer processes, although such processes have found increasing attention in recent years. Especially large heat transfer coefficients are created by a boiling or condensation process. Boiling heat transfer is therefore used in applications which have to deal with very large heat fluxes like chambers and nozzles of rockets or the anodes in electric arc devices. Heat transfer is also often combined with mass transfer processes. This is, for instance, the case in evaporation devices. Heat transfer may also occur combined with chemical reactions as in processes involving gases at very high temperature where combustion, dissociation, or ionization occur.

Radiation Energy can also be transferred from one location to another within a medium or from one medium to another in the form of photons (electromagnetic waves). Usually a multiplicity of wavelengths λ is involved in such energy transfer.* In vacuum, all waves regardless of their wavelength move with the same speed 2.9977 × 10^8 m/sec. In various substances, the wave velocity c changes somewhat with wavelength, and the ratio of the wave velocity in vacuum to the velocity in a substance is equal to the optical refraction index. Air and generally all gases have refraction indices which differ from one only in the fourth decimal. Their wave velocity is, therefore, practically equal to that in vacuum.

Prévost's principle states that the amount of energy emitted by a volume element within a radiating substance is completely independent of its surroundings. Whether the volume element increases or decreases its temperature by the process of radiation depends on whether it absorbs more foreign radiation than it emits or vice versa. One talks about thermal radiation when the emission of photons is thermally excited, i.e., when the substance within the volume element is nearly in thermodynamic equilibrium. The discussion in this section will be restricted to thermal radiation. For such radiation, Kirchhoff was able to derive a number of relations by consideration of a system of media in thermodynamic equilibrium. If j_ν indicates the co-efficient of emission, i.e., the radiative flux at the frequency ν* emitted per unit volume into a unit solid angle, and κ is the coefficient of absorption at the same frequency, that is, the fraction of the intensity of a radiant beam which is absorbed per unit path length, then one of these relations states

$$c^2 \frac{j_\nu}{\kappa_\nu} = f(T, \nu) \tag{6}$$

with c denoting the wave velocity. According to this relation, the combination of parameters on the left-hand side of the equation is a function of temperature T and frequency ν of the radiation only, but does not depend on the substance under consideration. Kirchhoff's law can also be expressed in parameters which refer to the interface of two media 1 and 2. It then takes the form

$$c^2 \frac{i_\nu}{\alpha_\nu} = f(T, \nu) \tag{7}$$

in which i_ν is the monochromatic intensity (flux per unit area and unit solid angle) of the radiative flux at frequency ν originating in medium 2 and traveling through the interface into medium 1 per unit solid angle and area normal to the direction of the radiant beam. α_ν is the monochromatic absorptance or absorptivity, i.e., that fraction of a radiant beam approaching the interface in the medium 1 in the opposite direction that is absorbed in medium 2. c is the wave velocity in medium 1. Kirchoff's law states that the combination of the parameters of the left-hand side of Eq. (7) is again a function of temperature and frequency only, but does not depend on the nature of the medium. A medium which absorbs all the radiation traveling into it through an interface ($\alpha_\nu = 1$) is called a blackbody. The intensity of radiation emitted by an arbitrary medium is, according to Eq. (7), in the following way related to the intensity of radiation $i_{b\nu}$ emitted by a blackbody at the same temperature and frequency

$$\frac{i_\nu}{\alpha_\nu} = i_{b\nu} \tag{8}$$

From the consideration of a system in thermodynamic equilibrium, it is also easily shown that $i_{b\nu}$ is independent of direction and that the total monochromatic radiant flux emitted by a blackbody per unit interface area and unit time into all directions in space is equal to $\pi i_{b\nu}$.

The law describing the monochromatic intensity of radiation of a blackbody is given by Planck's equation

$$i_{b\nu} = \frac{2h\nu^3}{c^2(e^{h\nu/kT} - 1)} \tag{9}$$

(where h is Planck's quantum constant and k is Boltzmann's constant). Experimentalists prefer to use the intensity $i_{b\lambda}$ per unit wavelength ($i_{b\lambda} d\lambda = i_{b\nu} d\nu$). Figure 2 presents the wavelength dependence of the intensity of blackbody monochromatic radiation for a number of temperatures. It may be observed that for each temperature, the intensity has a maximum at a certain wavelength and that this maximum shifts toward short wavelengths with increasing temperature (Wien's law). The wavelength λ is plotted on the abscissa in micrometers, μm, (1000 μm = 1mm). Our eye is sensitive to radiation in the range 0.4 to 0.7 μm (the dashed range). It may be observed that for temperatures with which we have largely to deal, the bulk of blackbody radiation is contained in the range of wavelengths larger than the visible ones (infrared range). This statement also holds for other media because Eq. (8) shows that no medium can have a monochromatic intensity which is higher than that of a blackbody. Only

*Frequency and wavelength are used interchangeably. They are connected by the relation $\lambda\nu = c$.

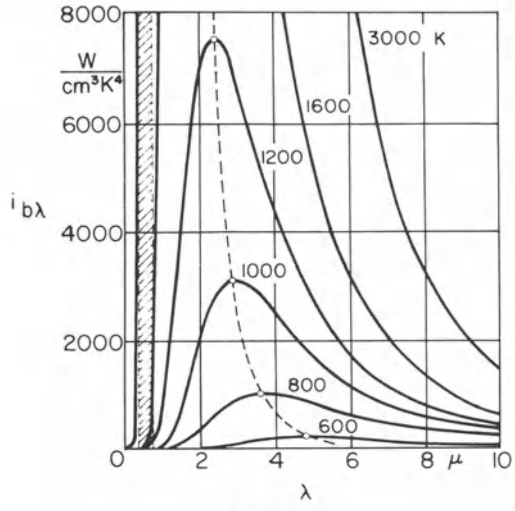

FIG. 2.

radiation coming from the sun has a major portion of the energy in the visible wavelength range (corresponding to a temperature of 6500 K).

The total energy flux q emitted per unit area and time from a blackbody into all directions in space can be obtained by integration of Eq. (9) over all frequencies and by multiplication of the result by π. For blackbody radiation into a vacuum (or with good approximation into a gas), the result is

$$q = \sigma T^4 \tag{10}$$

The Stefan-Boltzmann constant σ has the value 5.67×10^{-8} W/m³K⁴

The following additional relation exists at an interface between two substances.

$$\rho_\nu + \alpha_\nu + \tau_\nu = 1 \tag{11}$$

This equation describes that monochromatic radiant energy in a beam approaching in a medium 1 the interface with a medium 2 is found again either as radiation reflected back into the medium 1 or absorbed in the medium 2 or transmitted through the medium 2 into other media or back into medium 1. The monochromatic reflectance or reflectivity ρ_ν is the ratio of reflected to incident radiant energy, α_ν is the corresponding ratio for the absorbed, and τ_ν for the transmitted energy. The vast majority of solids and liquids absorb radiant energy over most wavelengths in the infrared range within a very thin layer adjacent to the interface (of order 1 μ to 1 mm). In heat transfer calculations, it can therefore usually be assumed that the transmissivity of such substances is equal to zero and that reflectivity and absorptivity are connected to the temperature of the interface. One talks then often in a simplified manner about radiative interchange between surfaces. Kirchhoff's law, Eq. (8), additionally connects the intensity of a beam emitted through the interface with the absorptivity and the intensity of a beam leaving a blackbody at the same temperature. Electromagnetic theory shows that electric nonconducting materials have in the infrared range generally high values of the absorptivity and correspondingly low values of the reflectivity. Metals (electric conductors), on the other hand, behave in the opposite way, having low absorptivity and high reflectivity values. This fact is utilized in aluminum-insulations and in vacuum thermos bottles. In the visible range, the appearance of surfaces on various materials to the eye already supplies information on approximate values of the reflectivity and absorptivity. The values of these parameters largely determine the reflective and absorption characteristics of surfaces for solar irradiation. A white surface, for instance, has a very low absorptivity and reflects the major part of solar irradiation. Gases behave differently with respect to radiation. They need fairly large layers in order to absorb the major part of incident radiation and radiate only in restricted wavelength ranges whereas solids and liquids have a more continuous spectrum. Diatomic gases (O_2, N_2) do not absorb energy with good approximation. Solar irradiation is absorbed in the atmosphere by carbon dioxide and water vapor. Values for reflectivities, absorptivities, and transmissivities of various substances are contained in the Handbook reference listed at the end of the ariticle.

Values for the radiation properties (ρ_ν, α_ν, τ_ν) together with the relations for blackbody radiation are the basis of calculations to determine heat exchange by radiation in a system with locally varying temperature. Calculations of such interchange are in general very involved, especially when substances with small absorption coefficients are involved. The formulation of such interchange leads to integral differential equations. The reader has in this connection to be referred to the books listed at the end of this section, and only a few relations for simple geometries will be presented here. Consider two area elements, dA_1 and dA_2, belonging to two blackbodies with the temperatures T_1 and T_2. The distance between the two area elements is s, and β_1 and β_2 are the angles between the two surface normals and the interconnecting line. The following equation then describes the net heat transfer dQ from area element dA_1 to area element dA_2 per unit time assuming that no radiation is absorbed or emitted in the space between the two surfaces.

$$dQ = \frac{\cos\beta_1 \cos\beta_2}{\pi s^2} dA_1 dA_2 \ \sigma(T_1{}^4 - T_2{}^4) \tag{12}$$

If non-black surfaces are involved, then the process of radiant interchange is much more involved, since part of the incident radiation is now reflected from the surfaces and travels in this way back and forth until it is finally absorbed. Simple relations exist in this case for the radiative interchange between the surfaces of two concentric spheres or cylinders with areas A_1 and A_2 and temperatures T_1 and T_2. It is further assumed that both surfaces are emitting and reflecting in a perfectly diffuse way and that they are separated by a medium which does neither emit nor absorb radiation. The net monochromatic interchange $d\Phi_\nu$ between the two surfaces is then described by the equation

$$d\Phi_\nu = \frac{\pi}{\dfrac{1}{\alpha_{\nu 1}} + \dfrac{A_1}{A_2}\left(\dfrac{1}{\alpha_{\nu 2}} - 1\right)} dA_1(i_{b\nu 1} - i_{b\nu 2}) \tag{13}$$

The monochromatic intensities $i_{b\nu 1}$ and $i_{b\nu 2}$ are calculated with Eq. (9). The relation changes when the outer cylinder reflects radiation mirror-like (specularly) to

$$d\Phi_\nu = \frac{\pi}{\dfrac{1}{\alpha_{\nu 1}} + \left(\dfrac{1}{\alpha_{\nu 2}} - 1\right)} dA_1(i_{b\nu 1} - i_{b\nu 2}) \tag{14}$$

Both equations merge asymptotically into the same relation when the differences between the two radii become small. The corresponding relation then also holds for two parallel infinite planes. Equations (13) and (14) have to be integrated over all frequencies to obtain the net heat transfer between the two surfaces. The result is simple when the absorptances $\alpha_{\nu 1}$ and $\alpha_{\nu 2}$ are independent of frequency (gray surfaces). Equations (13) and (14) describe then the net heat transfer, when $i_{b\nu 1}$ and $i_{b\nu 2}$ are replaced by $(\sigma/\pi)T_1{}^4$ and $(\sigma/\pi)T_2{}^4$, respectively.

HEISENBERG UNCERTAINTY PRINCIPLE

Classical physics is based on two assumptions that have been found experimentally to be untenable. The first of these is the existence of signals that can travel with infinite speed; the second is that the magnitude of the interaction between two systems can be reduced to arbitrarily small values. The realization that the speed of propagation of signals has a finite upper limit led to the development of relativity theory. The recognition of the existence of a finite quantum of action has been incorporated in quantum (wave) mechanics.

Quantum mechanics assigns a physical reality only to those variables whose value can, in principle, be experimentally determined. About the existence of phenomena or systems that cannot be experimentally observed, quantum mechanics is noncommittal. Questions regarding an isolated system are meaningless in quantum mechanics, for any observation made on such a system necessarily disturbs its isolation by at least one quantum of action. Heisenberg[5] observed that any measurement made on a system destroys some of the knowledge gained about that system through previous measurements. Any prediction about the future course of a system must be contingent on a knowledge about the measurements that will be made on that system, and is subject to uncertainties introduced by the measurements. Whereas one might speculate with some reliability about the future course of a system under the restriction that no more measurements will be performed on it, such speculations would be physically meaningless, as they could not be experimentally confirmed or denied.

In the broadest sense, then, the Heisenberg Uncertainty Principle states that the partitioning of the universe into observer (either a human observer, or a recording device such as a photographic plate) and observed is subject to a finite inaccuracy; one might say that the "knife" or "pencil" that makes the partition has a finite "thickness," h.

The concept of a monochromatic beam of radiation is not a difficult one to accept. Yet the experimental determination of the frequency of such a beam requires an infinite time interval; any finite portion chopped from the beam is shown by Fourier analysis to have a spectrum of finite width, hence not a single frequency at all. Quantum mechanics does not deny the existence of a monochromatic beam, but it does render the assignment of a definite frequency in a given time interval meaningless.

Fourier analysis shows that the specifications of the time interval, Δt, and of the spectral width, $\Delta\nu$, are reciprocally related:

$$\Delta\nu\,\Delta t \geqslant 1 \qquad (1)$$

This equation represents the uncertainty relation for classical waves: any attempt to specify the frequency at an instant of time results in a broadening of the frequency spectrum. This uncertainty relation applies to any wave, whether electromagnetic, acoustic, or otherwise.

Interference patterns observed when electron beams are reflected from crystalline surfaces[3] or transmitted through thin metallic films[7] indicate that these beams possess some wave characteristics. DeBroglie[2], by independent theoretical considerations (see WAVE MECHANICS), postulated the following relations between the dynamic variables, energy (E) and linear momentum (p) of the beam, on the one hand, and the wave variables, frequency (ν) and wavelength (λ), on the other:

$$E = h\nu \qquad (2)$$

$$p = h/\lambda \qquad (3)$$

Substitution of Eq. (2) in Eq. (1) gives the uncertainty relation between energy and time:

$$\Delta E \cdot \Delta t \geqslant h \qquad (4)$$

For a beam of free electrons of mass m, traveling in the x direction, $\Delta t = m\,\Delta x/p_x$, where p_x is the linear momentum and Δx is the distance traveled in the time interval Δt. Since $E = p_x^2/2m$, $\Delta E \cong p_x\,\Delta p_x/m$, so that $\Delta E \cdot \Delta t = \Delta p_x \cdot \Delta x$, and

$$\Delta p_x \cdot \Delta x \geqslant h \qquad (5)$$

The pairs of variables (E, t) and (p_x, x) are called canonically conjugate pairs of variables. In quantum mechanics, the operators corresponding to canonically conjugate variables do not commute (see QUANTUM THEORY). Heisenberg originally stated his uncertainty principle in the following form: the values of canonically conjugate variables of a given system can only be determined with a finite lower limit of accuracy.

Among the many important experimental phenomena illustrating the uncertainty principle in the COMPTON EFFECT. Here, a photon is scattered by an electron; the momentum of the photon is rendered uncertain as a result of its scattering by the electron and the electron is moved from its original position by the impact received from the photon. If we consider the photon and the electron as separate systems, then their interaction (the collision) introduces uncertainties for each system, given by Equation (5).

A general uncertainty relation follows from the postulates of WAVE MECHANICS. Consider two variables, a and b, of a system, whose operators are $\mathcal{A}$ and $\mathcal{B}$. The expectation values of a and b are called $\bar{a}$ and $\bar{b}$ respectively. The uncertainties in a and b can then be defined quantitatively as their respective rms deviations from their expectation values; it follows from the postulates that

$$(\Delta a)^2 \equiv \oint \Psi^*(\mathcal{A} - \bar{a})^2\,\Psi\,dq$$

where Ψ is the normalized wave function of the system under observation, and $\oint \ldots dq$ indicates integration over all values of all coordinates. Similarly,

$$(\Delta b)^2 \equiv \oint \Psi^*(\mathcal{B} - \bar{b})^2\,\Psi\,dq$$

If $\mathcal{A}$ and $\mathcal{B}$ are Hermitian,* $(\mathcal{A} - \bar{a})^2$ and $(\mathcal{B} - \bar{b})^2$ are also Hermitian. Therefore:

$$
\begin{aligned}
(\Delta a)^2 \cdot (\Delta b)^2 &= \\
&= \oint \Psi^*(\mathcal{A} - \bar{a})^2\,\Psi\,dq \cdot \oint \Psi^*(\mathcal{B} - \bar{b})^2\,\Psi\,dq \\
&= \oint (\mathcal{A} - \bar{a})\,\Psi\,(\mathcal{A} - \bar{a})^*\,\Psi^*\,dq \\
&\qquad \cdot \oint (\mathcal{B} - \bar{b})\,\Psi\,(\mathcal{B} - \bar{b})^*\,\Psi^*\,dq \\
&= \oint |(\mathcal{A} - \bar{a})\Psi|^2\,dq \cdot \oint |(\mathcal{B} - \bar{b})\Psi|^2\,dq.
\end{aligned}
$$

To put this product of two definite integrals in a more useful form, consider the function

$$f(q) = \lambda(\mathcal{A} - \bar{a})\,\Psi + i(\mathcal{B} - \bar{b})\,\Psi$$

where λ is real, and independent of coordinates, and $i \equiv \sqrt{-1}$. The function $|f(q)|^2$ must be non-negative:

$$
\begin{aligned}
&\lambda^2 |(\mathcal{A} - \bar{a})\Psi|^2 + i\lambda\,[(\mathcal{A}^* - \bar{a})\,\Psi^*(\mathcal{B} - \bar{b})\,\Psi + \\
&\quad - (\mathcal{A} - \bar{a})\Psi(\mathcal{B}^* - \bar{b})\,\Psi^*] + |(\mathcal{B} - \bar{b})\,\Psi|^2 \geqslant 0
\end{aligned}
$$

When the left-hand side of this inequality is integrated over all values of all coordinates:

*An operator $\mathcal{F}$ is Hermitian, if for any properly behaved functions u and v: $\oint u\mathcal{F}v\,dq = \oint v\mathcal{F}^*u\,dq$, where * indicates complex conjugation. Quantum mechanical operators usually are, or can be made to be, Hermitian.

$$\lambda^2(\Delta a)^2+(\Delta b)^2+i\lambda\left[\oint(\mathcal{A}^*-\bar{a})\Psi^*(\mathcal{B}-\bar{b})\Psi\,dq+\right.$$

$$\left.-\oint(\mathcal{A}-\bar{a})\Psi(\mathcal{B}^*-\bar{b})\Psi^*\,dq\right]\geqslant 0$$

Since λ is real, the left-hand side of this inequality becomes negative unless the discriminant becomes zero or negative:

$$4(\Delta a)^2(\Delta b)^2\geqslant-\left[\oint(\mathcal{A}^*-\bar{a})\Psi^*(\mathcal{B}-\bar{b})\Psi\,dq+\right.$$

$$\left.-\oint(\mathcal{A}-\bar{a})\Psi(\mathcal{B}^*-\bar{b})\Psi^*\,dq\right]^2$$

The right-hand side of this inequality is reduced as follows (remember that Ψ is normalized):

$$\oint(\mathcal{A}^*-\bar{a})\Psi^*(\mathcal{B}-\bar{b})\Psi\,dq=\oint(\mathcal{A}\Psi)^*\mathcal{B}\Psi\,dq+$$

$$-\bar{a}\oint\Psi^*\mathcal{B}\Psi\,dq-\bar{b}\oint\Psi(\mathcal{A}\Psi)^*\,dq+\bar{a}\bar{b}$$

$$\oint(\mathcal{A}-\bar{a})\Psi(\mathcal{B}^*-\bar{b})\Psi^*\,dq=\oint(\mathcal{A}\Psi)(\mathcal{B}\Psi)^*\,dq+$$

$$-\bar{a}\oint\Psi(\mathcal{B}\Psi)^*\,dq-\bar{b}\oint\Psi^*(\mathcal{A}\Psi)\,dq+\bar{a}\bar{b}$$

Since $\bar{b}=\oint\Psi^*\mathcal{B}\Psi\,dq=\oint\Psi(\mathcal{B}\Psi)^*\,dq$, and

$$\bar{a}=\oint\Psi^*\mathcal{A}\Psi\,dq=\oint\Psi(\mathcal{A}\Psi)^*\,dq,$$

$$4(\Delta a)^2(\Delta b)^2\geqslant-\left[\oint(\mathcal{A}\Psi)^*(\mathcal{B}\Psi)\,dq+\right.$$

$$\left.-\oint(\mathcal{A}\Psi)(\mathcal{B}\Psi)^*\,dq\right]^2$$

Since $\mathcal{A}$ and $\mathcal{B}$ are Hermitian

$$\oint(\mathcal{A}\Psi)^*(\mathcal{B}\Psi)\,dq\equiv\oint(\mathcal{B}\Psi)(\mathcal{A}\Psi)^*\,dq=$$

$$=\oint\Psi^*\mathcal{A}\mathcal{B}\Psi\,dq,$$

$$\oint(\mathcal{A}\Psi)(\mathcal{B}\Psi)^*\,dq=\oint\Psi^*\mathcal{B}\mathcal{A}\Psi\,dq \quad (6)$$

$$\therefore\ 4(\Delta a)^2(\Delta b)^2\geqslant-\left[\oint\Psi^*(\mathcal{A}\mathcal{B}-\mathcal{B}\mathcal{A})\Psi\,dq\right]^2$$

and $|\Delta a|\cdot|\Delta b|\geqslant\frac{1}{2}i\oint\Psi^*(\mathcal{A}\mathcal{B}-\mathcal{B}\mathcal{A})\Psi\,dq$

According to the postulates of wave mechanics, the operators for momentum and position are given respectively by: $\mathcal{P}=-i\hbar\nabla$, where $\hbar=h/2\pi$, and $\mathcal{Q}=q$ (multiplication by q).

For linear motion in the x direction, $\mathcal{P}_x=-i\hbar\partial/\partial x$, $\mathcal{Q}=x$. Hence $(\mathcal{P}\mathcal{Q}-\mathcal{Q}\mathcal{P})\Psi=$ $=-i\hbar(\partial/\partial x)(x\Psi)+i\hbar x(\partial\Psi/\partial x)=-i\hbar\Psi$. When this expression is substituted into Eq. (6), it follows that:

$$|\Delta p_x|\,|\Delta x|\geqslant h/4\pi$$

which is in agreement with Eq. (5). Equation (4) can be similarly derived from the postulates of wave mechanics by setting $\mathcal{E}=(ih/2\pi)(\partial/\partial t)$, $\mathcal{T}=t$.

HIGH-VOLTAGE RESEARCH

High-voltage research deals with phenomena evoked by high voltages and intense electric fields, with the behavior of dielectrics and electrical components under such electrical stress, and with the utilization of electrostatic fields and forces for various purposes of science and industry. In the laboratory, this electrical stress is produced by the presence of electric charge on the opposing surfaces of two electrodes between which a voltage is applied. Pulsed, alternating and constant voltages ranging from a few kilovolts to 20 MV have been used in such studies. In nature, air currents and water precipitation cause electric charge to become separated between cloud and earth or between clouds; the stressed region may reach electrical pressure differences in excess of 1000 MV. Lightning, a rapid high-current discharge, completes the breakdown of the over-stressed air and dissipates the accumulated electrical energy. Many aspects of this natural high-voltage phenomena have been the subject of investigation because of their scientific interest and the danger of lightning to life and to susceptible structures such as electric power systems.

In the industrial high-voltage laboratory, the direct and induced effects of lightning discharges on electrical apparatus are often simulated by high-voltage impulse generators. These use the Marx method of first slowly charging a number of condensers in parallel and then suddenly connecting them in series by spark-gap switches which at the same instant impress the multiplied voltage upon the test circuit. A typical voltage wave produced by such impulse generators rises to its peak value of several million volts in 1 μsec and then diminishes exponentially reaching half-voltage in 10 μsec.

Electric Field between High-voltage Electrodes The region between and around electrodes which have been charged by the application of a voltage V between them is occupied by the electric field of that charge. In an isolated system, the positive electrode has a deficiency of electrons exactly equal to the excess electrons on the negative electrode. The amount of electric charge Q on either electrode surface at any instant is given by $Q = CV$ where Q is in coulombs and C is the capacitance of the electrode system in farads. Energy is stored in the electrically stressed space between the electrodes; the amount of this electrical energy W can be expressed in terms of applied voltage or separated charge by $W = CV^2/2 = Q^2/2C$ joules.

The electric field intensity at any point is defined by the magnitude and direction of the force which would be experienced by a unit positive charge placed in the field at that point. Following Faraday, if we define a line of electric flux as a line drawn so that its direction is everywhere the direction of the force on a positive particle, and require that one line must originate on each unit positive charge and terminate on each unit negative charge, then the lines of flux will map out the electric field and the lines per unit area will be directly related to the electrical field intensity E. The electrostatic force acting on a particle with charge q placed in an electric field of intensity E volts per meter is given by $f = qE$ newtons. The electric field distribution depends upon the geometry of the electrodes but is affected by the presence of dielectric materials or of charged particles; a quantitative picture of the static or changing field picture is usually essential to high-voltage research.

Objectives of High-Voltage Research From antiquity to the present, the history of high-voltage research sparkles with many names well-known in electrical science—Thales of Miletus, von Guericke, Newton, Franklin whose kite experiment established the identity of natural lightning and electricity, Cavendish, Faraday, and Roentgen whose discovery of x-rays in 1895 marked the beginning of the atomic age. During the 60 years centered on the turn of the twentieth century, physicists studied the passage of electricity through gases at normal and reduced pressure, sought an understanding of long sparks and corona in atmospheric air, measured the conductivity and breakdown strength of liquid dielectrics, and examined the flashover of solid insulators in these media.

More recent research has been directed at the performance under high electrical stress of a wide range of solid, liquid, and gaseous dielectrics as well as vacuum-insulated systems. The solid materials vary from porcelains and glasses to hydrocarbon polymers and loaded epoxies. Superior gaseous insulation is now obtained by the combined use of such electronegative gas molecules as sulfur hexafluoride (SF_6) and Freon (CCl_2F_2) with elevated pressures sometimes exceeding 5 or 10 atmospheres. Solid insulator supports are indispensable in gas, liquid, and vacuum insulated systems and are studied in combination with these media.

Research in the high-voltage field may also be directed at testing and increasing the insulation strength of power equipment subject to lightning or switching surges. The increasing trend toward higher voltages for the transmission of electric power over long distances has directed research toward reduction of radio interference and power loss by corona and surface leakage from high-voltage transmission line conductors and their suspension insulators. The need to bring such power into urban areas has produced the requirement for ac power cables in which the center conductor is reliably insulated for hundreds of kilovolts above earth. The inherent efficiency and stability of dc power transmission have led to the development of more adequate high-voltage rectification and conversion apparatus. For these purposes, the low-pressure metallic vapor tube has reached the highest power levels though solid state devices offer much promise for high-voltage, high-power switching.

In the field of science and medicine, high-voltage research seeks improved methods of producing high constant voltages, of measuring and stabilizing such voltages, and of applying them to the acceleration of atomic ions and electrons to high energies. Such particle accelerators are needed for nuclear structure research; for the study of the properties of energetic atoms, electrons, x-rays, and neutrons; for the treatment of deep-seated tumors with energetic particles and radiation, and for the radiation processing of materials.

Industrial objectives of high-voltage research include the development of high-power, high-frequency tubes and their power supplies for radar and long-range radio communication, the ionization of particulate matter by corona and its electrostatic collection as in smoke and chemical precipitators, and the elimination of electrostatic hazards which arise in processes such as the transfer or mixing of volatile hydrocarbons, dusts, and explosive gases.

HISTORY OF PHYSICS

Any attempt to trace the beginning of man's ideas on the nature of the physical world brings us to anthropomorphic, mythological cosmology. It is impossible to trace any absolute adumbration of some scientific doctrine. If a hint could be suggested, then the Western world appears to have drawn more from Mesopotamian sources and traditions than from the Nile civilization. No archeological dust will reveal the inscrutable past. As for physics, in the limited space available we can start only with the era when specific names emerged that are associated with the earliest formation of scientific ideas, described at that time as philosophy. The Ionian period, that amazing flow of intellectual energy, paved the way for the rise of the fathers of Hellenic science. Physics, then closely linked with philosophy and mythological astronomy, played an auxiliary role in man's overwhelming concern in cosmography and cosmogony.

Although physics as an independent field originated in the age of Renaissance and was associated with such giants as Galileo, Kepler, and Newton, even in this brief sketch it is indispensable to trace the fountainhead of this science, which is in the cornerstone of Western civilization. The port of Miletus in Ionia, on the eastern coast of the Aegean sea, can be singled out as among the most significant birthplaces of physical science. Located in a favorable geographic position, its flourishing commerce since the second millenium before our era provided an excellent clearing house between two river civilizations, Egypt and Mesopotamia. Exposing people to divergent ideas and traditions, it created an atmosphere of open-mindedness where new, unrestrained ideas could flourish. Consequently, several most unique rationalizing minds had their roots in this town alone.

Of the galaxy of great pioneers of Ionian science, Thales of Miletus (624-565 B.C.) stands out as a symbol of the era. Sir James Jeans maintains that most of the major achievements of physical science of our age can be traced back to the stream of knowledge started by this Ionian intellectual giant in Miletus. Pythagoras, Democritus, Anaxagoras, Aristarchos of Samos, to mention a few, represent as one historian exclaims, that "miracle of ancient Greece" that prepared and shaped the climax of Plato and Aristotle, who for two millenia were to inspire and guide, for better or worse, the evolution of physics.

Liberated from the mythology of pre-Socratic time, these ancient astounding thinkers represent every school of philosophy from the extreme idealism of illusion and nonexistence of the world of sense perception, in the Pythagorean-Platonic sense, to the atomism and materialism of Democritus and Anaxagoras with their doctrine of the primacy of matter in a universe manipulated by accidental mechanism. It has been said that everyone by nature is a disciple of either Plato or Aristotle, and Raphael in his famous painting of the School of Athens on the wall of the Vatican Palace appropriately illustrates Plato pointing upward and Aristotle downward to the ground. Thus, the Alexandrian School in Hellenistic Egypt with its lighthouse, Pharos, as a symbol irradiated the glory of Hellenic science for centuries, nourishing Western civilization with Euclides' *Stoicheia* and Ptolemy's *Almagest* which, outside the Bible, were the most widespread literary sources in physical science relegated to antiquity.

With the rise of Christianity, followed by Islam half a millenium later, interest in the studies of natural science was temporarily paralyzed, to be later zealously renewed under the aegis of the theology of the new religion. A convert to Christianity, St. Augustine (A.D. 354–430), later Bishop of Hippo, was a pioneer in the realization that Plato's ideas on sense delusion conveniently responded to the devout Christian's search for the salvation of the soul. Like Socrates and Sophists about a millenium previously, so St. Augustine also turned his back on nature and advised, "Return to thyself. In the inner man dwells truth." Thus, for a thousand years the men who guided the thought of the Western world did not observe out-of-doors and learn from natural phenomena. Monasteries became leading establishments where sedentary monks pored over volumes of Plato and Aristotle. More than half a millenium after St. Augustine, St. Thomas Aquinas (A.D. 1227-1274) petrified Aristotelian peripatetic scholasticism into an authoritarian *Summa Theologica* that included all the answers man should know on the nature of the physical world. It must be mentioned that the science of Western Islam helped to shape the cosmological ideas of St. Thomas Aquinas and, through him, the whole thought of Catholic Europe. We should stress that Ptolemy's masterpiece, *Almagest*, first reached Europe in the Arabic language.

This marked the climax of the Middle Ages, described unjustly as "dark ages." Although theology was the queen of sciences, this period was not devoid of scientific activity because speculations in physics were constantly being nourished by the mystery of the *Primum Mobile*, a sphere beyond the fixed stars. It was this Prime Mover to which Aristotelians ascribed the first supernatural impulses or "impetus." How else could motion first have started? With the rise of Humanism, the rediscovery of Greek literature of antiquity revealed vast subjects dealing with fields other than theology. Invigorating new studies spread through Western Europe invading universities, not by-passing some monasteries. Bold, unusual views on the nature of the physical world and methods of investigation aroused the suspicion of watchful scholasticians but the age of Renaissance could not be diverted. Even the prominent ecclesiastic Oresme (1332–1382), Bishop of Lisieux, sustained the main interest by challenging the Aristotelian doctrine of the fixity of the earth. Nearly a century later this was continued by Cardinal Nicolas of Cusa who, like the Franciscan monk, Roger Bacon, in the thirteenth century also advocated experimentation in order to learn how the laws of nature operate. Very penetrating studies on the mystery of "violent" motion and inertia were accomplished long before their actual fruition with the appearance of Galileo and Newton.

Signs of a new era in physics were imminent with ideas of the universal genius, Leonardo da Vinci, maintaining like Democritus and Anaximander that the whole universe conforms to unalterable mechanical laws. The coming dawn was evident when Nicolaus Copernicus (1473–1543) came to study in Bologna and Padua. Being more an ancient Greek philosopher in his use of geometry in support of the heliocentric system, Copernicus at least prepared the way of Galileo (1564–1642), who finally mobilized all known physics with his inventive experimentalism that adumbrated the first full stream of scientific revolution. Symptomatically, Galileo's first work was on motion, *De motu*, a subject of great concern through the Middle Ages, and his was the final challenging blow to the Aristotelian doctrine, when he verified that force primarily produces acceleration instead of mere movement.

As a sign of continuity, Newton was born (1642–1727) the year Galileo passed away. The trend of mechanism of physical phenomena as a consequence of mathematical determinism reached its portentous finalization with the Galilean-Newtonian revolution. Newtonian classical physics, associated with the world view of the majestic Newtonian universe, eternal and infinite, was formulated in three laws of motion, climaxed by the universal law of gravitation. This physics continued in its progressive refinement until it was confirmed by the triumphant mathematical discovery of the planet Neptune by J. C. Adams and Leverrier in 1845. It was then considered the final shape of knowledge man was in position to realize. Previously, Laplace produced an overwhelming impression on the entire century when, in 1798, he used in his *Origin of the World System* his deterministic equations in the formulation of his hypothesis on the origin of the solar system.

With advancing crystallization, Newtonian physics radiated with a galaxy of great names, inspired builders of the classical view of the physical world. Only a few principal milestones can be indicated, each a giant of his own in a panoramic view of the glorious century of promise of a scientific paradise. From Laplace at the beginning of the nineteenth century, the epic unfolds from Avogadro to Faraday, from Carnot and Joule to Kelvin and Helmholtz, attaining its pre-Einsteinian peak in Maxwellian equations formulating the electromagnetic theory of light. These equations were impressively described by Boltzmann, himself at the cradle of thermodynamics, when he quoted from Goethe's *Faust*: "Who was the god who wrote these lines?" Yet, these equations so brilliantly describing natural processes, pointed inevitably to a deterministic and mechanistic universe. Although rigorous mechanicism had flourished in the past in varying degrees, Newton must be regarded as the founder of the mechanistic world view even though he had difficulty in harmonizing mechanistic natural philosophy with his belief in a God who not only created the world but also constantly preserves it. This mechanization of the world picture systematically led to the conception of God as a retired engineer, and it was only another step to His complete exclusion. Therefore, the universe was ultimately knowable and predictable. This *Weltanschauung* of triumphant physics encouraged the rise of materialistic philosophy, that actually shaped the dialectic materialism of Marx and Engels, which became the official doctrine of the ruling communist state in the twentieth century.

Newtonian physics was not destined to remain the last form in the evolution of physics. When it appeared to reach its perfection, as some leading physicists advocated, the turn of the twentieth century again witnessed another tidal wave that changed the course of physics. By 1895, this second scientific revolution started with discoveries of the first magnitude, containing unfathomable consequences for the future. Becquerel's radioactivity, Roentgen's x-rays, J. J. Thomson's electron, Planck's quantum, Bohr's atom, Rutherford's nucleus, Einstein's relativity and equality of mass and energy, represent a revolution that will carry the exploring mind incomparably farther into the mysteries of the universe than Copernicus, Galileo, Kepler, or even Newton ever dreamed of. Heisenberg's principle of indeterminacy in the realm of microphysics not only shatters the once cherished corpuscular-kinetic determinism but points to a microcosmos much more complex than what Whitehead called "provincialism in time and space," and as valid in Newtonian mechanism. Combining this with the staggering discoveries in astrophysical macrocosmos, the Dopplerian red shift of external galaxies, quasars, neutron stars, and black holes, we confront a truly unprecedented era of future centuries that will bring about unimaginable amendments in the physics we know today and its subsequent world view.

As the end of the twentieth century looms ahead with all the problems of turbulent humanity combining utility with the catastrophic abuse of applied physical science, it is important to note in retrospect that the unparalleled advance of man's understanding of the physical world in the present century was not appropriately balanced by any corresponding increase in man's ethical enlightenment. Einstein's centenary, celebrated throughout the entire cultural world in 1979, more than justifies the inevitability of this comment in this encyclopedia. The genial author of the new, post-Newtonian concept of our universe never failed to express his concern in the fate of mankind alongside his world view of New Physics.

The Second Scientific Revolution, as historians like to call it, starting at the turn of this century, is not only intellectually longer in its three quarters of a century than were the three centuries since Newton, but far surpasses the length separating the world view of Newton from that of Aristotle, two thousand years ago. Even Laplace with his classical, mathematical physics belongs in a category that separates him from such wizards of the New Physics of our contemporary age as Einstein, Bohr, Planck, de Broglie, and Heisenberg. These conclusions are drawn because both Newton and Aristotle built world views from facts acquired by our sensory perceptions, as demanded by Victorian physics. Yet we can never perceive nor directly observe an electron, a nucleus, a quantum, or any ultimate particle of microphysics. We build their representation from a highly complex laboratory procedure which does not guarantee their actual reality. The great pioneer of New Physics, Ernst Mach, once stated that "Senses do not lie, but they do not tell us truth." This was supplemented a century later by J. M. Jauch, the late Director of the Institute of Theoretical Physics at the University of Geneva: "Bohr, by denying objective reality to properties whose simultaneous presence would require for their verification mutually exclusive physical situations, puts in question that very concept of reality which has been the cornerstone of all of physics as it has developed from the time of Galileo and Newton."

The dilemma arising from the Einsteinian world view was aptly described by Whitehead when he suggested our rooting in spatiotemporal provincialism. The Victorian physicist operated in what Reichenbach called the "world of middle dimensions," his Newtonian-Euclidian space between microcosmos and macrocosmos. In relativistic physics the rigid homogeneous Newtonian-Euclidian infinite space melts away in a constant spatiotemporal dislocation that depends on the presence of matter and a finite four-dimensional universe. Matter produces local distortions of space-time metric with its non-Euclidean geometry, which manifest themselves through force fields, inertia, and the "constant" of universal gravitation (G) that is subject to change with the progressive expansion of the universe.

In the microworld, Heisenberg's principle of indeterminacy denies the objective reality of sharply localized particles, so that the so-called particle blends into the background from which it should be distinct to deserve to be identified as a particle. The shocking problem of the inconstancy of the reality of such particles as the electron is well described by Oppenheimer:

> If we ask whether the position of the electron remains the same, we must say "No;" if we ask whether the electron's position changes with time, we must say "No;" if we ask whether the electron is at rest, we must say "No;" if we ask whether it is in motion, we must say "No."

The Second Scientific Revolution has hardly begun to build its history with Einstein's unfinished dream of unified field theory and unfold a new universe from the immensity of extraordinary facts, whether observable or unobservable, pointing to an unprecedented magnitude of the changing new world of physics and its cosmology in the forthcoming centuries. It dwarfs all preceding world concepts of accommodating, enduring anthropomorphic views.

HOLOGRAPHY

In 1948, British scientist Dennis Gabor (1900–1979) proposed and demonstrated a new, two-step method of optical imagery. However, because of the extreme difficulty of implementing the method in those early days, it was not until the decade of the 1960s that the method became widely known and used. This renaissance of interest in the method was largely due to the general availability of the laser with the great temporal and spatial coherence of its light and to the efforts in the early 1960s of J. Upatnieks and E. N. Leith of the University of Michigan. As Gabor's method grew in significance, the genius of the idea was recognized and Gabor was awarded the Nobel Prize in physics in 1971.

The method proposed by Gabor is now known as *holography*. It is similar to photography in many respects, yet is fundamentally different. With photography, one generally records, by means of lens and film, the two-dimensional irradiance distribution in the image of an object. With holography, however, one records not the optically formed image of an object but the object wave itself. This wave is recorded (usually on photographic film) in such a way that a subsequent illumination of this record, called a *hologram*, reconstructs the original object wave. A visual observation of this reconstructed wavefront then yields a view of the object which is practically indiscernible from the original, including three-dimensional parallax effects.

Figure 1(a) shows schematically how a hologram is recorded. One starts with a single, monochromatic beam of light that has originated from a very small source. This single beam is split into two components, one of which is directed toward the object and the other to a suitable recording medium, most commonly a photographic emulsion. The component that is incident on the object is scattered by it, and this scattered radiation, now called the object wave, impinges on the recording medium. The wave that proceeds directly to the recording medium is called the *reference wave*. Since the object and reference waves originate from the same source, they are mutually coherent and form a stable interference pattern when they meet at the recording medium. The detailed record of this interference pattern constitutes the hologram.

When the hologram is illuminated with a beam similar to the original reference wave, it modulates the phase and/or amplitude of the illuminating wave in such a way that the transmitted wave divides into three separate components, *one of which exactly duplicates the original object wave*.

If the two interfering beams are traveling in substantially the same direction, the recording of the interference pattern is said to be a *Gabor hologram* or an *in-line* hologram. If the two interfering beams arrive at the recording medium from substantially different directions, the recording is a *Leith-Upatnieks* or *off-axis* hologram. If the two interfering beams are traveling in essentially opposite directions, the recorded hologram is said to be a *Lippmann* or *reflection* hologram, first invented by Y. N. Denisyuk.

Electromagnetic radiation is most commonly used, although acoustic radiation can be used. The most common electromagnetic radiation employed is light, but holograms have also been recorded successfully with electron beams, x-radiation, and microwaves.

Holograms can be classified by the way they diffract light. In an *amplitude hologram* the varying irradiance distribution of the interference pattern is recorded as a density variation of the recording medium. In this type of hologram the illuminating wave is always partially absorbed, i.e., the illuminating wave is *amplitude-modulated*. In a *phase hologram*, a *phase modulation* is imposed on the illuminating beam which in turn results in diffraction of the light. Phase modulation occurs when the optical path (thickness X index) varies with position. A phase hologram results from either relief-image or index variation, or both.

Either phase or amplitude holograms can be classified further as *Fresnel holograms* or as *Fraunhofer holograms*. Generally speaking, if the object is reasonably close to the recording medium, say just a few hologram or object diameters distant, the field at the hologram plane is the Fresnel diffraction pattern of the object. A hologram recorded in this manner is termed a *Fresnel hologram*.

If the object and hologram are separated by many object or hologram diameters, the field at the hologram due to the object alone is the Fraunhofer diffraction pattern of the object. A hologram recorded in this manner is termed a *Fraunhofer hologram*.

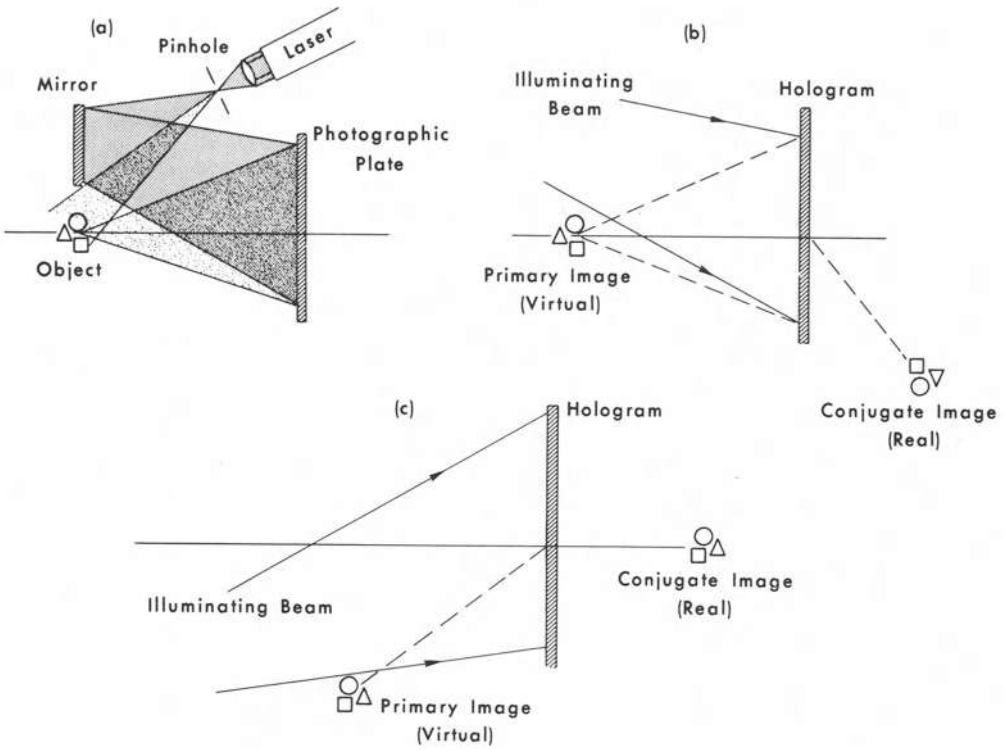

FIG. 1. A typical holographic arrangement. (a) Recording the hologram. (b) Reconstructing the primary object wave. (c) Reconstructing an undistorted conjugate wave.

Any of these hologram types may be recorded as either a *thick* or a *thin* hologram. A *thin hologram* is one for which the thickness of the recording medium is thin compared to the spacing between the recorded interference fringes. A *thick* or *volume hologram* is one in which the thickness of the recording medium is of the order of or greater than the spacing of the recorded fringes.

Conceptually, the simplest form of an off-axis hologram is one for which the object is just a single, infinitely distant point so that the object wave at the recording medium is a plane wave. If the reference wave is also plane, and incident on the recording medium at an angle to the object wave, the hologram will consist of a series of Young's interference fringes. These recorded fringes are equally spaced straight lines running perpendicular to the plane of incidence. Since the hologram consists of a series of alternating clear and opaque strips, it is in the form of a diffraction grating. When the hologram is illuminated with a plane wave, the transmitted light consists of a zero-order wave traveling in the direction of the illuminating wave, plus two first-order waves. The higher diffracted orders are generally missing or very weak since the irradiance distribution of a two-beam interference pattern is sinusoidal. As long as the recording is essentially linear (irradiance proportional to final amplitude transmittance), the hologram will be a diffraction grating varying sinusoidally in amplitude transmittance, and only the first diffracted orders will be observed. One of these first-order waves will be traveling in the same direction as the object wave; this is the reconstructed wave.

To describe the recording of a hologram of a more complicated object, let O be a monochromatic wave from the object incident on the recording medium H, and let R be a wave coherent with O. The wave O contains information about the object, since the object has uniquely determined the amplitude and phase of O. The object can be thin and transmitting, such as a transparency, or it can be opaque and diffusely reflecting. Both the amplitude and phase of the wave O can be recorded with the aid of the reference beam R. The total field on H is $O + R$. A square-law recording medium, such as a photographic emulsion, will respond to the irradiance of the light $|O + R|^2$. Assume that after processing, the hologram possesses a certain complex amplitude transmittance $t(x)$ that can be expressed as a function of the exposure $E(x)$,

$$t(x) = f[E(x)]. \qquad (1)$$

The expansion of this function will yield a term linear in exposure, and by ignoring all terms except this one, one can write

$$t(x) = \beta E(x) = \beta\,|O + R|^2 \cdot T$$
$$= \beta T(|O|^2 + |R|^2 + OR^* + O^*R), \qquad (2)$$

where T is the exposure time, * indicates complex conjugate, and β is the constant coefficient of the linear term. When the hologram with this amplitude transmittance is illuminated with a wave C, the transmitted field at the hologram is

$$C \cdot t(x) = \beta T[C|O|^2 + C|R|^2 + CR^*O + CRO^*]. \qquad (3)$$

If the illuminating wave C is sufficiently uniform so that CR^* is approximately constant across the hologram, the third term of Eq. (3) is βTCR^*O = const. × O. This term represents a wave identical with the object wave O. This wave has all of the properties of the original wave and can form an image of the object. The fact that this wave is separated from the rest can be seen most clearly by analogy with the diffraction-grating hologram described above. It can be shown that the other first-order diffracted wave corresponds to the conjugate image term $\beta TCRO^*$ of Eq. (3) and that the zero-order wave corresponds to the first two terms $\beta TC(|O|^2 + |R|^2)$. The object wave O is separated from the others and may be viewed independently.

Figure 1 illustrates the recording of a hologram and the subsequent reconstruction. In Fig. 1(a), the laser beam is first expanded and then divided by a mirror, which directs part of the beam directly onto the photographic plate; the rest of the light is reflected from the object. After processing, the hologram plate may be replaced in its original position [Fig. 1(b)] and the object removed. The light diffracted by the hologram forms, in part, the same wavefront that was originally scattered by the object. A viewer looking through the hologram will see an undistorted view of the object, just as if it were still present. Figure 2(a) shows a photomicrograph of an actual hologram, and 2(b), (c), and (d) photographs of three perspectives of the resulting image.

In addition to this virtual image, or *primary image*, a real, or *conjugate image* will be formed on the observer's side of the hologram. This image will appear unsharp and highly distorted, and it will also be inverted in depth, i.e., reversed front to back, as shown in Fig. 1(b). However, a distortion-free real image can be formed by changing the position of the illuminating beam so that all of the rays of the reference beam are reversed in direction. In this way, an undistorted, real, three-dimensional image of the object scene appears in front of the hologram as shown in Fig. 1(c).

Holograms may be recorded with diverging, parallel, or converging reference beams. If care is taken to maintain the recording geometry during reconstruction, it is even possible to form holograms with an arbitrary reference beam, the only requirement being that it be coherent with the object beam.

It is possible to produce color holograms by recording three separate holograms on a single photographic plate, each in a different color. Subsequent illumination with a three-color beam yields three separate wavefronts, one in each of the three colors representing the portion of the object corresponding to that color.

It is possible to make holograms that can be viewed in reflection. This is done by allowing the reference and object beams to enter the recording medium from opposite sides [Fig. 3(a)]. The fringes formed are planes lying approximately parallel to the plane of the hologram. When such a hologram is illuminated by a beam similar to the reference wave, a reflected wave is formed which exactly duplicates the object wave. The image is viewed in reflected light [Fig. 3(b)]. It is possible to illuminate this type of hologram with white light. The interference planes filter the light by acting as a $\lambda/2$ multilayer interference filter, in the same way as in Lippmann color photography.

Many applications have been proposed for holography. The most important of these are the ones that exploit the unique features of holography, rather than those that just do old tasks in a new way. The best example of this is holographic interferometry, whereby *arbitrary* wavefronts interfere with each other in such a way that interference bands are produced that depict only the *differences* between them. In practice the two wavefronts are nearly identical. There are several types of holographic interferometry.

For *single-exposure holographic interferometry*, a hologram of the object wave O is recorded in the usual way. The hologram is then placed in exactly the same position it occupied during exposure and it is illuminated with the reference wave and a slightly distorted object wave O'. The reference wave reconstructs the original object wave O, which interferes with the directly transmitted wave O'. This is a real-time technique, because when the wave O' changes, so do the interference bands. This technique can be used to measure surface deformations of all kinds, including thermal expansion and contraction, swelling caused by absorption, and any minute changes that might occur in an object.

Double-exposure holographic interferometry requires making two holograms on a single recording medium. One of the two holograms yields a primary image which constitutes the comparison wave, just as in the single-exposure case. The test wave is not the object itself, however, but a reconstructed wave from the changed object. Interference phenomena,

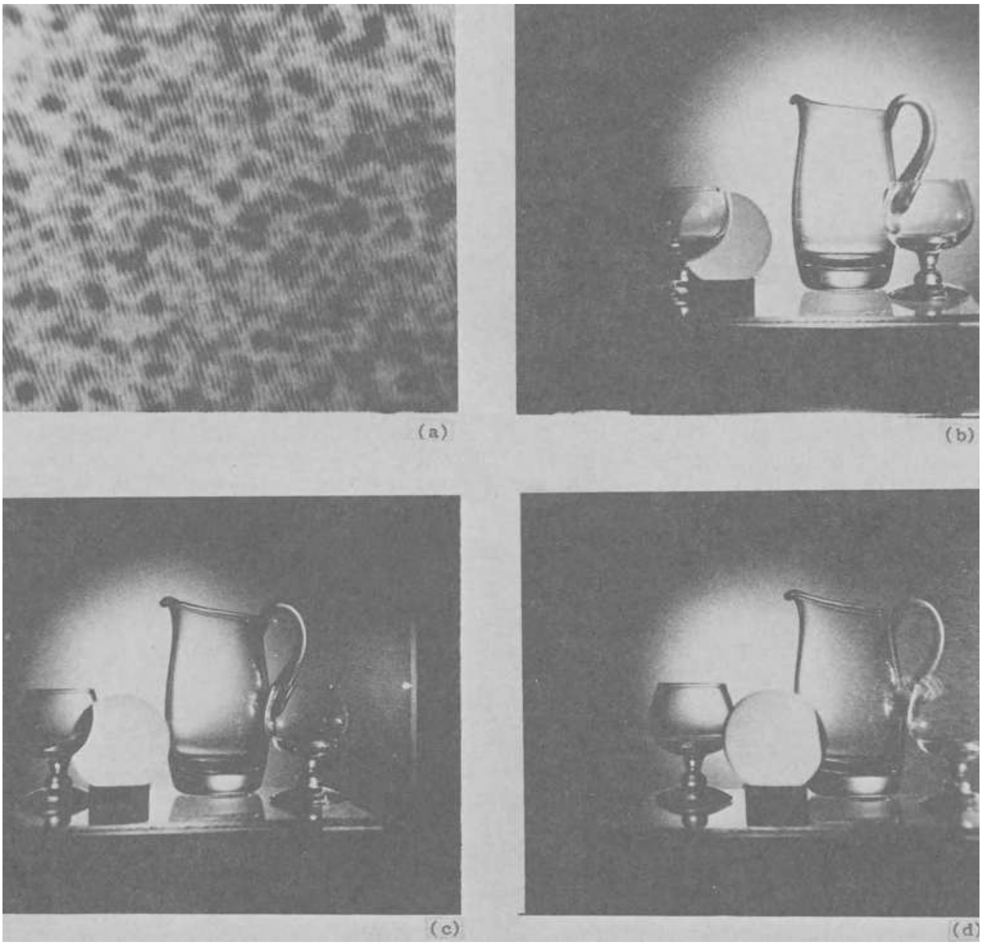

FIG. 2. A hologram of a diffusely illuminated object. (a) A highly magnified image of the hologram. (b), (c), (d) Three perspectives of the resulting image.

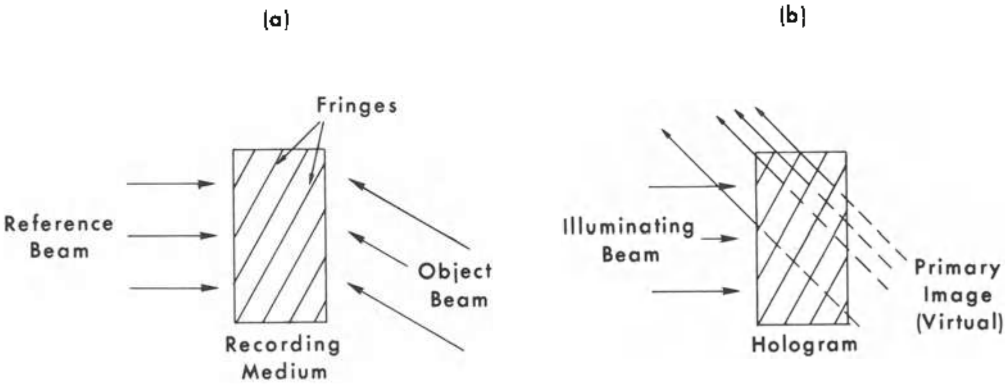

FIG. 3. Volume holograms that can be viewed in reflection. (a) Recording the hologram with object and reference waves incident in nearly opposite directions. (b) Reconstructing the primary wave in reflection.

caused by changes in optical path through the object between exposures, are produced when the doubly exposed hologram is illuminated. This technique is well suited to interferometric recording of transient phenomena, such as shock waves and fluid flow, when a pulsed laser is used as the source. All of the principles discussed thus far apply equally well to time-dependent events, and the very short pulse of light from a ruby laser can record the interference phenomena at a single instant of time. The very wide range of applicability of the method has been well demonstrated. This technique can also be extended to multiple exposures.

The idea of multiple-exposure interferometry can be extended to the limiting case of a continuum of exposures, resulting in what is called *time-average holographic interferometry*. This technique lends itself nicely to the problem of vibration analysis and may well be the best method yet devised for such analysis. The basis of the method is that since holography itself is an interferometric process, any instabilities of the interferometer cause fringe motion. Thus the hologram of a vibrating object is a record of the time-average irradiance distribution at the hologram plane. Since the amount of light flux diffracted from any region of the hologram depends on the fringe contrast, any object motion that causes the fringes to move during the exposure, causing a loss of contrast, will result in less diffracted flux from that region of the hologram. The strength of the reconstructed wave is therefore a function of the fringe motion during the exposure. If the object is vibrating in a normal mode, there will be standing waves of vibration on the surface, so that at the nodes the object motion will be very small or nonexistent. At the antinodes the vibration amplitude will be large. A hologram of such an object will then produce a bright image of the regions of the object for which little or no motion occurred during the exposure, whereas it will not produce images of antinodal points at all. This holographic method of vibration analysis has all of the advantages of all holographic interferometry. The method can be used regardless of the shape or complexity of the object; the vibration nodes can be examined in three dimensions, or at least from a variety of perspectives; and the method works regardless of whether the surface is optically smooth or diffusely reflecting.

One of the most striking aspects of the modern hologram is the three-dimensional image that it is capable of producing. This three-dimensional image indicates that there is a large amount of information contained in a single hologram—much more than is contained in a conventional photograph of the same size. Because of the many perspectives available, the hologram is well suited to display purposes. With a hologram, one can present all of the observable characteristics of a three-dimensional object clearly and concisely. Complicated molecular or anatomical structure can be simply presented with a single holographic image, with little chance of error or misinterpretation on the part of the viewer. Such a hologram could take the place of several conventional drawings or photographs. The use of holograms in textbooks would be a great aid to the student in many fields. Holograms made to be viewed with a small penlight and a colored filter have already been produced in large quantities and distributed in magazines and books.

Holographic microscopy is another important application. There are basically two distinct methods of holographic microscopy: (1) conventional holography with magnification achieved by changing the scale of the hologram, the illuminating wavelength, or the radius of curvature of the illuminating wavefront; by optically magnifying the holographic image; or by using any combination of these; or (2) holographically recording the optically magnified wavefront. For the first method, the lateral magnification is given by the formula

$$M = \frac{\mu m Z_c Z_R}{\mu Z_c (Z_R - Z_o) + m^2 Z_o Z_R},$$

where μ is the ratio of the illuminating and recording wavelengths, m is the factor by which the hologram has been scaled, and Z_c, Z_o, and Z_R are the radii of curvature of the illuminating, object, and reference wavefronts, respectively. Because aberrations are introduced when the wavelength is changed or the wavefront radii are changed, most of the current work in holographic microscopy involves optically magnifying the holographic image or using the second method, in which an optically magnified wavefront is recorded holographically. Holographic microscopy offers the following advantages: One can avoid the problems of limited depth of focus, off-axis observation, and the short working distance of the classical microscope. The hologram records a large volume of object space instantaneously. All of the usual image-processing techniques can be applied to the reconstructed wave, which may represent a large volume of space at an instant of time. No other method for doing this exists.

Recently, holograms used as optical elements (holographic optical elements, or HOEs) have become an important aspect of holography. An HOE is a generalized diffraction grating having many advantages over conventional optics (such as their light weight, thinness, and low cost), along with some disadvantages (such as requiring narrow bandwidth light). In principle, HOEs are able to perform the functions of conventional optical elements, such as beamsplitters, lenses, scanners, mirrors, and even spectral filters. HOEs can not only be designed with a computer, as can conventional optical elements, but they can also be generated with a computer, allowing inexpensive fabrication of such things as aspherics and off-axis elements.

I

IMPULSE AND MOMENTUM

The concept of impulse and momentum derives directly from Newton's law of motion.

Consider first the case of *linear* impulse and *linear* momentum. Newton's law states that in the proper frame of reference, force is equal to the (time) rate of change of momentum, where momentum is defined as the product of mass and velocity. Consider a force F acting for a time Δt on a particle of mass m, thereby changing its velocity from v_1 to v_2. The rate of change of momentum in this case is the change of momentum divided by the time interval during which the change occurs. Thus, Newton's law states

$$F = \frac{(mv)_2 - (mv)_1}{\Delta t} \qquad (1)$$

Now if we multiply each side of this equation by Δt, we obtain

$$F\,\Delta t = (mv)_2 - (mv)_1 \qquad (2)$$

The left-hand side of this equation, $F\,\Delta t$, representing the product of a force and the time interval through which the force acts, is called "impulse." Thus, this equation states what is often known as the *Law of Impulse and Momentum*: Impulse is equal to the change of momentum.

It becomes apparent that a body will experience the same change of momentum irrespective of the separate values of F and Δt as long as their product $F\,\Delta t$ is the same. Thus, a large force acting briefly may have the same net effect as a smaller force acting longer, if the two impulses are the same. Going to the limit, we may consider an infinite force acting for an infinitesimal time such that their product remains a finite quantity. Under the action of such an impulse, a body will experience an instantaneous change of velocity. A common example is the change of velocity of a baseball as it is hit by a bat. For all practical purposes the change occurs instantaneously.

As a consequence of the Law of Impulse and Momentum described above, we find that if the total force is zero, so is the total impulse, and the momentum will remain unchanged. This is known as the *Conservation Law of Momentum*. It applies either to one particle or to a system of particles. Consider, for instance, the collision of two billiard balls, A and B. Taking each ball separately, the impulse on A by B is equal in magnitude but opposite in direction to the impulse on B by A. Thus, upon collision, the change of momentum of A is also equal and opposite to that of B. On the other hand, if we take *both* A and B as our system, then the two impulses are acting on the same system. Since the two are equal and opposite, they cancel out and the total impulse on this system due to collision is zero. The Conservation Law of Momentum then predicts that the total momentum of the system (which is the sum of momenta of all particles in the system) remains a constant no matter what goes on in the system as long as there are no external forces acting on the sytem.

The Conservation Law of Momentum forms one of the basic cornerstones in physics and engineering. Its application is all-pervading, from the motion of stars to the encounter and scattering of molecules, atoms and electrons.

We will now continue our discussion at a more precise level. First of all, in calculating the momentum mv, the mass m should be relativistic mass defined as

$$m = \frac{m_0}{\sqrt{1-(v/c)^2}}$$

where m_0 is the rest mass, i.e., mass at zero velocity, and c is the velocity of light. It is seen that at velocities much less than the velocity of light, the relativistic mass and the rest mass are indistinguishable, and m may be considered constant. Secondly, both force and velocity are vector quantities, i.e., they have a magnitude and a direction and obey the parallelogram law of addition, and we shall use letters **F** and **v** to represent them. Finally, as the time interval Δt approaches zero as a limit, the rate of change of momentum during Δt becomes a derivative and Newton's law becomes:

$$\mathbf{F} = \frac{d}{dt}(m\mathbf{v}) \qquad (3)$$

After integrating each side of this equation with respect to time t and taking the integration limits from $t = t_1$ to $t = t_2$, the result is:

$$\int_{t_1}^{t_2} \mathbf{F}\,dt = (m\mathbf{v})_2 - (m\mathbf{v})_1 \qquad (4)$$

The integral on the left-hand side, analogous to the left-hand side of Eq. (2), is the "impulse," and we again reach the Law of Impulse and Momentum given previously. In evaluating this integral, we must know the variation of **F** as a function of time, i.e., $\mathbf{F} = \mathbf{F}(t)$. Furthermore, in applying this law to a system of particles, we need only to count those impulses that are caused by *external* forces acting on the particles due to sources outside the system. As has been illustrated by the previous example on two billiard balls, the *internal* forces that any two particles exert on each other will generally cancel out if both particles are included in the system.

A dramatic illustration of the above principle is the case of an exploding shell. Before the explosion, the shell will travel a parabolic path under the influence of the only external force, the gravitational force, if the forces due to air resistance are neglected. During explosion, all the forces acting on the exploding pieces due to explosion are internal forces and they cancel out if we include *all* pieces of the shell as our system. The conservation law of momentum then predicts that the center of gravity of the system will continue to travel along the same parabolic path even after explosion, until some new external force acts on the system (as, for example, when a piece of the shell hits an object).

Up to this point we have discussed the laws of linear impulse and linear momentum. Entirely similar laws hold for *angular* impulse and *angular* momentum. The angular momentum **L** of a particle about a point O is defined as the vector product of **r**, the radius vector from O to the particle, and $m\mathbf{v}$, the momentum vector of the particle. Thus,

$$\mathbf{L} = \mathbf{r} \times m\mathbf{v}$$

The moment of force or *torque* about O is defined as

$$\mathbf{T} = \mathbf{r} \times \mathbf{F}$$

If we take the cross product of **r** with each side of the expression for Newton's law, Eq. (3), we obtain

$$\mathbf{r} \times \mathbf{F} = \mathbf{T} = \mathbf{r} \times \frac{d}{dt}(m\mathbf{v})$$

The right-hand side can be identified to be just $d\mathbf{L}/dt$ on account of the vector identity:

$$\frac{d\mathbf{L}}{dt} = \frac{d}{dt}(\mathbf{r} \times m\mathbf{v}) = \mathbf{v} \times m\mathbf{v} + \mathbf{r} \times \frac{d}{dt}(m\mathbf{v})$$

where the first term on the right-hand side vanishes. Thus,

$$\mathbf{T} = \frac{d\mathbf{L}}{dt} \qquad (5)$$

We now integrate this equation with respect to t and take the integration limits from $t = t_1$ to $t = t_2$. The result is

$$\int_{t_1}^{t_2} \mathbf{T}\,dt = \mathbf{L}_2 - \mathbf{L}_1 \qquad (6)$$

Analogous to the linear impulse, we may call the integral on the left-hand side of the above equation the angular impulse. Thus this equation states: Angular impulse is equal to the change of angular momentum. In particular, if the total torque is zero, so is the total angular impulse, and the angular momentum will remain unchanged. This is known as the *Conservation Law of Angular Momentum.*

When applied to common problems, we take the axial component of the vector equations (5) or (6), i.e., along the direction perpendicular to the plane of motion. Along such a direction, the magnitudes of **T** and **L** assume the following values:

$$T = rF_t$$

$$L = mrv_t$$

where r again is the distance from the axis to the particle, F_t the tangential component of the force acting on the particle, and v_t the tangential velocity of the particle. Equation (5) then becomes a scalar equation.

$$T = rF_t = \frac{d}{dt}(mrv_t) \qquad (7)$$

If $T = 0$, then the angular momentum mrv_t remains constant.

Equation (7) is the basis of the operation of pumps and turbines. In the case of a turbine, the angular momentum of the working fluid is large at entrance and small or zero at exist. Hence the fluid imparts a torque to the shaft. In a pump or compressor the reverse is the case, i.e., the angular momentum of the working fluid is small at entrance but large at exit, hence the shaft supplies torque as well as energy to the fluid.

A remarkable example of the conservation law of angular momentum is the motion of planets around the sun. The attractive force between a planet and the sun is in the direction of the line connecting the two, hence it has no tangential component and contributes no torque. Equation (7) then concludes that rv_t must be a constant. This means that when the planet is at a larger distance from the sun, its tangential velocity must be smaller, and vice versa. This led Newton to explain the experimental finding of Kepler, namely, a planet sweeps equal sectorial areas in equal times. The same explanation applies to figure skaters and ballet dancers when they increase their spin speed by pulling in their arms.

INDUCED ELECTROMOTIVE FORCE

Electromotive force and voltage drop are usually regarded as synonymous. When an electromotive force, or simply emf, is impressed on a closed metallic circuit, current results. The emf along a specified path C in space is defined as the work per unit charge W/q done by the electromagnetic fields on a small test charge moved along C. Since work is the line integral of force $\mathbf{F}$, the work per unit charge is the line integral of the force per unit charge. Letting $\mathbf{F}/q$ denote the vector electromagnetic force per unit charge in newtons per coulomb, we have

$$\text{emf} = \int_C \frac{\mathbf{F}}{q} \cdot d\mathbf{l} \text{ volts} \tag{1}$$

The scalar product $(\mathbf{F}/q) \cdot d\mathbf{l}$ is the product $(F/q) \cos \theta \, dl$, with θ denoting the angle between the vectors $\mathbf{F}/q$ and $d\mathbf{l}$.

The electric force per unit charge is the electric field intensity $\mathbf{E}$ (volts per meter) and the magnetic force per unit charge is $\mathbf{v} \times \mathbf{B}$, with $\mathbf{v}$ denoting the velocity of the test charge in meters per second and $\mathbf{B}$ denoting the magnetic flux density in webers per square meter. In terms of the smaller angle θ between $\mathbf{v}$ and $\mathbf{B}$, the cross product $\mathbf{v} \times \mathbf{B}$ is a vector having magnitude $vB \sin \theta$; the direction of the vector $\mathbf{v} \times \mathbf{B}$ is normal to the plane of the vectors $\mathbf{v}$ and $\mathbf{B}$, with the sense of that of the extended thumb of the right hand oriented so that its fingers curl through the angle θ from $\mathbf{v}$ toward $\mathbf{B}$. As the total force per unit charge is $\mathbf{E} + \mathbf{v} \times \mathbf{B}$, the emf in terms of the fields is

$$\text{emf} = \int_C (\mathbf{E} + \mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l} \tag{2}$$

It might appear from Eq. (2) that the emf depends on the forward velocity with which the test charge is moved along the path C. However, this is not the case. If $\mathbf{v}$ and $d\mathbf{l}$ in Eq. (2) have the same direction, then the vectors $(\mathbf{v} \times \mathbf{B})$ and $d\mathbf{l}$ are normal, and their scalar product is zero. Consequently, only the component of $\mathbf{v}$ normal to $d\mathbf{l}$ can contribute to the emf. This component has value only if the differential path length $d\mathbf{l}$ has sideways motion. *Thus* $\mathbf{v}$ *in Eq.* (2) *represents the sideways motion, if any, of* $d\mathbf{l}$. The fields $\mathbf{E}$ and $\mathbf{B}$ of Eq. (2) may be functions of time as well as functions of the space coordinates. In addition, the velocity $\mathbf{v}$ of each differential path length $d\mathbf{l}$ may vary with time. However, Eq. (2) correctly expresses the emf, or voltage drop, along the path C as a function of time. That component of the emf consisting of the line integral of $\mathbf{v} \times \mathbf{B}$ is known as the *motional emf*, because it has value only when the path C is moving through a magnetic field, cutting lines of magnetic flux. For stationary paths there is no motional emf, and the voltage drop is simply the line integral of the electric field $\mathbf{E}$.

For an emf to exist along a stationary path, it is necessary to have an electric field present. As electric charges are surrounded by electric fields, emfs are generated by devices that separate charge. A familiar example is the battery, which utilizes chemical forces to separate charge. Some other methods of separating charge are the heating of a thermocouple, the exposure of a photocell to incident light, and the rubbing together of different materials. Electric fields are also produced by time-changing magnetic fields, and this principle is extensively exploited, as is motional emf, to generate electric power. The remainder of this article is devoted to electromotive force induced by magnetic means.

A fundamental law of electromagnetism, often called the *Maxwell-Faraday law*, or the *first law of electromagnetic induction*, states that the line integral of the electric field intensity $\mathbf{E}$ around any closed path C equals $-\partial\phi/\partial t$, with ϕ representing the magnetic flux over any surface S having the closed path C as its contour. The positive side of the surface S and the direction of the line integral around the contour C are related by the right-hand rule; by this rule, the curled fingers are oriented so as to point around the loop in the direction of the integration and the extended thumb points out of the positive side of the surface S. The magnetic flux ϕ is the surface integral of the magnetic flux density $\mathbf{B}$; that is,

$$\phi = \iint_S \mathbf{B} \cdot d\mathbf{S} \text{ webers} \tag{3}$$

In Eq. (3) the vector differential surface $d\mathbf{S}$ has area dS and is directed normal to the plane of dS out of the positive side. The partial time derivative of ϕ is defined as

$$\frac{\partial \phi}{\partial t} = \iint_S \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} \text{ volts} \tag{4}$$

and this is often referred to as the *magnetic current* through the surface S. For a moving surface S the limits of the surface integral of Eq. (4) are functions of time, but Eq. (4) still applies. It is important to understand that in evaluating $\partial\phi/\partial t$ over a surface that is moving in a region containing a magnetic field, *we treat the surface at the instant under consideration as though it were stationary.* The partial time derivative of ϕ is the time rate of increase of the flux over the surface S due only to the changing magnetic field $\mathbf{B}$; any increase in ϕ due to the motion of the surface in the $\mathbf{B}$-field is *not* included. The Maxwell-Faraday law is

$$\oint_C \mathbf{E} \cdot d\mathbf{l} = -\frac{\partial \phi}{\partial t} \tag{5}$$

with ϕ being the magnetic flux in webers out of the positive side of *any* surface having the path C as its contour. The small circle on the integral sign indicates a closed path. We note from Eq. (5) that *an electric field must be present in any region containing a time-changing magnetic field.*

The application of Eq. (2) to a closed path C gives

$$\text{emf} = \oint_C \mathbf{E} \cdot d\mathbf{l} + \oint_C (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l} \tag{6}$$

Utilizing Eq. (5) enables us to write Eq. (6) in the form

$$\text{emf} = -\frac{\partial \phi}{\partial t} + \oint_C (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l} \tag{7}$$

Thus the emf around a closed path consists, in general, of two components. The component $-\partial\phi/\partial t$ is often referred to as the *variational emf* (or *transformer emf*), and the second component is, of course, the motional emf.

In Eq. (7) the relation $(\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l}$ can, by means of a common vector identity, be replaced with $-\mathbf{B} \cdot (\mathbf{v} \times d\mathbf{l}$ has magnitude $v\,dl$ and of $d\mathbf{l}$, the vector $\mathbf{v} \times d\mathbf{l}$ has magnitude $v\,dl$ and direction normal to the differential surface dS swept out by the moving length $d\mathbf{l}$ in the time dt. Letting B_n denote the component of $\mathbf{B}$ normal to this area, we note that $-\mathbf{B} \cdot (\mathbf{v} \times d\mathbf{l})$ becomes $-B_n\,v\,dl$, and Eq. (7) can be written

$$\text{emf} = -\left[\frac{\partial \phi}{\partial t} + \oint_C B_n v\,dl\right] \tag{8}$$

Clearly the integral of $B_n v$ around the closed contour C, with v denoting the magnitude of the sideways velocity of each dl, is simply the time rate of increase of the magnetic flux over the surface bounded by C due to the path C cutting lines of magnetic flux. Hence, the complete expression in brackets is the time rate of increase of the magnetic flux ϕ, over any surface S bounded by the closed path C, *due to the changing magnetic field and also due to the moving path cutting through the magnetic field.* Equation (8) is often written

$$\text{emf} = -\frac{d\phi}{dt} \tag{9}$$

It is important to note carefully the distinction between Eqs. (5) and (9). Equation (5) is only the variational emf, and Eq. (9) is the sum of the variational and motional emfs. In Eq. (5), the partial time derivative of the magnetic flux ϕ is the rate of change of the flux due only to the time-changing magnetic field; in Eq. (9), the total time derivative is the rate of change of the flux due to the time-changing $\mathbf{B}$-field and also to the path cutting through the magnetic field. Of course, if the closed path is not cutting lines of magnetic flux, then Eqs. (5) and (9) are equivalent. It is also important to note that $d\phi/dt$ in Eq. (9) does not necessarily mean the total time rate of change of the flux ϕ over the surface S. For example, the flux over a surface S bounded by the closed contour C of the left-hand electric circuit of Fig. 1 is changing when the coil is being unwound by the rotation of the cylinder. However, as $\mathbf{B}$ is static there is no variational emf, and since the conductors are not cutting flux lines, there is no motional emf. Consequently, $d\phi/dt$ as used in Eq. (9) is zero even though the flux is changing with time. Note that $d\phi/dt$ in Eq. (9) was *defined* as representing the bracketed expression of Eq. (8), and $d\phi/dt$ must not be more broadly interpreted.

In the applications of the equations which have been presented, we must refer all flux densities and movements to a single specified coordinate system. In particular, the velocities are with respect to this system and are not relative velocities between conductors and moving lines of flux. Of course the coordinate system is arbitrarily selected, and *the relative magnitudes of the variational and motional emfs depend upon the selection.* Let us consider two examples.

Example 1 An electric generator is shown in Fig. 2. The parallel stationary conductors separated a distance l have a stationary voltmeter connected between them. The electric circuit is completed through a moving conductor that is connected electrically by means of sliding taps. This conductor is at $y = 0$ at time $t = 0$ and moves to the right with constant velocity $\mathbf{v} = v\mathbf{a}_y$. The applied flux density $\mathbf{B}$, represented in Fig. 2 by dots, is $B_0 \cos \beta y \cos \omega t\, \mathbf{a}_x$. Unit vectors in the directions of the respective coordi-

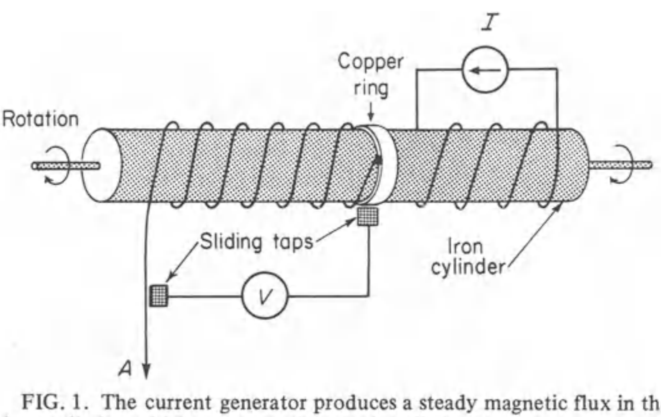

FIG. 1. The current generator produces a steady magnetic flux in the iron cylinder, which rotates as the wire is pulled at A.

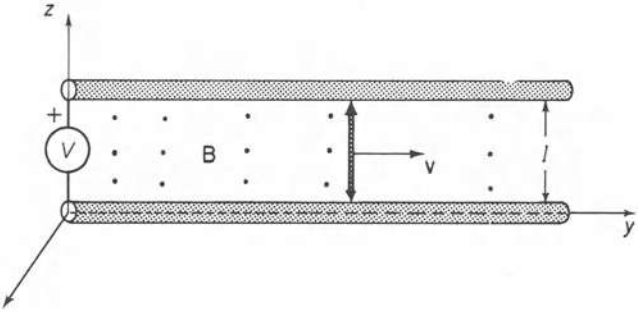

FIG. 2. Elementary electric generator.

nate axes are $\mathbf{a}_x$, $\mathbf{a}_y$, and $\mathbf{a}_z$. Find the instantaneous voltage across the voltmeter.

Solution. Let S denote the plane rectangular surface bounded by the closed electric circuit, with the positive side selected as the side facing the reader. The counterclockwise emf around the electric circuit is $-d\phi/dt$, with ϕ signifying the magnetic flux out of the positive side of S. As $d\mathbf{S} = l\,dy\,\mathbf{a}_x$, the scalar product $\mathbf{B} \cdot d\mathbf{S}$ is $B_o l \cos \beta y \cos \omega t\, dy$; integrating from $y = 0$ to $y = y_1$ gives

$$\phi = (B_o l/\beta) \sin \beta y_1 \cos \omega t \qquad (10)$$

with y_1 denoting the instantaneous y-position of the moving wire. The counterclockwise emf is found by replacing y_1 with vt and evaluating $-d\phi/dt$. The result is

$$\text{emf} = \omega B_o l/\beta \sin \beta vt \sin \omega t$$
$$- B_o lv \cos \beta vt \cos \omega t \quad (11)$$

The variational (transformer) component is $-\partial\phi/\partial t$, which is determined with the aid of Eq. (10) to be $\omega B_o l/\beta \sin \beta y_1 \sin \omega t$, with $y_1 = vt$. This is the first component on the right side of Eq. (11). Note that y_1 was treated as constant when evaluating the partial time derivative of ϕ. The motional emf is the line integral of $\mathbf{v} \times \mathbf{B}$ along the path of the moving conductor. As $\mathbf{v} \times \mathbf{B}$ is $-B_o v \cos \beta y_1 \cos \omega t\, \mathbf{a}_z$ and as $d\mathbf{l}$ is $dz\, \mathbf{a}_z$, we evaluate the integral of $-B_o v \cos \beta y_1 \cos \omega t\, dz$ from $z = 0$ to $z = l$, obtaining a motional emf of $-B_o lv \cos \beta y_1 \cos \omega t$. This component results from the cutting of lines of magnetic flux by the moving conductor.

If the voltmeter draws no current, there can be no electromagnetic force on the free electrons of the wires. Therefore, *the emf along the path of the metal conductors, including the moving conductor, is zero*. The total voltage of Eq. (11) appears across the voltmeter.

Example 2 Suppose the conductor with sliding taps in Fig. 2 is stationary ($\mathbf{v} = 0$) and located at $y = y_1$. Also suppose that the magnetic field $\mathbf{B}$ is produced by a system of steady currents in conductors (not shown in Fig. 2) that are moving with constant velocity $\mathbf{v} = v\mathbf{a}_y$. At time $t = 0$ the magnetic field $\mathbf{B}$ is $B_o \sin \beta y\, \mathbf{a}_x$. Determine the voltage across the voltmeter.

Solution. There is no motional emf because the conductors of Fig. 2 are stationary with respect to our selected coordinate system. However, the magnetic field at points fixed with respect to the coordinate system is changing with time, and hence there is a variational emf.

As the **B**-field at $t = 0$ is $B_o \sin \beta y \, \mathbf{a}_x$ and moving with velocity $v \, \mathbf{a}_y$, the **B**-field as a function of time is $B_o \sin [\beta(y - vt)] \, \mathbf{a}_x$. This is verified by noting that an observer at y_o at $t = 0$ moving in the y-direction with the velocity v of the moving current-carrying conductors, would have a y-coordinate of $y_o + vt$; hence according to the expression for **B**, he would observe a constant field. The magnetic current density is

$$\partial \mathbf{B}/\partial t = -\beta v B_o \cos \beta(y - vt) \, \mathbf{a}_x$$

The negative of the integral of this over the rectangular surface bounded by the electric circuit, with the positive side selected as the side facing the reader and with y limits of zero and y_1, gives the counter-clockwise emf. The result is

$$\text{emf} = B_o l v [\sin \beta(y_1 - vt) + \sin \beta vt]$$

This is the voltage across the meter.

INDUCTANCE

Inductance is a ratio of a magnetic flux Φ to an electric current i. The unit is the henry; 1 henry, $\equiv$ 1 weber/ampere. The *mutual inductance M* of two circuits is defined as the ratio of the magnetic flux, linking with one circuit, to the current in the other

$$M_{12} = \frac{\Phi_2}{i_1}, M_{21} = \frac{\Phi_1}{i_2}$$

The *self-inductance L* of a single circuit is defined as the ratio of the flux linking the circuit to the current flowing in the circuit.

$$L = \frac{\Phi}{i}$$

In the absence of any magnetic material, M and L depend only on the geometry of the circuits concerned. The mutual inductance of two circuits 1 and 2 can be calculated from the Neumann equation*

$$M_{12} = M_{21} = \frac{\mu_0}{4\pi} \oint_1 \oint_2 \frac{\mathbf{dl}_1 \cdot \mathbf{dl}_2}{r}$$

where $\mathbf{dl}_1$ and $\mathbf{dl}_2$ are vector elements of length in circuits 1 and 2, respectively, and $\mathbf{r}$ is the distance between these two elements. Note that this expression is completely symmetrical with respect to the two circuits. The self-inductance is calculated from the same equation, where the elements $\mathbf{dl}_1$ and $\mathbf{dl}_2$ are now situated on the same circuit. The double integral is evaluated by first keeping the position of $\mathbf{dl}_2$ fixed and integrating $\mathbf{dl}_1/r$ around the circuit. The process is then repeated for all other elements such as $\mathbf{dl}_2$, and the results are summed.

The *external inductance* of a circuit is the part of its self-inductance which is due to flux lying outside the surface of the conductor while the *internal inductance* is the contribution from the magnetic flux within the conductor itself.

If the current, and therefore the magnetic flux associated with it, varies with time, an electromotive force (emf) will be induced in any circuit linked by the flux. This provides an alternative method of defining inductance in terms of the emf induced by a given rate of change of current.

$$\mathcal{E}_2 = -M \frac{di_1}{dt}$$

$$\mathcal{E}_1 = -M \frac{di_2}{dt}$$

$$\mathcal{E} = -L \frac{di}{dt}$$

The negative signs are used to imply that the direction of the emf is always such as to tend to oppose the change of current (Lenz's law). Note, however, that although the self-inductance must always be positive, the mutual inductance of two circuits may be either positive or negative. An inductance of 1 henry corresponds to an induced emf of 1 volt for a rate of change of current of 1 ampere/sec.

In order to maintain a current i, the induced emf $-Ldi/dt$ must be balanced by an equal and opposite applied voltage so that the total applied voltage is

$$v = Ri + L \frac{di}{dt}$$

and the power supplied to the circuit is

$$vi = Ri^2 + \frac{d}{dt}\left(\frac{1}{2} Li^2\right)$$

*μ_0 is the permeability of free space; $\mu_0 = 4\pi \times 10^{-7}$ henrys/m.

where the resistance R is a measure of the power dissipated. This equation shows another way of interpreting inductance, namely as a measure of the amount of energy stored in the magnetic field when a given current flows. The stored energy is $\frac{1}{2}Li^2$ joules when L is measured in henrys and i in amperes.

Electric circuit theory is based on the use of sinusoidally varying currents and voltages. When the current varies sinusoidally with time, the rate of change of current has the same time waveform except for a phase shift of $\pi/2$ radians. This leads to the idea of a complex impedance, of which the real part is associated with the power lost from the circuit and the imaginary part is a reactance given by the ratio of the magnitude of the induced emf to that of the current. Since the phase of the applied voltage leads that of the current, the magnetically induced reactance is taken as being positive. We thus have

$$i = I \sin \omega t$$

$$v = Ri + L\,\frac{di}{dt}$$

The circuit impedance is Z where

$$Z = \frac{v}{i} = R + j\omega L$$

The self-inductance of a circuit can be regarded as a parameter which determines the inductive reactance presented to a sinusoidally varying current of given amplitude and frequency. In the same way, the mutual inductance determines the mutual reactance between two circuits.

Owing to magnetic hysteresis, the voltage and current time waveforms cannot both be sinusoidal if any magnetic material is present. Under these conditions, the reactance is defined as the ratio of the fundamental-frequency components of the voltage and current waveforms.

The sign of the mutual inductance can be specified in the following way. Suppose that the two circuits are connected in series. Then the total induced emf will be

$$-(L_1 + L_2 + 2M)\,\frac{di}{dt}$$

and the total reactance will therefore be

$$j\omega(L_1 + L_2 + 2M)$$

and will be greater than the sum of the reactances of the separate circuits when M is positive. A combination of two coils is said to be series aiding or series opposing, depending on whether they are connected so that M is positive or negative, respectively.

The *Q-factor* is used in describing the properties of an inductor. It is defined as

$$Q = \frac{\omega L}{R} = \tan\phi$$

where ϕ is the phase angle of the complex impedance Z. An alternative term is the *power-factor* $\cos\phi$, particularly when the emphasis is on power dissipated rather than on the damping of tuned circuits.

An impedance Z can be represented by an equivalent circuit consisting of a resistance R in series with an ideal *series inductance* L. An alternative is to start with the admittance $Y = 1/Z$ and to represent this by the parallel combination of a resistance R' and a *parallel inductance* L'.

$$R = \frac{R'}{1 + Q^2}$$

$$L = L\left(\frac{Q^2}{1 + Q^2}\right)$$

Note that, when Q is sufficiently large,

$$L' \simeq L$$

$$R' \simeq Q^2 R$$

Inductance Coil (Inductor). This is a device which is specially designed to possess inductance. The winding may have a ferromagnetic core composed of a dust-core material, metallic laminations or ferrite. An *air-cored* coil is one with no magnetic core.

Although it is the inductance which is of interest, the influence of the electric field often cannot be neglected and causes the effect known as self-capacitance. At relatively low frequencies, the inductor will behave as if an equivalent lumped capacitance were shunted across its terminals. This simple equivalent circuit fails as the frequency is approached at which the apparent lumped capacitance would resonate with the inductance of the coil. The problem then becomes one of electromagnetic wave propagation, and the concept of inductance is no longer relevant. The effect of a fixed parallel capacitance C is to reduce the Q-factor to Q_c, where

$$Q_c = Q\left[1 - \omega^2 LC\left(1 + \frac{1}{Q^2}\right)\right]$$

When Q is large, this becomes

$$Q_c \simeq Q(1 - \omega^2 LC)$$

The self-resonance effect is sometimes an advantage, e.g., in choke coils, where the object is to obtain a high impedance, irrespective of its phase angle. Generally however self-capacitance is an undesirable property, particularly in electrical networks in which the inductor forms part of a series resonant circuit.

The self-capacitance of a coil can be kept to a minimum by spacing the turns of the winding well apart and also, in the case of a multi-layer winding, by ensuring that wires which lie physically close together always belong to adjacent parts of the winding so that the potential difference between them is relatively small.

The inductance of some types of coil can be calculated directly, without recourse to the Neumann equation. An example is the *toroidal coil*, i.e., one consisting of a uniform winding around a ring-shaped former. In this case the magnetic flux exists in a well-defined magnetic circuit and the inductance is given, very nearly, by

$$L = \frac{\mu_0 N^2 A}{l}$$

where N is the number of turns in the winding and A and l are, respectively, the cross-sectional area and the length of the magnetic circuit. The same formula also holds for a long, thin *solenoidal coil*. Corrections must be applied unless both the diameter of each turn and the radial depth of the winding are small compared with the length of the magnetic circuit for the toroid or the length of the coil itself for the solenoid.

If the toroidal former is replaced by one made of a magnetic material having a relative permeability μ, the inductance will be increased by a factor μ. For coils of other geometrical shapes, where some of the flux linking the winding may lie partly or wholly outside the magnetic core, the presence of the latter will increase the inductance by a factor called the *effective permeability* μ_e. This can never exceed μ and may be considerably smaller than μ.

The relative permeability of a ferromagnetic material is not a constant but is a function of the instantaneous flux density. This increases power losses and causes distortion of the current and voltage time waveforms.

Power dissipation in a metallic core can be represented approximately by an equivalent series resistance R, where

$$\frac{R}{\mu_e f L} = c + hB_{\max} + ef$$

and $B_{\max}$ is the peak flux density. The parameters c and h depend on the hysteresis properties of the core material. The parameter e is a measure of eddy-current losses in the core.

Ferrite materials are practically insulators; therefore eddy-current losses are negligible. For a ferrite, however, the relative permeability must be regarded as a complex quantity

$$\mu = \mu'(1 - j \tan \delta)$$

Both μ' and the dissipation coefficients $\tan \delta$ are functions of frequency.

The useful frequency range of coils with laminated cores is often limited by magnetic skin effect. This causes both the inductance and the Q-factor to start to fall as the depth of penetration of the electromagnetic field becomes comparable with the thickness of the laminations. The depth of penetration d is given by

$$\frac{2}{d^2} = \omega \mu_0 \mu \sigma$$

where σ is the conductivity of the core material.

The inductance of a coil with a magnetic core is reduced if there is a superimposed unidirectional polarizing flux, caused for example by a dc current in the winding. This may be an unwanted effect or it may be used as a means of controlling the inductance.

Transverse air gaps are often introduced into the magnetic circuit. There are several reasons for this. An air gap reduces the flux density for a given magnetizing force, thus reducing the inductance of a given coil. The power losses are, however, reduced at a greater rate than the inductance so that the power factor is improved. The performance of the inductor is made less dependent on the magnetic parameters of the core material. The waveform distortion due to hysteresis is also reduced. An air gap may be used to prevent saturation of the core by the polarizing flux when the coil is required to carry a dc current.

If the inductance of a coil, with a closed magnetic circuit of length l, is L, an air gap of length g will reduce the inductance to L_g where

$$Lg = L \cdot \left[\frac{\mu}{1 + \mu(g/l)}\right]$$

As the gap ratio g/l is increased, the inductance tends to become independent of μ, particularly when μ is large. Note however that the formula assumes that the presence of the air gap does not change the geometry of the flux distribution; an assumption which is generally only justified for relatively small gap ratios.

Dust-cored or ferrite-cored coils, for which the core eddy-current losses are small, are often wound with stranded wire. This is done to keep the eddy-current losses in the winding low by ensuring that the individual conductor strands have diameters which are small compared with the depth of penetration of the electromagnetic field into the material of which they are made. At very high frequencies, where this condition cannot be met, solid wire is often used and the diameter of the wire is increased to compensate for the fact that only part of its cross-sectional area is effective as a conductor.

INDUCTION HEATING

Induction heating is a technique for generating heat in electrically conductive articles by causing current to circulate in them by induction from an adjacent coil carrying alternating current.

The frequency of the current exciting the coil ranges from supply frequency, 60 Hz, up to typically 450 kHz. Except for 60-Hz applications, current may be obtained from rotary motor alternators, up to 10 kHz; magnetic multipliers using saturating cores, up to 540 Hz; valve oscillators, to over 1 MHz; and solid-state frequency changers up to 10 kHz. Coil-exciting voltages range from 400, 800, and 1 200 V in low-frequency systems (up to 10 kHz), to as much as 5 000 V for high-frequency valve oscillators.

Typical applications include general heating of metal parts, annealing, case and through hardening, melting in crucible-type furnaces, and heating of billets prior to forging.

In all cases of induction heating the fundamental principle is transformer action between the exciting coil and the workpiece which forms the secondary circuit. A typical arrangement is a solenoidal coil with a solid cylindrical workpiece. The currents induced in the charge flow in cylindrical paths centered on the longitudinal axis of the workpiece. Each of these paths has inductance and there is a consequent progressive decrease in current strength toward the center of the workpiece. This effect increases with increase in frequency, and as the current at any depth from the surface determines the rate of heat generation at that depth, the frequency can be chosen to control the heat pattern.

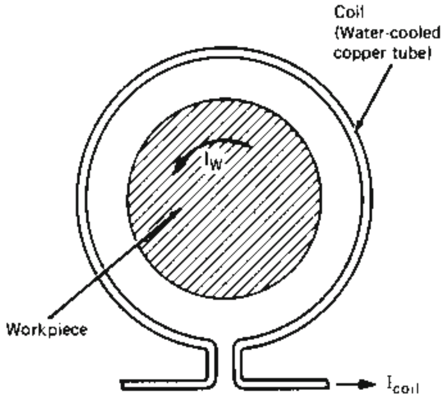

FIG. 1. Heating coil. I_W = current induced in material to be heated. I_{coil} = current through the water cooled coil.

TABLE 1. EFFECTIVE DEPTH OF CURRENT PENETRATION (in inches)

Frequency	50 Hz	1000 Hz	100 kHz
Copper	0.300	0.080	0.008
Aluminium	0.450	0.120	0.012
Brass	0.700	0.180	0.018
Steel	0.065	0.015	0.0015
Steel (above Curie)	3.200	0.750	0.075

The effective depth of current penetration is a function not only of frequency, but also magnetic permeability and specific resistivity. It can be expressed by the relation:

$$D = 1.98\sqrt{\frac{\rho}{\mu \times f}}$$

where D = depth in inches, ρ = resistivity in $\mu\Omega$, μ = permeability, and f = frequency in Hz.

The very marked change in current depth in ferromagnetic material (steel) as it passes from its high permeability state through Curie temperature to its low permeability, higher resistivity state should be noted.

The exciting coil together with the workpiece can be represented by an inductor in parallel with a resistor. To achieve efficient operation when used with the power sources described it is necessary to compensate for the reactive KVA taken by the inductance by adding capacitance in parallel to bring the power factor close to unity. Once this is achieved the effective load resistance must then be matched to the source resistance to achieve maximum power transfer to the workpiece.

Induction heating makes possible power densities (KW/in.^{2} of workpiece area) up to 100 KW/in.^{2} compared with the maximum equivalent power density from an oxyacetylene flame of about 10 KW/in.^{2}.

INERTIAL GUIDANCE*

Inertial guidance is an on-board means to provide a steering control function that will hold a moving vehicle on a prescribed course, relying solely upon inertial measurements. *Inertial navigation* is an on-board means to determine the location of a vehicle relying solely upon inertial measurements. Hence, an inertial guidance system (IGS) employs an inertial navigation system (INS).

The steering function is formulated by comparing the location vector $\mathbf{Q}_{\mathbf{ins}}$ (as determined by the INS) to the steering command vector $\mathbf{Q}_{\mathbf{sc}}$. (See Fig. 1.) Note that solid lines represent signals while dotted lines represent physical or actual dynamics. In performing its task, the INS measures the vehicle acceleration vector $\ddot{\mathbf{Q}}$ and vehicle rate vector Ω. Employing a gyro-stabilized coordinate reference system, the INS computes the position or location vector $\mathbf{Q}_{\mathbf{ins}}$. In actual practice, the vectors are handled as three scalar components, utilizing three channels each like that in Fig. 1.

Basic INS Essentially, the INS measures vehicle acceleration and integrates twice. See Fig. 2. Consider the X component of vehicle acceleration, $\ddot{X}$. The X accelerometer a_x measures this, producing an electrical signal. The signal is integrated twice, thus computing the X component of vehicle position. For a three dimensional system, there would be a similar channel each for the Y and Z components.

Stable Platform While Fig. 2 represents the basic INS, it is not practicable. It has several shortcomings—the lack of a coordinate system (implied in Fig. 1) being the primary one. In order to provide a coordinate system, it is necessary to physically orient the accelerometers appropriately. This can be accomplished by mounting the accelerometer on a stabilized platform (a surface whose orientation in space is maintained by physical means). For discussion purposes, let us employ a pendulum and a compass. (See Fig. 3.) For this hypothetical case, the X accelerometer would be level and pointed north.

The price paid for this particular form of stabilization is that the accelerometer rotates. (See Fig. 4). As a result, it senses the acceleration of constraint $\ddot{C}$ (Coriolis, centripital accelerations, etc.). This must be computed and then it must be subtracted from the accelerometer signal. (Return to Fig. 3.) Following this with an integration determines the vehicle velocity $\dot{X}$. Division by earth's radius R yields the angular rate $\dot{\lambda}$ (latitude rate about the earth), which upon integration provides the instantaneous latutude λ. (See Fig. 5.)

Schuler Tuned INS The simple pendulum used in Fig. 3 is unsatisfactory, since vehicle acceleration would cause the pendulum to seek a false vertical. Einstein's special theory of relativity states that it is impossible to distinguish between inertial reaction (acceleration) forces and mass attraction (gravitational) forces. Consequently, if a real pendulum were employed, the accelerometer would erroneously include a component of gravity. With an incorrect vertical, and an incorrect measure of acceleration, there would be no way to correct either.

Instead of a simple pendulum, a more sophisticated scheme is required. The pendulous effect is achieved by means of the accelerometer and a gyroscope. The same accelerometer will serve in two capacities (since they cannot be separated anyway). It will read the vehicle acceleration and act as part of the vertical seeking device. (See Fig. 6.) The vehicle rate $\dot{\lambda}$ is applied to the gyro, which precesses at that rate. After a time t, the platform turns through an angle λ which is the integral of $\dot{\lambda}$. Thus, when the system is operating properly, the platform is physically turned through the same angle that the vehicle has traveled around the earth. Consequently, the platform is still level. The INS is an analog of the actual system, maintaining a true vertical and measuring true acceleration. As such, the INS acts like a pendulum whose period T is given by

$$T = \frac{1}{2\pi}\sqrt{\frac{R}{g}}; \qquad (1)$$

whereupon, applying numerical values, the period becomes

$$T = 84 \text{ minutes}. \qquad (2)$$

This is referred to as a *Schuler pendulum* or a *Schuler tuned system*.

Complete INS The preceding section indicates one means by which the INS may be instrumented. Other schemes involve considera-

tions such as: the shape of the earth, free gyros, platform fixed in space, platform affixed to the vehicle frame (strap down), free azimuth, slaved to arbitrary heading, etc. A universal model is shown in vector form in Fig. 7. The boxes marked G and T are universal transformations involving gravity and terrestrial coordinates, respectively.

A specific INS, one that is level and north-slaved, is shown in Fig. 8. Note that there are two Schuler loops, one each for the X and Y axes. The third axis, Z, is aligned along the

earth's radius vector (up). The accelerometer for this channel senses the full magnitude of gravity, requiring that this be computed accurately. The latitude channel λ has already been described. The longitude channel ϕ differs somewhat, since it requires some trigonometric manipulations. Refer to Fig. 5. A rate $\dot{\Omega}_x$, about a vector that is tangent to the earth and pointing north, is multiplied by sec λ in order to obtain the polar rate $\dot{\Omega}_p$, where,

$$\dot{\Omega}_p = \omega_e + \dot{\phi}. \tag{3}$$

The polar rate includes the earth's rate of rotation ω_e, which must be subtracted in order to derive the longitude rate $\dot{\phi}$. Upon subsequent integration, this reveals the longitude ϕ. The azimuth Z gyro torquing rate $\dot{\Omega}_z$ is generated by multiplying $\dot{\Omega}_x$ by tan λ.

System Errors Upon examination of the INS in Fig. 8, it should be pointed out that many quantities are fed back, making the INS a multicoupled system. Thus, error sources in various parts of the system will effect many other parts. Also, since these are fed back and cross coupled, the errors may either grow unbounded, or they may be self-limiting.

In order to quantitatively accomplish a complete error analysis, first perturb the system, as shown in Fig. 9. Approximate the error sources in the system as phantom inputs (step functions) by the following six quantities: accelerometer errors α_x and α_y; computer error β_λ; and gyro drift rates γ_x, γ_y, and γ_z. Assume that the vehicle travels at constant altitude ($\dot{R} = 0$) and at constant latitude ($\dot{\lambda} = 0$). Also assume that the Schuler loops limit the tilt errors to small values. The closed loop cross coupled analysis is treated with matrices,* and the resulting errors are shown in Fig. 10. Note the following:

ω = Schuler frequency whose period is given by Eq. (1), which is equal to 84 minutes at sea level.

P = Polar frequency $\dot{\Omega}_p$ given by Eq. (3), which is about 2 rev/day for a vehicle traveling east at the equator at about 1600 km/hr.

It should be noted that a gyro drift rate equal to 0.01°/hr results in maximum velocity

*See chapters 8 and 9 of Ref. 2.

errors of 2 km/hr; maximum latitude error of 2 km; maximum longitude error of 6 km; maximum platform tilt off the vertical of 2 arc-min; and maximum heading error of 6 arc-min. The most significant conclusion is that *no errors are unbounded*—a bonus provided by the multicoupling in the INS.

INFRARED RADIATION

The region of the electromagnetic spectrum between the wavelength limits 0.7 and 1000μm (7×10^{-5} and 1×10^{-1} cm) has become known as infrared radiation. The lower wavelength limit is set to coincide with the upper limit of the visible radiation region. Radiation of wavelength greater than 1000μm is generally thought of as the microwave spectrum. Both limits are arbitrary, and represent no change in characteristics as they are passed. Conventionally, the region between 0.7 and 1.5μm is called the *near infrared region*; that between 1.5 and 20μm, the *intermediate infrared region*; and that between 20 and 1000μm, the *far infrared region*.

For many applications, the location of infrared radiation in the spectrum is described by/ :s wavelength in micrometers, μm, (1μm = 10^{-4} cm). In applications where the relative energy of the radiation is of interest, the *wave number*, σ, is used. The wave number is defined as the reciprocal of the wavelength, λ, in centimeters, and is expressed in units of cm^{-1} (called the kayser). This quantity is used more commonly than the frequency ν of the radiation, which is related to σ as follows:

$$\sigma = \nu / c \tag{1}$$

where c is the velocity of light.

Infrared radiation is produced principally by the emission of solid and liquid materials as a result of thermal excitation and by the emission of molecules of gases. Thermal emission from solids is contained in a continuous spectrum, whose wavelength distribution is described by the relation

$$M_\lambda d\lambda = \frac{2\pi c^2 h\epsilon_\lambda}{\lambda^5} \frac{1}{e^{ch/\lambda kT} - 1} d\lambda \tag{2}$$

where

M_λ = spectral radiant exitance of the solid into a hemisphere in the wavelength range from λ to $(\lambda + d\lambda)$
h = Planck's constant = 6.62×10^{-27} erg sec
ϵ_λ = spectral emittance
k = Boltzmann's constant = 1.38×10^{-16} erg/K
T = absolute temperature of the solid emitter, K.

The spectral emittance, ϵ_λ, is defined as the ratio of the emission at wavelength λ of the object to that of an ideal blackbody at the same temperature and wavelength. When ϵ_λ is unity, Eq. (2) becomes the Planck radiation equation for a blackbody. The distribution of radiant exitance with wavelength for blackbody radiators at different temperatures is shown in Fig. 1. It is apparent from the figure that blackbody radiation from emitters at temperatures below about 2000 K falls predominantly in the infrared region. An emitter which exhibits a constant value less than unity of spectral emit-

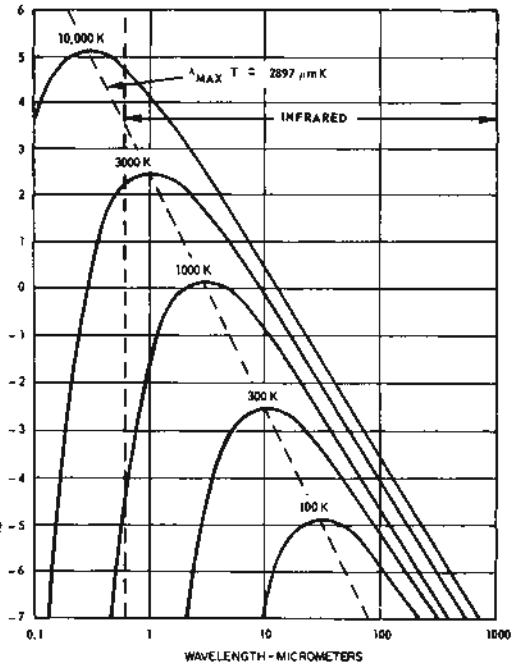

FIG. 1. Spectral radiant exitance of a blackbody at various temperatures.

tance at all wavelengths is called a *gray-body* radiator. Most solid radiators show a general decrease in spectral emittance with increasing wavelength in the infrared; however, over limited spectral ranges, many materials are approximately gray-body radiators. Radiators which approach the characteristics of ideal blackbodies can be made in the form of uniformly heated cavities. A relatively small aperture, through which the cavity can be observed, serves as the source of blackbody radiation.

Infrared radiation is also observed as emitted from excited molecules of gases. Many of the energy transitions which take place in gases excited thermally or electrically result in radiation emission in the infrared region. Gaseous emission differs in character from solid emission in that the former consists of discrete spectrum lines or bands, with significant discontinuities, while the latter shows a continuous distribution of energy throughout the spectrum. The predominant source of molecular radiation in the infrared is the result of vibration of the molecules in characteristic modes. Energy transitions between various states of molecular rotation also produce infrared radiation. Complex molecular gases radiate intricate spectra, which may be analyzed to give information of the nature of the molecules or of the composition of the gas.

The propagation of infrared radiation through various media is, in general, subject to absorption which varies with the wavelength of the radiation. Molecular vibration and rotation in gases, which are related to the emission of radiation, are also responsible for resonance absorption of energy. The gases in the atmosphere, for example, exhibit pronounced absorption throughout the infrared spectrum. The principal gases of the atmosphere, nitrogen and oxygen, do not absorb significantly in the infrared region. However, the lesser constituents, water vapor (H_2O), carbon dioxide (CO_2), and ozone (O_3), are responsible for strong absorption in the infrared. The absorption of radiation is so prevalent that those spectral bands in which relatively little absorption occurs are identified as *atmospheric windows*.

Solid and liquid materials show, as a rule, strong absorption in the infrared. There are, however, many solids which transmit well in broad regions of the infrared spectrum. Many materials, such as water and silica glasses, which show little absorption in the visible, are opaque to infrared radiation at wavelengths greater than a few microns. Many of the electrically insulating crystals, such as the alkali halides and the alkaline-earth halides, which transmit well in the visible, also are transparent to much of the near and intermediate infrared spectrum. Several of the semiconductor materials absorb strongly in the visible, but become transparent in the infrared beyond certain wavelengths characteristic of the semiconductor.

Detection of the presence, distribution and/or quantity of infrared radiation requires techniques which are, in part, unique to this spectral region. The frequency of the radiation is such that essentially optical methods may be used to collect, direct, and filter the radiation. Transmitting optical elements, including lenses and windows, must be made of suitable materials, which may or may not be transparent in the visible spectrum. Table 1 gives characteristics of several transmitting materials suitable foı use in infrared optical systems. To avoid chromatic aberration, reflecting mirrors are commonly used in infrared optical systems to focus and deviate the radiation when broad spectral bands are observed. Filters for the infrared are designed and constructed like those for the visible, except for the choice of materials and, in the case of interference filters, the thickness of the layers.

The detector element for infrared represents the most unique component of the detection system. Photographic techniques can be used for the near infrared out to about 1.3μm. Photoemissive devices, comparable to the visible- and ultraviolet-sensitive photocells, are available with sensitivity also extending to about 1.3μm. The intermediate infrared region is most effectively detected by photoconductors. These elements, photosensitive semiconductors, are essentially photon detectors, which respond in proportion to the number of infrared photons in the spectral region of wavelength shorter than the cut-off wavelength. This cut-off wavelength corresponds to the minimum photon energy necessary to overcome the forbidden gap of the semiconductor. A number of sensitive photoconductors are available with spectral cutoff at various wavelengths in the infrared. Photoconductors are employed as resistive elements, as photovoltaic *p-n* diodes, or as photoelectromagnetic elements, according to the particular electrical advantage to be gained. All spectral regions from ultraviolet through visible, infrared, and microwaves, can be detected by an appropriately designed thermal element, which responds by being heated by the absorption of the incident radiation. In the infrared, thermal detectors take the forms of thermocouples, bolometers, and pneumatic devices. The thermal elements, in general, are not as sensitive or as rapidly responding as photoconductors in spectral regions where they both respond. However, the broad spectral response and uniform energy sensitivity characteristics make them highly useful. Two-dimensional image information is obtained in the infrared by one-dimensional scanning of a linear array of detectors, or by a two-dimensional array of detector elements which are scanned electronically or by electron beam. A "push-broom" scan arrangement of a row of detectors is commonly used for the preparation of infrared maps of the terrain. "Staring" sensors, with a

TABLE 1. INFRARED TRANSMITTING MATERIALS

Material	Useful Transmission Region (μm)	Refractive Index Near Transmission Peak	Special Characteristics
Optical glasses	0.3–2.7	1.48–1.70	Best for near infrared
Fused silica	0.2–3.5–4.5	1.43	Some types show absorption near 2.7μm
Arsenic trisulfide	0.6–12.0	2.4	A glass; subject to striations
Calcium aluminate	0.3–5.5	1.8	A glass; subject to attack by water
Sapphire	0.17–6.0	1.7	Single crystal, hard, refractory
Silicon	1.1–>20	3.4	Low density; opaque to visible
Germanium	1.8–>20	4.0	Opaque to visible
NaCl	0.2–15	1.52	Water soluble
KBr	0.21–27	1.54	Water soluble
LiF	0.11–6	1.35	Low solubility in water
CaF_2	0.13–9	1.41	Insoluble
Thallium bromide-iodide (KRS-5)	0.5–40	2.38	Fairly soft; cold flows
AgCl	0.4–25	2.0	Soft; cold flows
Irtran 1	0.5–9	1.3	Polycrystalline MgF_2

two-dimensional array of detectors, are used for imaging fields-of-view in which the object of interest may appear unpredictably. Imaging sensors may contain built-in amplification in the form of charge-coupled devices or electron beam scan with electron multiplication. Thermal-type response for infrared detection is also obtained by means of pyroelectric materials, such as triglycine sulfate, which change their surface charge with temperature. This type of detector shows wide spectral band response with short time constant at room temperature. Table 2 gives representative characteristics of several commonly used infrared detectors.

The most common application of infrared radiation is, of course, radiant heating. Solid radiators, such as hot tungsten filaments, alloy wires, and silicon carbide rods are employed extensively as sources of infrared to provide surface heating by radiation.

Infrared spectroscopy has become a powerful analytical tool in the chemistry laboratory. Organic molecules, in general, contain interatomic valence bonds which exhibit character-

TABLE 2. INFRARED DETECTORS

istic resonance frequencies which can be identified in the absorption spectrum of the material in gaseous form. Such information can be used to study the structure of complex molecules. It also serves in aiding the identification of the presence of known valence bonds in chemical analysis. Most absorption lines and bonds due to molecular vibrations fall in the frequency range 500 to 5000 cm^{-1} (wavelength range 2 to 20μm). A large quantity of data has been gathered on the detailed absorption spectra of many gaseous materials. The characteristic spectra of many organic molecules are such that identification of the presence of the molecules, as well as the presence of particular radicals within the molecules, can be readily observed. Petroleum chemistry, for example, has been greatly aided by the application of infrared spectroscopy to the identification of many of the complex constituents in petroleum products.

Observation of infrared absorption spectra is carried out by means of an infrared spectrophotometer, in which the transmission of monochromatic radiation by a gaseous sample in a cell is compared with that of a blank cell, while the wavelength of the radiation is scanned through the spectral range of interest. Prism dispersing elements are usually used in the infrared, rather than gratings, because of the difficulty with the latter of separating the several orders in the wide spectral range covered. Far infrared spectroscopy is complicated by the omnipresence of background and scattered radiation of shorter wavelength emitted inside the instrument at room temperature. Special techniques of filtering must be employed to eliminate the effects of the short-wavelength radiation.

Optical-electronic devices of many varieties have been designed to determine the direction of weakly radiating remote objects by means of detection of their infrared emission. Military applications have been found which have been made possible uniquely by this technique. Missiles can be guided to their target by infrared detection of the self-emission of heated segments of the target. Detailed maps of the earth's surface can be made from aircraft at night by observing the varying infrared emission of the ground. Personnel can be detected in total darkness by the infrared radiation they emit as warm objects. Space applications have included remote sensing of terrestrial surface characteristics for weather mapping, pollution detection and agricultural conditions detection from satellites. Nondestructive testing of electronic components, heat-processing plants, and thermal insulation effectiveness are now commonplace applications of infrared radiation detection.

Such devices require the detection of low-level radiation in the intermediate infrared region. Optical lenses or mirrors are used to collect the observed radiation and concentrate it onto the sensitive infrared detector. High-gain, low-noise electronic amplifiers must be provided to increase the weak signal from the detector to a level which can be used to operate controls or displays, as demanded by the application. Optical filtering is applied in order to restrict the observed spectral region to one in which the target is effectively detected, with a minimum of interference from radiation from its background. The wavelength of detection is such that angular resolution capability, as set by diffraction, is much greater with infrared devices than that of radar devices. Detection of targets at great distances through intervening atmosphere is more effective in the infrared than in the visible because of the much lower atmospheric scattering in the infrared.

Detailed discussions of the characteristics, detection and applications of infrared radiation may be found in the references.

INTERFERENCE AND INTERFEROMETRY

Interference is the term used to denote the physical effects of superimposing two or more waves of the same wavelength. *Interferometry* is the technique of measurement using these effects. Interference occurs whenever waves emanating from sources which have a constant phase relationship (i.e., which are coherent) are present at the same place. Depending on the phase difference between the waves, the interference may be constructive, so that the waves reinforce, or it may be destructive, so that the waves cancel each other. It may seem paradoxical that two waves—e.g., sound waves—can combine at one place to produce no effect—e.g., silence. However, the effects are easily observable under the proper conditions and are explicable by elementary theories.

Interference can occur for all wave phenomena. Vibrational waves such as sound or water waves and electromagnetic waves such as radio and light waves all behave similarly. Interference is a consequence of the *principle of superposition*. That principle states that the resultant effect of two or more waves—that is, the atomic displacements in the case of vibrational waves or the electric and magnetic fields in the case of electromagnetic waves—is simply the algebraic sum of the effects that the individual waves would produce alone. Superposition holds as long as the wave amplitudes are within the range of the normal, linear response of the propagating medium. It always holds when electromagnetic waves traverse a vacuum. Coherence of the sources is essential to the observation of interference (see COHERENCE). If the sources of the waves do not have a constant phase relationship, the superposition of the waves, while instantaneously producing a rapidly varying pattern of reinforcement and cancellation, will, on the average, produce no observable interference effects.

A simple illustration of interference is shown in Fig. 1. Concentric circles represent wavefronts moving out, at regular intervals (with wavelength λ), from the two sources S_1 and S_2. The dark areas represent the minima of the wave patterns and the light areas between them represent the maxima. The overlapping patterns show bands of reinforcement alternating with bands of cancellation. If the sources were light sources, a screen placed along the right edge of the figure would display alternating light (L) and dark (D) bands. Note that there is a light band at the center, equidistant from the two sources. Because the path of each wave from its source to that point is the same, there is no phase difference between them and constructive interference results. Away from the center, there is a path difference and hence a phase difference. When that path difference is an integral number of wavelengths, constructive interference results; when the path difference is an odd number of half-wavelengths (e.g., $\lambda/2$, $3\lambda/2$, $5\lambda/2, \ldots$), there is destructive interference.

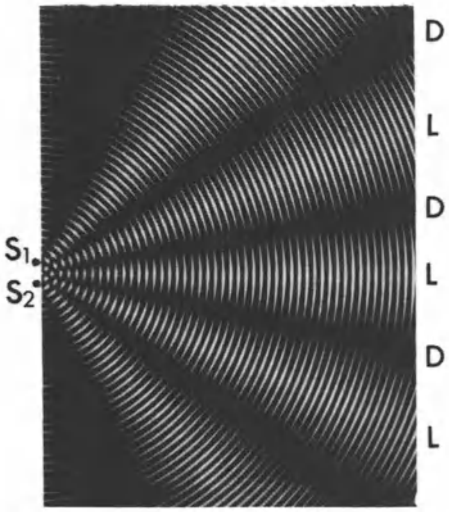

FIG. 1.

Figure 2 is a schematic representation of Thomas Young's classic experiment performed in 1802. His two sources were closely spaced pinholes which were both illuminated by light from a single pinhole (SL). Diffraction at this pinhole ensured that the two sources were coherent. Young placed a screen some distance away and observed a series of alternating bright and dark fringes. The fringes would vanish if either of the sources was covered; they would be replaced by a nearly uniform illumination of the screen. By this experiment, Young provided the first firm experimental evidence for the wave nature of light. The competing corpuscular theory of light, advocated by Isaac Newton a century earlier, still had many adherents. Young was also able to calculate the wavelengths of various colors of light; these were the first such measurements.

Theory A traveling wave can be represented mathematically by

$$M(x, t) = a \cos\left(2\pi\nu t - 2\pi \frac{x}{\lambda} + \alpha\right) \qquad (1)$$

where $M(x, t)$ is the magnitude of the wave at distance x from the source and at time t, a is the amplitude, which is the maximum magnitude, ν is the frequency, λ is the wavelength, and α is the phase. The wave velocity $v = \lambda\nu$. The intensity of the wave, which is the observable quantity, is proportional to the square of the amplitude.

To calculate the effects of interference, one considers the sum of two waves of the same frequency and wavelength. Denoting the two

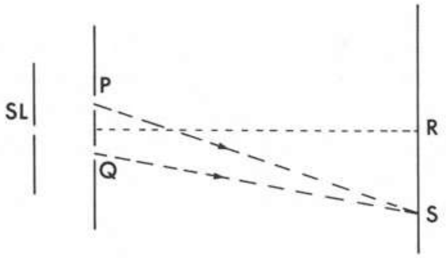

FIG. 2.

waves by subscripts 1 and 2, one obtains a resultant magnitude:

$$\begin{aligned} M &= M_1 + M_2 \\ &= a_1 \cos(2\pi\nu t - 2\pi x_1/\lambda + \alpha_1) \\ &\quad + a_2 \cos(2\pi\nu t - 2\pi x_2/\lambda + \alpha_2). \quad (2) \end{aligned}$$

For simplicity, one considers the case of two sources of equal amplitude ($a_1 = a_2 = a$), which are in phase ($\alpha_1 = \alpha_2$). This situation is exemplified by Young's experiment.

Using the trigonometric relationship for the sum of the cosines of two angles, it is found that the amplitude A of the resultant wave is:

$$A = 2a \cos(\theta/2) \qquad (3)$$

where $\theta = 2\pi(x_1 - x_2)/\lambda$ is the total phase difference between the waves at the point of interference. The quantity $x_1 - x_2$ is the difference in the paths from the sources to that point. The amplitude $A = \pm 2a$ when $\theta = 2m\pi$ ($m = 0, 1, 2, 3, \ldots$), so that $x_1 - x_2 = m\lambda$; $A = 0$ when $\theta = (2m + 1)\pi$, so that $x_1 - x_2 = (m + \frac{1}{2})\lambda$.

Because the intensity is proportional to A^2, the peak intensity is $4a^2$—four times that due to either wave acting alone and twice that due two incoherent sources (which would not interfere). Peaks in intensity occur whenever $A = \pm 2a$; i.e., whenever $x_1 - x_2 = m\lambda$, as stated above.

In Young's experiment (Fig. 2), the path difference $x_1 - x_2 = \mathrm{PS} - \mathrm{QS}$ may be easily calculated. Point S denotes the location of the first ($m = 1$) peak in intensity. Let $\mathrm{PQ} = s$ and $\mathrm{RS} = y$; let D be the distance of the screen from the plane of the slits. Then, using the Pythagorean theorem:

$$\begin{aligned} \mathrm{PS}^2 - \mathrm{QS}^2 &= \left[D^2 + \left(y + \frac{s}{2}\right)^2\right] \\ &\quad - \left[D^2 + \left(y - \frac{s}{2}\right)^2\right] = 2ys \end{aligned}$$

$$\mathrm{PS} - \mathrm{QS} = 2ys/(\mathrm{PS} + \mathrm{QS}).$$

For all cases of practical interest, $y \ll D$, so that $(\mathrm{PS} + \mathrm{QS}) \approx 2D$. At S, $\mathrm{PS} - \mathrm{QS} = x_1 - x_2 = \lambda$, so that

$$\lambda \approx ys/D. \qquad (4)$$

Equation (4) provided Young with the basis for the first experimental determination of the wavelength of light. His results were remarkably accurate, yielding 420–700 nm as the range of visible wavelengths.

Practical problems made Young's experiment difficult to perform. For visible light, $\lambda \approx 500$ nm. If the separation of the sources $s = 1$ mm and the distance to the screen $D = 2$ m, the separation of the fringes $y \approx 1$ mm. Light sources available to Young were weak and slit separations of less than 1 mm were difficult to attain. This resulted in fringes that were weak and indistinct. The experimental results, while historically decisive, were not immediately convincing. However, over the following few years, refinements were made by Fresnel and others. These permitted greatly reduced separation of the sources which, in turn, increased the spacing and observability of the fringes. In addition, Fresnel produced a more complete theoretical formulation of interference.

The logical extension of Young's experiment to more than two slits yields a tremendously useful device, the diffraction grating. A grating consists of a large number of equally spaced rulings. (See DIFFRACTION BY MATTER AND DIFFRACTION GRATINGS.) Analysis of its properties, along the same lines which led to Eq. (4) above, predicts very narrow fringes. These occur in the same places as those produced by two slits whose separation is the same as that of the rulings of the grating. Narrow fringes permit the resolution of closely spaced spectral features. Many spectrometers and spectrophotometers used in the infrared, visible, and ultraviolet spectral ranges incorporate diffraction gratings as their central elements for spectral analysis.

Thin Film Interference An important application of the theory is in the analysis of interference which occurs in thin films of transparent media. The most common example of this is the interference of visible light in soap bubbles and in oil slicks, which produces a range of colors in reflection. These may be explained easily by the use of Eq. (3) and reference to Fig. 3. Here, light from the source reflects from the upper surface of the film at A and from the lower surface at B. The two coherent sources in this case are the two reflected images of the source. For light that is incident nearly perpendicular to the film, the geometrical difference between lengths of the two paths $x_1 - x_2 = 2d$. The optical path difference is $2dn$, where n is the index of refraction of the film (see REFRACTION). One additional complication is the phase reversal (corresponding to a phase shift of π) that occurs whenever light is reflected from a medium whose index of refraction is greater than the index of the medium in which the light is propagating. This is exactly the case at point A in Fig. 3; no such

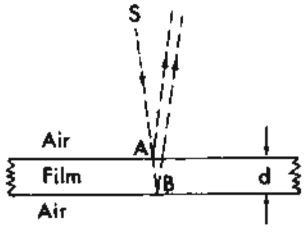

FIG. 3.

reversal occurs at point B since the index of refraction of air ($n = 1$) is less than that of the film. The condition for constructive interference remains a phase difference $\theta = 2m\pi$ [in Eq. (3)]; however, θ is now the sum of two terms:

$$\theta = \pi + 2\pi(2nd/\lambda). \tag{6}$$

The first term is due to the phase reversal at A, the second to the optical path difference $2nd$.

Equation (6) has one surprising prediction: for very thin films, there is no light reflected. If $d/\lambda \ll 1$, $\theta \approx \pi$ so that $A \approx 0$ in Eq. (3). This effect is easily demonstrated by viewing in reflected light a film of soapy water held vertical in a loop of wire. As the fluid drains downward, and the thickness of the film decreases, the film appears to change color. The portion of the film at the top of the loop seems to disappear (no light is reflected from it) once its thickness is reduced to much less than the wavelength of light.

Equations (3) and (6) can be used to predict the apparent color of a thin film. For example, a film of soapy water whose thickness is 300 nm, and whose index of refraction $n = 1.40$ produces a phase difference in reflection of $\theta = \pi + 2\pi$ (840 nm/λ). Setting this equal to $2m\pi$ (for integer m) to obtain the conditions for constructive interference and solving for λ, it is found that only $m = 2$ gives a solution lying within the visible spectrum: $\lambda = 560$ nm. This corresponds to a yellow-green shade; if the film is viewed in reflection, it will appear that color.

Soap bubbles and oil slicks vary in thickness over their surfaces. Depending on the thickness, different spectral regions are enhanced by interference and brilliant bands of various colors are observed. Each continuous band corresponds to a region of constant film thickness.

A very common practical application of thin film interference is the "anti-reflection" coating used on lenses in optical instruments and cameras. The coating is a thin layer of transparent material whose thickness is carefully selected to minimize reflection (and thus maximize transmission) in the visible. The analysis is similar to that which led to Equation (6).

The Fabry-Perot interferometer is another application of thin film interference, one which leads directly to the topic of interferometry. It consists of two parallel plates of glass or quartz (see Fig. 4). Their inner surfaces are optically flat and partially silvered to enhance their reflectivity. Light from the source (S) is collimated by lens L_1 and is focused by lens L_2. The high reflectivity results in a large number of reflected images of the source combining to interfere in the focal plane (F) of lens L_2. As in the case of the diffraction grating, this produces very sharp interference fringes, permitting high resolution measurements. Optical filters based on the Fabry-Perot interferometer are used to produce nearly monochromatic light from polychromatic sources.

Interferometry Interferometers are instruments which utilize the principle of interference to make measurements. As in the case of the Fabry-Perot interferometer, a single wave is split into two or more waves which are recombined after they have traveled paths of different opticai lengths. This introduces a phase difference, so that interference effects will generally be observed. The discussion here will focus mainly on several applications of the most widely used one, the Michelson interferometer.

The Michelson interferometer is shown schematically in Fig. 5. The discussion which follows will be in terms of visible light, but any other wave phenomenon will produce the same effects. Collimated light from source S is incident on the beamsplitter B which reflects half of the intensity to mirror M1 and transmits half to mirror M2. After reflection from the two mirrors, the two beams again encounter the beamsplitter. Half of each beam is now directed toward the observer or detector of O. Because the two beams at O originate at the same source, they will be coherent (as long as the difference in their optical paths does not exceed the coherence length of the light—typically ≈ 10 cm for conventional light sources). Thus they will interfere. Neglecting phase changes that may occur at the beamsplitter, one expects constructive interference if the optical path difference $(x_1 - x_2)$ equals $m\lambda$ and destructive interference if it equals $(m + \frac{1}{2})\lambda$. If the mirrors M1

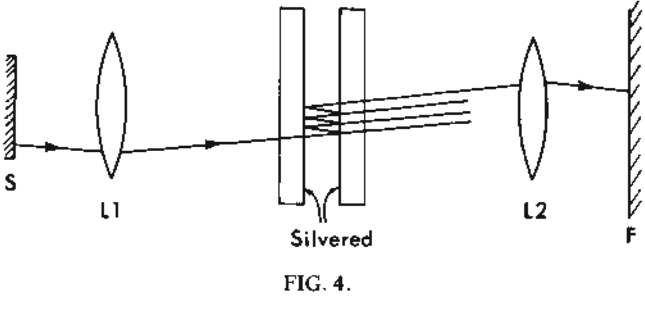

FIG. 4.

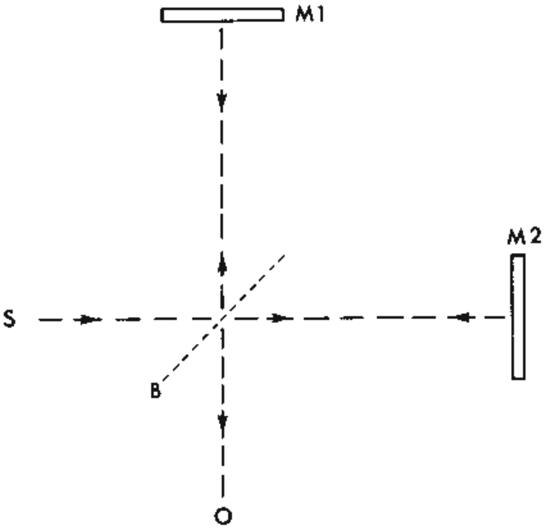

FIG. 5.

and M2 are aligned precisely perpendicular, analysis predicts the observation of a series of circular interference fringes at O. As the path difference is changed, say by moving mirror M1 toward the beamsplitter, the fringe pattern shifts: each time M1 is moved a distance λ/2, the optical path difference changes by λ, and the fringe pattern shifts by one fringe.

Among the applications of the Michelson interferometer that will be discussed here, there are two of historical significance. In 1892, Michelson and Benoit measured the primary standard of length, the International Prototype Meter which is kept in Paris, in units of the wavelength of the red line emitted by cadmium. By carefully counting fringes as one mirror was moved slowly, they determined that the standard meter is equivalent to 1,553,163.5 wavelengths of this line. Ultimately, it was decided by the International Commission of Weights and Measures (1960) to define the meter as exactly 1,650,763.74 wavelengths of the orange-red line of krypton-86. This made the primary standard of length easily accessible to all scientists around the world, obviating the need to travel to Paris for a precise comparison of measured lengths with the standard. This line of krypton was chosen because it is extremely narrow and therefore has a very long coherence length. This permits the use of long optical path differences needed for measurements of objects of appreciable length.

The Michelson-Morley Experiment of 1887 was an ingenious attempt to measure the velocity of the earth in its orbital motion through the "luminiferous ether." Scientists up to that time had postulated the existence of the ether as the medium of propagation for light through the otherwise empty reaches of outer space. If one arm of a Michelson interferometer is oriented along the direction of the earth's motion relative to the (fixed) ether, the other must be perpendicular to it. A calculation of the effective optical paths and transit times for light along the two paths through the ether is straightforward. It predicts a phase difference between the two beams, even if the geometrical path lengths are identically equal. It also predicts that when the interferometer is rotated 90° so that the roles of the two arms are interchanged, there should be a significant shift in the observed fringe pattern.

For the interferometer used in the Michelson-Morley experiment, this shift was predicted to be 0.4 of a fringe; the instrument could resolve a shift of about 0.01 fringe. Repeated measurements at differing times and in differing seasons never showed any shift upon rotation through 90°. This null result pointed to a fatal flaw in the classical theory of relativity. Only Einstein's theory of special relativity (1903), in which there is no ether and in which the speed of light is independent of the relative motion of source and observer, can provide a consistent explanation of the Michelson-Morley null result. (See RELATIVITY.)

Another application of the Michelson interferometer is in the measurement of the indices of refraction of gases. An evacuated cell with windows at each end is placed in one arm of the interferometer so that light passes through the windows. As gas is admitted slowly into the cell, the optical path in that arm is increased according to the laws of refraction. Thus the fringe pattern will shift due to the change in optical path. From the known length of the cell and the number of fringes that are observed to shift, the index of refraction of the gas may easily be found.

In the last 20 years the interferometer, in concert with digital computers, has revolutionized infrared spectroscopy. The light intensity detected at O in Fig. 5, as one mirror is moved steadily, is a sinusoidal function of the mirror displacement. The period of that function is proportional to the wavelength of the light. If the source is not monochromatic, but instead emits a range of wavelengths, the output signal at O is more complicated but is easily shown to be the Fourier transform of the spectral distribution of the source.

High-speed digital computers are capable of performing the transform in real time as the mirror is moved. Compared with conventional grating spectroscopy, the need for a computer is a disadvantage. However, this is heavily outweighed by the number of highly significant advantages in the areas of signal-to-noise ratio and spectral resolution. Such FTIR (Fourier transform infrared) spectrometers have gained rapid acceptance and application in several branches of physics and chemistry, including plasma diagnostics, astronomy, quantitative analysis, and solid state studies.

Two other applications of interference effects

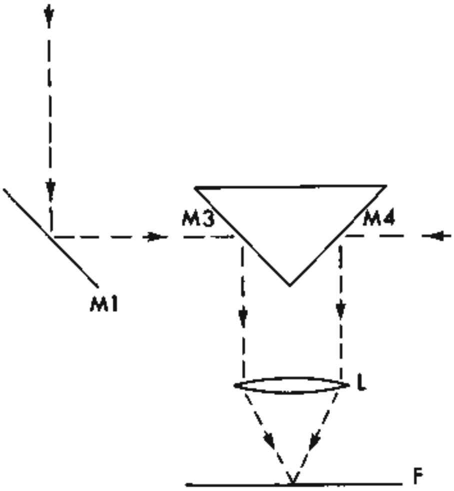

FIG. 6.

will complete this discussion of interferometry. The stellar interferometer constructed by Michelson (1920) can be understood as an example of the principle of Young's experiment. Here the distant star is the single source illuminating the device (see Fig. 6). However, the slits are replaced by two mirrors (M1 and M2), separated by several meters, which reflect the starlight into the objective lens (L) of an astronomical telescope. This produces a pattern of interference fringes in its focal plane (F). By varying the separation of the mirrors, the fringe pattern can be shifted. Analysis of the shifts permits the resolution of closely spaced binary stars or the measurement of the diameters of nearby red giant stars such as Betelgeuse and Antares. By this method, higher resolution than otherwise attainable with the same telescope can be realized.

Recent technological developments have permitted the extension of such stellar interferometry to the radio portion of the electromagnetic spectrum. In an exact analog of Michelson's stellar interferometer, signals from radiotelescopes separated by long distances can be combined to produce interference effects. This is termed very long baseline interferometry (VLBI). A Fourier transform converts the signals, which correspond to the fringes in Michelson's device, into an image of the astronomical object.

Originally, cables carried the signals to a central location for comparison. Subsequent development of highly stable and accurate atomic clocks permitted separations of the individual telescopes by thousands of kilometers. This has resulted in greatly improved performance: VLBI now yields angular resolution of 0.0001 arc-seconds, compared with 0.023 arc-seconds theoretically attainable with the 5 m optical telescope on Mt. Palomar. This is despite the tremendous difference in wavelength: resolution is proportional to λ, and radio wavelengths are typically a factor of 10^4 greater than those of light. The actual resolution of the VLBI system is close to that attainable theoretically because methods of eliminating the image-degrading effects of atmospheric turbulence have also been developed. This is not the case in optical astronomy, where such turbulence degrades the actual resolution of the Palomar instrument to about 1 arc-second. Thus, distant galaxies and quasars are being observed in far greater detail by very long baseline radio wave interferometry than by optical means.

INTERMOLECULAR FORCES

The terms "intermolecular forces" and "van der Waals forces" refer to the weak forces between molecules, and these forces are to be distinguished from the much stronger interatomic, intramolecular forces of chemical binding. The simplest example of an intermolecular force is provided by the interaction between two noble-gas atoms: The atoms are spherical and the force is central in this case.

Short-range Repulsion The volume of matter in the solid and liquid states is an extensive property, i.e., is proportional to the number of moles or molecules in the specimen, and this implies a molecular "size" or the existence of repulsive forces that prevent two molecules from occupying the same space at the same time. The very low compressibilities of solids and liquids indicate a very strong repulsion of two molecules when they begin to overlap each other. These self-evident conceptions were embodied in the nineteenth-century representation of molecules as little billiard balls. The origin of the "overlap forces" of repulsion was not explained until the advent of quantum mechanics and the Pauli exclusion principle. According to the latter, when two noble-gas atoms begin to overlap, the electrons tend to migrate from the crowded region in the middle to the far ends outside the nuclei, where they exert electrostatic forces that tend to pull the nuclei apart. This effect, which greatly exceeds the direct electrostatic repulsion of the partially shielded nuclei, cannot be represented by any simple analytic potential energy function. For reasons of mathematical convenience, however, an inverse-power law, especially r^{-12}, or a simple exponential function e^{-ar}, where r is the distance between the nuclei of the atoms, is often used to represent the potential energy of the overlap repulsion. The first calculation of an overlap repulsion (between H atoms) was made by Heitler and London in 1927.

Long-range Attraction When two noble-gas atoms are so far apart that there is negligible overlap of their charge clouds or wave packets, the atoms, although neutral and nonpolar, interact through a set of electrostatic multipole terms of which the most important is the lowest-order dipole-dipole term. An instantaneous electric dipole moment in one atom, which averages to zero, induces a dipole moment in the other atom which is proportional to the inducing moment and which interacts with it. It is readily seen that the interaction energy varies as r^{-6}, does not average to zero, and corresponds to an attraction between the atoms. Similarly an instantaneous electric quadrupole moment in one atom induces a dipole moment in the other which interacts with it to give an interaction energy, varying as r^{-8}, which is called the dipole-quadrupole term. These long-range multipole interactions, especially the dipole-dipole term, provide the explanation for the intermolecular attractive forces that are evidenced by imperfect-gas behavior, the Joule-Thomson effect, and the very existence of the liquid state. When the dipole-dipole term is calculated quantum-mechanically, the resulting attractive potential energy, varying as r^{-6}, is called the "dispersion potential." It was first treated by Wang (1927) and then by London (1930).

A Priori Calculations It has long been customary to assume that the intermolecular potential between two neutral, nonpolar molecules consists of a long-range dispersion attraction combined with a short-range overlap repulsion. The combined potential-energy curve for two noble-gas atoms then has a minimum at a distance r_m, and the potential vanishes at a distance σ which is referred to as the slow-collision diameter. However, it is questionable to decompose the interaction potential into parts, and in particular, to use the dispersion potential, which is an asymptotic expression, at distances as small as r_m. The coefficient of the dispersion potential for interactions between pairs of rare-gas atoms has been calculated with great accuracy in recent years, starting from the Schrödinger equation and using a small number of optical data. The a priori calculation of the complete potential energy curve, starting from Schrödinger's equation, is an extraordinarily difficult and laborious procedure even for the simplest atoms and even with the aid of modern electronic computers. Only since (1972) has it been possible to achieve sufficient accuracy to obtain the He–He potential in the neighborhood of its minimum.

Nonadditivity Effects When three or more rare-gas atoms are in proximity, the mutual energy of interaction cannot be expressed as the sum of potential energies for all the interacting pairs, except to a first approximation. The deviations from additivity are associated with many-body forces, and in recent years the three-body interaction has received particular attention. The asymptotic form of the nonadditive three-body interaction is called the triple-dipole potential; it arises from an instantaneous moment in one atom which induces moments in two other atoms, the induced moments then interacting to produce a three-body force. The quantum-mechanical calculation gives the result

$$u_{123} = \nu (r_{12} r_{23} r_{13})^{-3} \cdot (1 + 3 \cos \theta_1 \cos \theta_2 \cos \theta_3)$$

for the triple-dipole potential, where r_{ij} are the sides and θ_i the interior angles of the triangular array and ν is a constant which can be calculated for rare-gas combinations. Little is known about three-body interactions in the region of overlap, and higher-order many-body forces have usually been neglected. Three-body forces appear to make a large contribution to the values of the third virial coefficients of the noble gases at temperatures close to the critical point.

Polar Molecules When the molecules possess permanent electric moments, additional electrostatic terms contribute to the intermolecular force. The dipole moments of simple polar molecules, such as LiH, can be calculated with considerable accuracy from the Schrödinger equation and compared with experimental values deduced from the temperature dependence of the dielectric constant. The potential energy of alignment of two polar molecules varies as r^{-6} and is usually smaller than the dispersion energy, but in the important case of H_2O at 20°C the alignment energy is four times as large as the dispersion energy. The nonspherical shape of polar molecules and the noncentral character of the electric force greatly complicate the mathematical analysis for most physical properties. Permanent electric quadrupole moments Q have also been calculated and measured, and their contributions to intermolecular forces through dipole-quadrupole and quadrupole-quadrupole interactions are important in special cases, e.g., for H_2O. Methods of measuring Q include molecular beam radiofrequency resonance, microwave pressure broadening, collision-induced absorption, nuclear magnetic resonance, and second dielectric virial coefficients.

Empirical Potential Functions Enough has been said to indicate that the nature of the intermolecular forces is qualitatively well understood but that accurate quantitative results cannot be obtained from wave mechanics except in a few special cases. The most detailed information about the actual magnitudes of intermolecular forces is obtained by the empirical procedure of (1) choosing an intermolecular force law, with two or more adjustable constants, on the grounds of physical plausibility and mathematical convenience, (2) selecting a macroscopic property that can be accurately measured and accurately calculated from the force law assumed, and (3) using the results of measurements over a wide range of experimental conditions to fix the values of the adjustable parameters in the force law. The most popular of the empirical potential functions has been the Lennard-Jones (12, 6) potential

$$u(r) = 4\epsilon\,[(\sigma/r)^{12} - (\sigma/r)^6], \qquad \epsilon \equiv -u(r_m).$$

Here σ and ϵ are the adjustable parameters. The 6th-power term represents the dispersion forces and the 12th-power term, the repulsive forces. The parameter ϵ is the maximum energy of attraction, and σ is the value of r for which $u(r)$, the potential function, is zero. Although mathematically convenient and still widely used, this pair potential is now known to have serious defects (e.g., its behavior at small r and at large r are both greatly in error) which preclude its use in accurate, realistic investigations. Other simple two-parameter and three-parameter potentials have been proposed but they are insufficiently flexible to be able to account for the results of increasingly accurate measurements of numerous physical properties extended over wide ranges of the experimental variables. As an example of the multiparameter potential functions which have been employed, we mention the so-called Morse-spline-van der Waals function which uses a Morse potential for the short-range interaction, a combination of r^{-6} and r^{-8} for the long-range interaction, and a spline interpolation formula to join the two segments. Even more elaborate functions are in current use, some containing as many as 12 adjustable parameters.

Experimental Methods The types of experimental measurements that can be used to derive information about intermolecular forces include the following: (1) thermodynamic properties of gases, (2) transport properties of gases, (3) equilibrium properties of solids and liquids, (4) molecular beam scattering cross sections, and (5) spectroscopic and x-ray diffraction data. Although much used in the past, the calculation of lattice energies, lattice distances, compressibilities, and elastic constants of solids from assumed pair potentials cannot be regarded as an accurate method of determining intermolecular pair potentials because of uncertainty with regard to the contributions from many-body interactions, i.e., from nonadditivity effects. The use of the radial distribution function $g(r)$ of a liquid, determined from x-ray and neutron diffraction experiments, in conjunction with the vapor pressure near the triple point, provides information about the pair potential, and one may also use $g(r)$ in combination with the isotopic separation factor in liquid-vapor equilibrium to test the repulsive region of the potential. The x-ray diffraction results for dense gases and liquids can be analyzed in terms of theories of dense fluids (e.g., Percus-Yevick) to deduce a numerical intermolecular potential. All of these liquid-state methods are subject to uncertainties with respect to nonadditivity effects.

Although the latter may be small, it is safer to deduce the pair potentials from phenomena that involve only binary interactions. In this category are the second virial coefficients $B(T)$, the viscosity coefficients $\eta(T)$, and other gas transport properties. The values of $B(T)$ extending from high to low temperatures do not provide a sensitive test for assumed forms of the pair potential; even the square-well and (12, 6) potentials give a good representation of $B(T)$ data. It is also possible to fit viscosity data over a wide temperature range with simple potential functions; former disagreements at high temperatures have recently been shown to have resulted from experimental errors. However, the parameters of the simple potentials that give the best fit to $B(T)$ measurements differ from those needed to fit the viscosity data. Other transport properties which provide useful information about the pair potential are the isotopic thermal-diffusion coefficient, the isotopic mutual-diffusion coefficient, and the thermal conductivity (of monatomic gases) for like-molecule interactions and the mutual-diffusion coefficient for unlike-molecule interactions.

The most direct method of investigating the force between two molecules is to measure the elastic-scattering differential and total cross sections at different energies. Molecular beams formed from neutralized accelerated ions may be used with stationary gas targets to determine the repulsive wall of the potential at high energies. In order to investigate the region of the potential near its minimum, it is necessary to employ energies close to thermal, and the motion of the target molecules then precludes the use of a single beam. Two molecular beams passing through velocity selectors and intersecting at right angles have been used but much greater intensity is available from crossing two supersonic nozzle beams. Differential elastic-scattering cross sections measured by the latter method, showing well-resolved rainbow structure and symmetry oscillations, have recently provided accurate potential functions for pairs of rare-gas atoms (Lee et al., 1972).

Molecular spectroscopy furnishes a precision tool for investigating the potential energy curves for different electronic states of diatomic molecules, but these interatomic potentials refer to intramolecular rather than intermolecular interactions and will not be further discussed. The pressure broadening of spectral lines and the phenomenon of collision-induced absorption, measured in the microwave and infrared regions of the spectrum, provide additional methods for studying intermolecular forces. These methods are not accurate but they have yielded useful information about molecular quadrupole moments. A recent and important spectroscopic method of determining the intermolecular potential near its minimum, which has been applied to Ar and Ne, is to measure the ultraviolet absorption bands that correspond to electronic transitions out of the ground state of the dimer (Ar_2 and Ne_2). The spectroscopic constants derived from the vibrational levels of the ground state provide accurate information about the bowl of the potential curve including the well depth (ϵ), the curvature at the minimum, and the anharmonicity (Tanaka and Yoshino, 1970, 1972). The best-known intermolecular potential, for the interaction between two Ar atoms, currently has an accuracy of about ±4 per cent in the well depth.

INTERNATIONAL SOLAR-TERRESTRIAL PHYSICS PROGRAMS

It has been recognized for some time that the sun, ultimate source of practically all the energy utilized on earth (the only current exception being the relatively small amount of power produced by nuclear fuels), influences many earthly phenomena. Aside from the obvious solar control of the weather through visible and invisible light—electromagnetic radiation—continuously emitted by the sun, other less well-understood effects occur. For example, the so-called *earth storm* (not to be confused with a weather disturbance in the troposphere near the ground) results from the arrival not only of radiation but also of matter—streams of electrically charged particles—spewed out by the sun following violent eruptions or flares in the chromosphere, just above the sun's visible surface (photosphere).

A multitude of geophysical effects arise from the interactions of these radiation and particle fluxes with the upper reaches of the earth's atmosphere, manifesting themselves as phennomena such as magnetic storms, radio disburbances, and auroral displays. The frequency of occurrence of these transitory happenings in the upper atmosphere waxes and wanes as the level of solar activity changes during the well-known sunspot cycle (approximately 11 years).

The phenomena that occur in the earth's upper atmosphere (i.e., the entire region above the troposphere) obviously recognize no international boundaries. Thus, it was natural that the earliest international scientific programs were organized by geophysicists. In 1625, Francis Bacon emphasized the need for "experiments in concert." One early effort, organized by Friedrich von Humboldt in early 19th Century, investigated the earth's magnetism by means of many simultaneous observations at widely different locations. Karl Friedrich Gauss subsequently founded the Göttingen Magnetic

Union in 1834 for studies of geomagnetic variations by a network of 44 magnetic observatories dispersed around the world.

IPY 1 The First International Polar Year (IPY) in 1882-83 was the original direct progenitor of the current mode of conducting international cooperative scientific enterprises on a global scale. Its program, confined to the Arctic and the approaches to the Antarctic, was limited to meteorological, geomagnetic, and auroral observations at 14 stations established by 11 participating countries. The most commonly cited result was the discovery of the oval-shaped auroral zone—a band with geomagnetic latitude roughly 65-70° where this phenomenon is most prevalent.

IPY 2 The first IPY was followed 50 years later by the Second International Polar Year in 1932-33, with 44 participating nations. Planned and coordinated by the International Meteorological Organization, the second IPY program included stations not only in the polar regions, but at lower latitudes as well, and investigated for the first time the role played by polar phenomena in the concert of worldwide effects. To the three types of observation conducted during the First International Polar Year was added a fourth one, the new field of ionospheric research which had been opened up by the development of radio during the intervening period.

IGY The International Geophysical Year (IGY) in 1957-58 was originally conceived as a third Polar Year, but it was generally agreed during the early planning phases that the terms of reference should be extended beyond a study of polar influence to include the whole earth and its far-reaching atmosphere. IGY was a huge success, and its impact upon the development of many fields of science was tremendous and permanent. It was truly distinctive in that it initiated the first extensive program of *in situ* investigations of the earth's tenuous envelope utilizing the rapidly developing new technology for transporting scientific instruments into space. Furthermore, it opened up Antarctica as a scientific treasure trove.

Responsibility for some part of the IGY program was shared among 67 nations operating 4,000 primary stations and an equal number of secondary posts. It is estimated that approximately 30,000 scientists, plus another 30,000 volunteer observers, participated. Although there is, of course, no satisfactory index of the productivity of a scientific enterprise, it is noteworthy that more than 3,000 articles on IGY results were published in scientific journals by United States workers alone. The vast wealth of data was deposited at the several World Data Centers which were established during IGY and which still continue to be utilized extensively.

Since the broad objective of IGY was to study every aspect of the earth as a planet, from the properties of the terrestrial interior to what we now know as an exceedingly complex region surrounding it, its program embraced many, sometimes overlapping, scientific disciplines. Thus, in addition to investigating the properties of the earth's interior (seismology, latitude and longitude, and gravimetry) and studying its surface characteristics (oceanography and glaciology), the program embraced observations in and beyond the earth's atmosphere, including investigations of sun-earth relationships (meterology, nuclear radiations, geomagnetism, ionosphere, aurora and airglow, cosmic rays, and solar activity). An additional discipline, rockets and satellites, was defined in terms of technique rather than scientific subject matter. As a consequence, the Space Age was spawned. And, to increase basic knowledge about the solar influences acting upon the earth, IGY was planned to cover a period at or near solar maximum. (See also GEOPHYSICS and SOLAR PHYSICS.)

As hoped, IGY did take place at a peak of sunspot activity. Propitiously, it was not only the maximum for that particular eleven-year cycle—but the level of solar activity in 1957-58 has probably not been matched at least since Galileo first observed sunspots in the early 17th Century.

IQSY The International Years of the Quiet Sun (IQSY) in 1965-66 was to be the sequel of IGY aimed at catching the myriad interrelated changing phenomena of sun, space, and earth at the sun's nadir of activity. But the later enterprise was not a small-scale repetition if its illustrious predecessor. On the contrary, in the fields that it embraced, the level of effort far exceeded that which it had been possible to attain only seven years earlier.

However, in a real sense, IGY had set the stage for IQSY. A new scientific discipline, *solar-terrestrial physics* (STP)—alternatively called *solar-terrestrial relationships* or *solar-terrestrial research* (STR)—was emerging to embrace all processes whereby diverse forms of energy generated by the sun influence the terrestrial environment, with the resulting complex interplay of physical-chemical processes in every element of the sun-earth system.

The purpose of IQSY was threefold. Some of the studies that were conducted were feasible, or are best undertaken, ony at a time of solar minimum. Others were concerned with observing in detail isolated solar events, uncomplicated by the superposition in time of a number of concurrent outbursts. Finally, some investigations provided data characteristic of solar minimum conditions as benchmarks for comparison with data observed previously during a most remarkable solar maximum.

Actually, at sunspot minimum solar outbursts do not cease completely, but when they do occur their effects can be observed under relatively "clean" conditions, free from confusing interferences. Hence, the entire sequence of events associated with a single outburst can be followed through all of its aspects. Furthermore, smaller effects, previously lost in the high-level background of activity, become discernible. Thus, many IQSY projects took advantage of this period to make observations with greatly increased resolution or "amplification."

The IQSY program was organized into eight disciplines, although in most cases there were overlapping interests, and no sharp boundary lines were drawn. These were: meteorology (see METEOROLGY), geomagnetism (see GEOPHYSICS), aurora (see AURORA AND AIRGLOW), airglow (see AURORA AND AIRGLOW), ionospheric physics and radio astronomy (see IONOSPHERE AND RADIO ASTRONOMY), the sun and the interplanetary medium (see SOLAR PHYSICS AND SPACE PHYSICS), cosmic rays and geomagnetically trapped radiation (see COSMIC RAYS AND MAGNETOSPHERIC RADIATION BELTS), and aeronomy (see PLANETARY ATMOSPHERES).

The sponsorship and supervision of the 65 worldwide networks of more than 2,000 IQSY stations were the responsibility of 71 participating committees, as they were called, established by the Academy of Science or an equivalent body in each country. Innumerable balloons, some 500 rockets, and about 140 satellites and space probes were launched during the two-year campaign. The IQSY bibliography lists 5,359 publications, which themselves formed the basis for an untold number of subsequent papers in the scientific literature.

IQSY was the final broadly based international scientific undertaking. It became evident that future cooperative ventures should be somewhat more sharply focused, and the mechanism for accomplishing this was the establishment of several permanent international committees arising from the temporary single purpose, national and international groups that had been formed specifically to organize IGY and IQSY. Each of the latter were dissolved after their missions, including the publication of their respective annals, had been completed.

IUCSTP The modus operandi of IQSY has continued to be employed for mounting imaginative interdisciplinary and international research projects. Thus, when in 1966 the IQSY program was drawing to an orderly conclusion and its international organization was closing down, a new and continuing body, the Inter-Union Commission on Solar-Terrestrial Physics (IUCSTP) was established by the International Council of Scientific Unions (ICSU) to plan and coordinate future programs in solar-terrestrial physics.

ISCU, from among the several interested unions among its membership, had established the bodies that were responsible for the international coordination of IGY and IQSY. IUCSTP was established on a permanent basis to plan and organize the international coordination of international projects of those research workers throughout the world who are interested in solar-terrestrial physics, and who wish to concentrate attention on some of the more important problems that still awaited solution. Several representative recent programs will be cited here.

MIDDLE ATMOSPHERE PROGRAM (MAP) The Middle Atmosphere Program (MAP) is an international cooperative enterprise developed under the auspices of the Scientific Committee on Solar-Terrestrial Physics of the International Council of Scientific Unions and the World Meteorological Organization. Scheduled to run from January 1982 through December 1985, its chief objective is a comprehensive understanding of the structure, chemistry, energetics, and dynamics of the middle atmosphere (defined for MAP purposes as the region extending upward from the tropopause, including the stratosphere and mesosphere, to the lower thermosphere, i.e., from about 10 to 100 km). Contemplated studies include ozone climatology; stratospheric composition; mesospheric composition; basic climatology of the middle atmosphere; planetary waves in the middle atmosphere; equatorial waves; tides, gravity waves, and turbulence; troposphere-stratosphere coupling; the influence of middle-atmospheric conditions on lower-level climate; aerosol formation and properties; solar radiation, especially in the ultraviolet; the effects of energetic particles and x-rays on the middle atmosphere; ion composition; and the electrodynamics of the middle atmosphere. These fourteen areas have been tagged observational or experimantal MAP initiatives (MIs). The operational basis for MAP is an international plan for coordinated observations from spacecraft, rockets, balloons, aircraft, and ground-based facilities. This plan encourages cooperative data management, information exchanges on all appropriate time scales, and interaction between observers, modelers, and theoreticians.

THE INTERNATIONAL MAGNETOSPHERIC STUDY (IMS) The International Magnetospheric Study (IMS) is a highly coordinated, cooperative program designed to provide quantitative new information about certain key problems involving plasmas in the geomagnetic field. The IMS formally began in January 1976, and the primary data-collection period ran through 1979. A five-year follow-up program for data reduction and analysis was subsequently recommended by the IMS Steering Committee, and is in progress.

About 50 countries are participating in the IMS, and the four primary IMS spacecraft (ISEE-1, -2, -3 and GEOS-2) were successfully launched by the United States (NASA) and the European Space Agency (ESA). Japan and the Soviet Union also provided new spacecraft for the program. The key ingredients of the IMS were these dedicated new spacecraft and several sophisticated new ground-based instrument arrays, which greatly advanced international data-exchange standards by using simultaneous data collection, processing, and dissemination in near real time from central data facilities. Incoherent-scatter radars were operated at high latitudes, and a variety of ground-based, balloon, rocket, and aircraft experiments were conducted. While the IMS required a sizable number of specific new facilities, it also benefited greatly from the effective use of previously planned programs and from continued operation of certain older satellites and ground networks. The IMS Central Information Exchange (IMS CIE) Office was established in the World Data Center-A in Boulder, Colorado, and regional offices were set up in Paris, Moscow, and Tokyo; a monthly Newsletter transmitted schedules, plans for spacecraft and ground-based measurements, and general IMS news to several thousand scientists. NASA also established the Satellite Situation Center, which disseminated detailed trajectory data for all IMS spacecraft.

SOLAR MAXIMUM YEAR (SMY) During the next period of maximum solar activity following IQSY, programs were conducted in which several score observatories coordinated their observations with each other, and with spacecraft in particular. The NASA Solar Maximum Mission (SMM), carrying a new state-of-the-art set of instruments, ran from August 1979 through February 1981. Observing schedules were arranged by the SMY Steering Committee with special observational intervals being scheduled for the three activities subsumed under the SMY, namely the Flare Build-up Study (FBS), with emphasis on distinguishing the characteristics of localized solar active regions that subsequently produce flares from those that do not; Study of Energy Release in Flares (SERF), with emphasis on the flare process itself; and Study of Traveling Interplanetary Phenomena (STIP), with emphasis on the aftereffects of flares and other active phenomena. Coordination was effected by telex from several SMY control centers. Following the pattern of previous programs, the participants in the SMY engaged in a number of workshops to coordinate both their detailed planning and the analysis of their data sets.

CSTR In the United States, the Committee on Solar-Terrestrial Research (CSTR), formed in 1965 by the National Research Council's Geophysics Research Board, "looks after the health of this field" in our country, and represents the nation in International STR programs.

IONIZATION

Ionization is the name given to any process by which a net electrical charge may be imparted to an atom or group of atoms. In the case of liquid solvents, molecules or ionic salts become dissociated to form positive and negative ions. This ionization process is known as *electrolysis*, and the name *electrolyte* is given to the solute or to the conducting solution. The study of electrolysis is embodied in the subject of *electrochemistry*. Of great interest in recent years has been the study of ionized gases. Rockets, hypersonic flight, and space physics have spurred investigations of plasmas, shock waves and high-temperature chemical processes arising in a variety of terrestrial and celestial phenomena. Indeed, ionized gases make up a major portion of all matter in the universe. Our chronic need for new energy sources has transformed the speculation of a controlled thermonuclear fusion reaction into one of the greatest research efforts in history. These and other considerations have induced a vigorous growth in the study of ionization phenomena.

Electrolytes The degree of ionization found in electrolytes is highly variable and depends upon the solute, the solvent, and the interaction between them. *Weak* electrolytes, such as many organic compounds, are solutes which are barely dissociated into ions except in the limit of infinite dilution. *Strong* electrolytes are highly dissociated at any concentration. Ions formed in solution may bear one or several electronic charges. The *electrochemical equivalent weight* is the atomic weight divided by the number of charges carried by the ion. If electrodes are placed in an electrolyte and a current flows in the external circuit, the ions with positive charges, called *cations* (cathode + ions), will migrate toward the negative electrode (cathode).

Those ions possessing a negative charge (*anions*) will migrate to the positive electrode (anode). The ions arriving at the cathode are neutralized by the acquisition of electrons; the atoms or molecules thus formed may then be evolved as a gas or retained as a deposit on the electrode. The cations are said to undergo *reduction*. Likewise, the anions experience a loss of electrons at the anode; this process is called *oxidation*. The quantity of electricity required to deposit one gram equivalent is called the faraday, in honor of Michael Faraday (1791–1867). Based on the physical scale of atomic weights, the faraday is numerically equal to 96 520 coulombs per equivalent.

As for any solid conductor of uniform cross sectional area A and length l, the electrical resistance R of an electrolyte is given by $l/\kappa A$. The conductivity κ is independent of geometrical shape and size, and bears the units (ohm cm)$^{-1}$. Of greater importance in the study of electrolytes is the *equivalent conductivity*:

$$\Lambda = \kappa/C$$

where C is the concentration of the solute in equivalents per cubic centimeter. Plots of Λ as a function of concentration show very different behavior for weak and strong electrolytes. The latter exhibit a limiting value of Λ as C diminishes to zero, while the weak electrolytes do not. Such behavior provides insight into the nature of the ions, their mobilities and their interactions with the solvent material.

Formation of Gaseous Ions Studies in 1895 by J. J. Thomson of the effects of newly discovered x-rays on gases marked the beginning of a series of experiments which established the existence of the electron and clarified many questions on the nature of atomic structure.

Just as in electrolytes, both positive and negative ions may exist in an ionized gas. In addition to the ions, the presence of free electrons may profoundly influence the character of the gas. Negative ions may be formed by the attachment of free electrons to a neutral atom or molecule, by the dissociation of a neutral molecule into positive and negative fragments, or by electron transfer upon collision of two neutral atoms or molecules. Positive ions may be formed by dissociation, charge transfer, neutral-particle or electron collisions, or by photoabsorption (the absorption of electromagnetic radiation). Still another mechanism for the formation of ions is the emission of a nuclear particle, such as beta decay. Several of these processes are discussed below.

Photoionization Photoabsorption leading to excitation and ionization is of interest because of its significance in astrophysics and geophysics. The ionosphere is constituted of molecular and atomic ions which result from the absorption of solar ultraviolet and x-radiation. The frequency ν of the electromagnetic radiation giving rise to ionization must satisfy the relation $h\nu \geqslant V$, where h is Planck's constant and V is the *ionization potential*. The latter is defined as the energy required to remove completely an electron from an atom or molecule in the ground state, leaving the resulting ion in its lowest state. Photons having energy less than V may be absorbed by atoms or molecules, giving rise to excitation of internal states or perhaps molecular dissociation, or both.

Many laboratory investigations of photoabsorption have been performed. One type of experiment requires the measurement of the absorption coefficient, α, of a photon beam:

$$I = I_0 e^{-ax}$$

in which I_0 is the initial intensity of the beam and I is the intensity after the beam has traversed a distance x in the absorbing gas. The absorption coefficient may then be studied as a function of photon energy (i.e., wavelength). It can be expressed in terms of a microscopic cross section for absorption or for ionization as a function of incident wavelength. This cross section curve for photoionization usually exhibits a sharp peak at the ionization threshold. Only a single, outermost electron is ejected from an atom which absorbs an ultraviolet photon. An x-ray photon generally will eject a more tightly bound electron from one of the atom's inner shells.

Other types of experiments utilize photoionization to study the deionization process for the ions thus formed. Of major importance are such processes as electron-ion recombination:

$$A^+ + e^- \rightarrow A$$

and ion-ion recombination if both charged species are ions.

Ionization by Heavy-particle Collisions By heavy particles is meant both atoms and molecules and their ions, ranging in mass from the hydrogen atomic ion (proton) to very heavy molecular systems of large atomic number. When two heavy particles collide with sufficient energy, one or more electrons may be ejected from either or both particles. In experimental work, the *target* molecules or atoms are in the form of a low-density gas having an energy corresponding to room temperature and usually negligible compared to the energy of the projectile particles. The latter are usually obtained through ionization of a selected gas in an ion source, and acceleration through a large electric potential difference E. Regardless of the mass of projectile particles, their kinetic energy will be equal numerically to E electron volts, if the potential difference E is in volts and if the particles carry but one elementary charge. One electron volt (eV) is equal to 1.6×10^{-12} erg.

If a beam thus formed with an intensity of B particles per second is incident on a target chamber of area A containing N target particles as a low-density gas, the electron ionization current i which is released is given by

$$i = BN\sigma_{-}/A \text{ electrons/ sec.}$$

This equation defines the effective ionization cross section σ_{-}. For energies at which multiple ionization is improbable, σ_{-} approaches the cross section for singly charged ions. Often the distinction is made between ionization of the target particle and the beam particle. Ionization of the latter is referred to as stripping.

In the quantitative description of heavy-particle collisions, one usually introduces the concepts of the (a) laboratory and (b) center-of-mass (CM) coordinate systems. The laboratory system is used to describe the motion of the particles as would be viewed by an observer standing at rest in the laboratory. The origin of the CM system moves with the center-of-mass of the two-particle system. If m and M are the masses of the projectile and target particles, the former moving with a velocity v much greater than the target velocity, the center-of-mass velocity V_c is

$$V_c = mv/(m + M) = \mu v/M$$

The latter relation defines μ, the reduced mass. The kinetic energy in the CM system is $\frac{1}{2}\mu v^2$, which is the projectile energy multiplied by $M/(M + m)$. For the case in which target and projectile are identical, the kinetic energy in the CM system is half that of the projectile. Using the law of conservation of linear momentum, one may show that the kinetic energy in the CM system is the maximum energy available for excitation and/or ionization.

Collisions in general are classified as (a) elastic in which no changes in internal states occur, and for which kinetic energy is conserved, and (b) inelastic, in which a part of the kinetic energy is converted to internal energy. A *superelastic* collision is one in which internal energy is transformed into kinetic energy. Because of the extreme complexity encountered in quantum-theoretical calculations of ionization cross sections for heavy-particle collisions, very little progress has been made in this important area of collision theory.

Ion-neutral collisions may give rise to free electrons, or simply *charge exchange* which, in its simplest form, is expressed by the equation.

$$A^+ + B \rightarrow A + B^+ + \Delta E$$

The neutral particle B has been ionized, but the electron has transferred to the incident ion, neutralizing it. The energy ΔE released in this process is the difference between the ionization potentials of the neutral particles A and B. For the case in which A and B are identical, $\Delta E = 0$ and the process is called *symmetric resonant* charge transfer. At low ion beam energies, this transfer proceeds with a large cross section.

Ionization by Electron Impact Of great importance in atomic physics is the ionization produced by collimated beams of electrons incident on heavy particles. Whether the target particles are atoms or molecules, the ionization is usually by the removal of single electrons from the outer most shell, as in photoionization. As a function of the incident electron energy, the ionization cross section rises rapidly from zero for energies just below the ionization potential and increases to a maximum value in the neighborhood of 50 to 100 eV; thereafter it decreases slowly and monotonically with increasing electron energy. Since an electron with a given energy travels at much higher speed than does a heavy projectile of the same energy, the electron collision induces a much more rapid perturbation on the target's orbital electrons. Thus, a larger ionization cross section at low energies is to be anticipated.

Much of the definitive work on electron impact ionization was performed in the 1930's by Tate, Smith, and Bleakney (cf. reference 4).

Collective Processes If, as in a glow discharge, a large number of charged particles are created, the collective interactions of these particles with each other and with external fields may permit the charged fluid to exhibit very unusual and distinct properties. An ionized gas possessing both positive and negative charges is called a *plasma* if the distance over which the gas can have an appreciable departure from charge neutrality is small compared to the dimensions of the gas. This distance is described by the *Debye-Hückel radius*, a quantity borrowed from the theory of strong electrolytes, which characterizes the decay of the shielded Coulomb potential surrounding the ionized particles of the fluid. If the charge neutrality in a plasma is disturbed in some manner, the electrons will be forced to oscillate about their equilibrium positions in simple harmonic motion with a frequency characterized by the electron density. Longitudinal oscillation of the ions and electrons as a whole constitutes another type of motion called *ion-acoustical* waves. *Hydro-magnetic* waves, which appear in the presence of a magnetic field are still another form of motion not observed in a nonionized medium. The description of such phenomena goes beyond the scope of the ionization process.

IONOSPHERE

The ionosphere is the region of the upper atmosphere in which the density of thermal electrons and ions is large enough to affect the propagation of radio waves. The ionosphere is produced by the effects of ionizing radiation from the sun, and high energy particles impinging on the neutral upper atmosphere. This produces photoelectrons and ions. These then interact with the neutral atmosphere and the resultant densities are controlled by the production and loss processes as well as horizontal and vertical transport. Ionospheres are thus a general feature of planetary atmospheres.

The ionosphere of the earth was divided up into vertical regions based on radio soundings which are sensitive to the gradient in the electron density; these regions also correspond to regions of different ion chemistry. Typical values of the densities in the earth's ionosphere are shown in Fig. 1.

The lowest region of the ionosphere was called the *D* layer to allow for up to three lower layers had they been discovered later. Ionization due to galactic cosmic rays does penetrate to the ground, and below the *D* region the conductivity decreases steadily. This ionization in the region of 30–50 km is detectable in in-situ observations and is often referred to as the *C* layer. In the lower *D* region between 50 and 80 km, although N_2^+ and O_2^+ are the major ions produced, the predominant positive ions are those of water clusters, $H_3O^+ \cdot [H_2O]_n$. During the day the negative charge is mainly carried by electrons, but at night negative ions become important. This is the only region of the ionosphere in which negative ions are numerically important.

In the upper *D* region the positive ions are mainly NO^+ and O_2^+, as they are in the *E* and F_1 regions above. The *D* region has very different behaviors during times when the sun is very active and when it is quiet. The reason for this was discovered by Nicolet and Aikin (1960) to be that when the sun is active the X-ray emission is enhanced by orders of magnitude and is the dominant production source. Under quiet conditions the Lymann alpha line of the sun's radiation, which varies little with solar activity, dominates. This line, which is of too low an energy to ionize any of the major constituents above these altitudes, penetrates to the *D* region and ionizes a very minor neutral constituent, nitric oxide.

The boundary between the *E* region and the *D* region is normally taken to be at around 90 km, or the lower boundary of penetration of ultraviolet radiation sufficiently energetic to ionize molecular oxygen. The production and loss processes in the *E* and F_1 regions are essentially identical in the region up to 120–140 km, though there is a continuous change in the portions of the extreme-ultraviolet (EUV) spectrum producing the ionization. X-rays between 30 and 100 Å, in particular, ionize N_2 and O_2 in the *E* region.

An important feature of the ionosphere in the region of 100 km is the formation, on occasion, of extremely thin layers of ionization known as "sporadic *E*." Direct sampling has shown the ions in these regions to be similar to the composition of the chondritic meteors. It is believed that these meteoritic ions are produced by charge exchange with ambient ions and are compressed into thin layers by the interaction of wind shears with the Earth's magnetic field. It is this type of sporadic *E* that is occasionaly responsible for long-distance television reception.

The F_2 layer, which is generally regarded as beginning at about 140–150 km, is responsible for by far the largest portion of the total ionization. In the lower regions the molecular ions NO^+ and O_2^+ predominate, but in the region of the peak and above O^+ becomes more important. In this region of the neutral atmosphere atomic oxygen is the major constituent and O^+ is the major ion produced. The most important loss process for this ion is charge exchange with O_2 and N_2, and this proceeds much faster at lower altitudes where the molecular densities are larger. Vertical transport is extremely important, with most ions being produced above the peak and recombining below the peak. The effect of neutral winds and electric fields on this transport is large and consequently the layer displays a very complex morphology with large variations in geographic and magnetic coordinates as well as altitude, time, and season. Other large fluctuations occur whose cause is not at present well understood. As shown in Fig. 1 there are large systematic changes in the *F* region between sunspot maximum and minimum following the solar cycle. These are due to the large variations in the neutral thermospheric densities as well as to the changes in the EUV ionizing radiation.

Above the region where O^+ predominates is the protonosphere. At the lower boundary the protons undergo charge exchange reactions with neutral atomic oxygen and neutral hydrogen charge exchanges with atomic oxygen ions. This results in a generally downward flux of protons when the *F* layer is decreasing and an upward flux when it is increasing. Because the atomic oxygen ions are much heavier than the electrons the equilibrium profile of the densities in which the fluxes produced by diffusion would be balanced by gravity are very different.

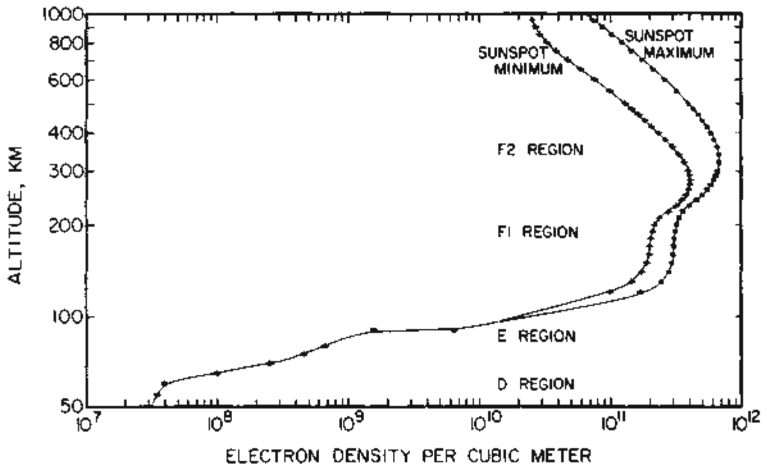

FIG. 1. Electron density at mid-latitudes at noon for high and low solar activity.

A vertical electric field is set up which keeps the two distributions the same. This electric field has a large effect on the protons in the region where O^+ predominates. In particular at high latitudes where the magnetic field lines are open to the solar wind, the protons are accelerated outward, leading to the escape of hydrogen. This is balanced by a poleward wind in the protonosphere.

The ionosphere of Mars and Venus, despite their lower atmospheres which are quite different from that of the earth, also have an O^+ "F_2 region" and an O_2^+ "F_1 region." The major difference is that, unlike the earth, the absence of a strong planetary magnetic field allows the solar wind to interact directly with the ionosphere, producing an extremely turbulent and variable upper boundary.

The thermal state of the ionosphere is quite interesting because the electrons, ions, and neutral particles all have different temperatures above about 200 km in the earth's ionosphere due to small collision frequencies between species, the very different energy inputs, and the importance of vertical transport. That part of the excess energy given to the photoelectrons produced in the ionization process which is not lost in inelastic collisions with the neutral gas is transmitted preferentially to the ambient electrons, which in turn heat the ambient ions. As a result, above about 200 km, in the daytime or when photoelectrons are entering the upper ionosphere from the conjugate hemisphere, the electrons are hotter than the ions, and the ions are hotter than the neutrals. Because of the comparative ease with which the electron and ion temperatures and densities can be measured remotely by radio waves these inputs provide a very valuable tool in studying the energy balance of both the ionosphere and the neutral atmosphere.

Many of the ions in the ionosphere are produced in excited states, or are excited by collisions with higher energy particles. Some of this excess energy is radiated and results in aurora and the airglow radiations in the infrared, the visible, and the ultraviolet (see AURORA and AIRGLOW). The major source of visible illumination, for example, on a moonless night is from the 630 nm radiation from atomic oxygen in the *F* region of the ionosphere.

Electrical currents flowing in the ionosphere cause perturbations in the earth's magnetic field that can be measured at the ground. There are two main current systems. The "dynamo system" is produced by *E* region winds blowing the ions and electrons across the earth's magnetic field. The "solar wind" of plasma flowing outward from the sun produces a voltage across the polar caps resulting in field-aligned Birkeland currents entering the ionosphere at high latitudes. The resulting ionospheric currents are enhanced and can penetrate to low latitudes during disturbed times.

The ionosphere is important for ground-to-ground propagation because it can refract or reflect radio waves and thus makes communication beyond the horizon possible. For satellite-to-ground communication the combined effects of refraction and electron density irregularities produce scintillations. These can be a problem especially if the ray path crosses the equatorial region. For satellite navigation systems refractive errors have to be compensated for. Radio astronomy from the ground is limited to frequencies below the critical frequency of the *F* region.

IRRADIANCE (ILLUMINANCE) CALCULATION

Introduction In geometrical optics the paraxial lens equation is applied at each surface to rough out a design. To determine the final image quality a designer may trace hundreds of nonparaxial rays to obtain a spot diagram in the image plane. Each spot is the point of intersection of a ray from a point on the object with the image plane, and the spot density is a measure of image spread and therefore of image quality.

A formula is available, however, for specifying the flux density, that is, the irradiance along each traced ray.[1] It is also applicable to ray acoustics and radiant heat transfer. For example, the formula enables one to vary a parameter, trace a new ray and immediately calculate the irradiance along that ray. To illustrate the ideas, we derive the formula here, referred to as the *flux equation*, for the special case of a two-dimensional geometry. This result is useful by itself since it gives some of the characteristics of the image formed by rays in the meridional plane of a three-dimensional geometry. The meridional plane is the plane formed by the object point (and image point) and the optical axis.

First, omitting mathematical details, we outline the procedure for calculating illuminance in three dimensions and then proceed in detail to the simpler two-dimensional geometry. As input to the flux equation in three dimensions one needs to know the principal radii of curvature of the wave front both before and after refraction. In any surface two curves may be formed at right angles to each other, one having a maximum curvature and the other a minimum curvature; they are called the *principal curvatures* of the surface. The radii of curvature are the reciprocals of the principal curvatures. The centers of the radii of curvature for a wave front emerging from a refracting surface define converging points for the wave front. They lie along the refracted ray vector and their loci, for a series of ray vectors, trace out two surfaces called *caustic surfaces*. In three dimensions, in optics, the principal curvatures after refraction may be obtained from the values of a pair of curvatures called the *parallel normal curvature* and the *perpendicular normal curvature* of the wave front. The parallel normal curvature is the curvature of the curve in the wave front whose tangent is a tangent of the surface and lies in the plane of incidence at the point of refraction. The perpendicular normal curvature of the wave front is the curvature of the curve in the wave front whose tangent is a tangent in the surface and is perpendicular to the plane of incidence at the point of refraction of a ray. There is an equation that relates the parallel normal curvature of the incident wave front to the parallel normal curvature of the refracted wave front. A second equation relates the corresponding perpendicular curvatures of the incident and refracted wave fronts. Two other equations relate the torsions of these respective curves. We call these the *generalized lens equations*. The two torsion equations can be shown to reduce to one, leaving three equations. From the generalized lens equations one can relate the principal curvatures of the wave front after refraction to the principal curvatures of the wave front before refraction, since the principal curvatures of a surface are related to the normal curvatures of the surface through an equation called *Euler's equation*. When the principal curvatures are thereby calculated one has the necessary data to evaluate the flux equation and also to locate points on the caustic surfaces associated with any ray, skew, or meriodional, in an optical system.

For the special case of meridional rays, the torsions of the normal curves are zero so the torsion equations do not appear. Also the normal curves and their associated curvatures become identical with the principal curves and their curvatures. Therefore, the two generalized lens equations become equations that directly relate the principal curvatures of the wave front before and after refraction. They also relate points on the caustic surface before refraction to the caustic surfaces after refraction; the caustic surfaces are therefore immediately determined.

The rather complicated three-dimensional problem described above is greatly simplified in two dimensions, as we shall see. Many of the key ideas are still involved, however, but can be made much clearer in two dimensions before proceeding to a full three-dimensional geometry.

Figure 1 shows the three-dimensional caustic surfaces formed by collimated rays after refraction by a spherical surface. A hornlike surface is formed (tangential caustic) and a caustic spike (saggital caustic). The latter is associated with the radial convergence of rays through the optical axis because of the axial symmetry. If the source lies off the axis, the caustic spike also spreads out into a hornlike surface. In a strict two-dimensional geometry only the tangential caustic appears.

Two-Dimensional Geometry We now derive an equation that relates the curvature of a two-

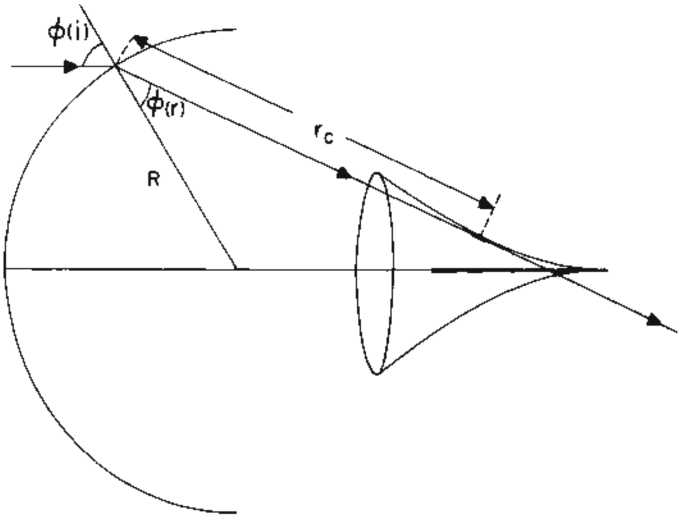

FIG. 1. Caustic cone and caustic spike along optical axis formed by incident collimated rays after refraction. In a 2-dimensional geometry only a slice of the cone in the plane of the figure is present.

dimensional wave front after refraction to the curvature of the wave front before refraction. This single equation is the two-dimensional analogue of the generalized lens equation for meridional rays in a three-dimensional geometry. Since the center of curvature of the wave front after refraction defines a point on the caustic, only one caustic is formed: a caustic curve, the tangential caustic. For small angles, with the optical axis, the two three-dimensional exact lens equations for meridional rays become the single paraxial lens equation. Likewise, the single two-dimensional generalized lens equation, the exact lens equation, becomes the par axial lens equation.

Definition of Curvature Let the position vector $\mathbf{x}(s)$ of arbitrary origin define the equation of a refracting surface in parametric form. The parameter s may be arbitrary, but in most derivations is the arc length along the curve. **I** and **J** are cartesian unit vectors. Then

$$\mathbf{x}(s) = \mathbf{I}x(s) + \mathbf{J}y(s), \tag{1}$$

where $x(s)$ and $y(s)$ are arbitrary functions of s. The unit tangent vector to the curve is given by

$$\mathbf{t}(s) = \frac{d\mathbf{x}(s)}{ds}. \tag{1a}$$

In turn the arc rate of change of the unit tangent vector is

$$\frac{d\mathbf{t}(s)}{ds} = \kappa\mathbf{N}(s) \tag{1b}$$

where $\mathbf{N}(s)$ is the unit normal to the curve, κ is the curvature, and $1/\kappa$ is the radius of curvature. The arc rate of change of the normal vector is

$$\frac{d\mathbf{N}(s)}{ds} = \kappa\mathbf{t}(s). \tag{1c}$$

Snell's Law in Vector Form Let a ray be incident upon the surface specified by $\mathbf{x}(s)$. A position vector on the ray after refraction is given by

$$\mathbf{X} = \mathbf{x}(s) + r\mathbf{A}(r)$$

where $\mathbf{A}(r)$ is a unit vector along the refracted ray and r is a distance along the ray. $\mathbf{A}(r)$ is related to $\mathbf{A}(i)$, the unit vector along the incident ray, and $\mathbf{N}$, the unit normal to the refracting surface, by Snell's law in vector form; that is

$$\mathbf{A}(r) = \gamma\mathbf{A}(i) + \Omega\mathbf{N}. \tag{2}$$

This equation merely expresses that fact that $\mathbf{A}(r)$, $\mathbf{A}(i)$, and $\mathbf{N}$ are coplanar, part of Snell's law, and that a vector $\mathbf{A}(r)$ may be expressed in terms of two independent vectors, $\mathbf{A}(i)$ and $\mathbf{N}$. To determine γ, form the cross product of $\mathbf{N}$ with the above. Thus

$$\mathbf{A}(r) \times \mathbf{N} = \gamma\mathbf{A}(i) \times \mathbf{N}$$

so that $\mathbf{J}\sin\phi(r) = \mathbf{J}\gamma\sin\phi(i)$, where $\mathbf{J}$ is a unit vector perpendicular to the plane of the figure. Therefore, $\sin\phi(r) = \gamma\sin\phi(i)$. Snell's law as usually stated is

$$\sin\phi(r) = \frac{n(i)}{n(r)}\sin\phi(i),$$

where $\phi(i)$ is the angle of incidence and $\phi(r)$ is the angle of refraction. Therefore $\gamma = n(i)/n(r)$, the ratio of the index of refraction on the incident side to the refracted side.

To determine Ω, form the scalar product of $\mathbf{N}$ with Eq. (2). Then $\mathbf{A}(r) \cdot \mathbf{N} = \gamma \mathbf{A}(i) \cdot \mathbf{N} + \Omega$. Since $\mathbf{A}(r) \cdot \mathbf{N} = \cos\phi(r)$ and $\mathbf{A}(i) \cdot \mathbf{N} = \cos\phi(i)$ we obtain

$$\Omega = -\gamma \cos\phi(i) + \cos\phi(r).$$

For reflection $\phi(r) = \pi - \phi(i)$ since $\mathbf{N}$ is taken in the same directional sense as $\mathbf{A}(i)$, that is, it is positive on the emerging side of the refracting surface. Thus for reflection,

$$\gamma = 1 \quad \text{and} \quad \Omega = -2\cos\phi(i).$$

With γ and Ω now known we form the complete differential of Eq. (2) and make use of the fact that the ray vector is perpendicular to the wave front. This is so because the wave front from the point source is spherical and is perpendicular to the ray vector which lies along the radius of the sphere. It is a general theorem in optics, known as the Malus-Dupin theorem,[2] that if the ray vector starts out perpendicular to the wave front it remains so after any number of refractions. Thus $\mathbf{A}(i)$, the unit ray vector before refraction, is also the unit normal to the wave front before refraction; likewise $\mathbf{A}(r)$, the unit ray vector after refraction is normal to the wave front after refraction. The complete differential of Eq. (2) is

$$\begin{aligned}\frac{dA(r)}{ds(r)}\, ds(r) - \gamma \frac{d\mathbf{A}(i)}{ds(i)}\, ds(i)& \\ - d\Omega\mathbf{N} - \Omega \frac{d\mathbf{N}}{ds}\, ds = 0,&\end{aligned} \tag{3}$$

where $ds(i)$, ds, $ds(r)$ are elements of length along the incident wave front, the refracting surface and the wave front after refraction. By Eq. (1c) we have

$$\begin{aligned}&\frac{d\mathbf{A}(r)}{ds(r)} = \kappa(r)\,\mathbf{t}(r), \qquad \frac{d\mathbf{N}}{ds} = \kappa\mathbf{t}, \\ &\frac{d\mathbf{A}(i)}{ds(i)} = \kappa(i)\,\mathbf{t}(i),\end{aligned} \tag{3a}$$

where $\kappa(r)$, $\kappa(i)$, and κ are the curvatures of the refracted wave front, the refracting surface, and the incident wave front, respectively, and $\mathbf{t}(r)$, $\mathbf{t}(i)$ and $\mathbf{t}$ are unit tangent vectors to the respective wave fronts.

If we form the vector cross product of $\mathbf{N}$ with Eq. (3) after inserting Eq. (3a) and use the fact that

$$\begin{aligned}&\mathbf{t}(r) \times \mathbf{N} = \mathbf{J}\cos\phi(r), \qquad \mathbf{t} \times \mathbf{N} = \mathbf{J}, \\ &\mathbf{t}(i) \times \mathbf{N} = \mathbf{J}\cos\phi(i)\end{aligned} \tag{3b}$$

where $\mathbf{J}$ is a unit vector normal to the figure, we have, after putting the coefficient of $\mathbf{J}$ in the resulting equation equal to zero,

$$\begin{aligned}&\kappa(r)\cos\phi(r)\, ds(r) - \gamma\kappa(i) \\ &\quad \cdot \cos\phi(i)\, ds(i) - \Omega\kappa\, ds = 0.\end{aligned} \tag{3c}$$

In order that flux be conserved (except for absorption) or that the wave front map continuously across the refracting surface, the following constraint must hold among $ds(i)$, ds, and $ds(r)$:

$$ds(i) = ds\cos\phi(i) \quad \text{and} \quad ds(r) = ds\cos\phi(r). \tag{4}$$

Putting Eq. (4) into Eq. (3b) yields

$$\kappa(r) = \gamma\kappa(i)\frac{\cos^2\phi(i)}{\cos^2\phi(r)} + \frac{\Omega\kappa}{\cos^2\phi(r)}. \tag{4a}$$

In terms of wave front radii of curvature, $r(i)$ for incident, $r(r)$ after refraction,

$$\kappa(r) = \frac{1}{r(r)}, \qquad \kappa(i) = \frac{1}{r(i)}, \qquad \kappa = \frac{1}{R}$$

we have

$$\frac{1}{r(r)} = \frac{\gamma\cos^2\phi(i)}{r(i)\cos^2\phi(r)} + \frac{\Omega}{R\cos^2\phi(r)} \tag{4b}$$

where $\gamma = n(i)/n(r)$ and $\Omega = -\gamma\cos\phi(i) + \cos\phi(r)$. The result applies to any surface. The corresponding mirror equation is

$$\frac{1}{r(r)} = \frac{1}{r(i)} + \frac{2}{R\cos\phi(i)}. \tag{4c}$$

Equation (4b) is the generalized lens equation, in that it relates the radius of curvature of the refracted wave front at the point of refraction to the radius of curvature of the incident wave front at the point of refraction and the radius of curvature R of the surface at the point of refraction. R may vary over the surface. The usual paraxial optics sign conventions apply if we begin by placing a minus sign in front of $r(i)$ in Eqs. (4b,c). When $\phi(r) \simeq \phi(i) \simeq 0$, Eq. (4b) becomes the paraxial equation

$$\frac{1}{r(r)} = \frac{\gamma}{r(i)} + \frac{\Omega}{R}, \qquad \Omega = -\gamma + 1. \tag{5a}$$

For reflection, Eq. (4c) becomes

$$\frac{1}{r(r)} = \frac{1}{r(i)} + \frac{2}{R}, \tag{5b}$$

the mirror equation; $r(i)$ is negative in both cases, when the incident wave front is diverging from the left.

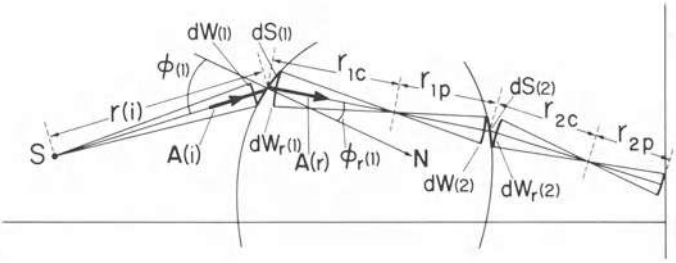

FIG. 2. Converging element of wave front of radius of curvature r_{2c} after refraction at surface 2. r_{2c} is also the distance along the refracted ray to a point on the caustic r_{2p} is the radius of curvature of the wave front incident upon surface 3.

Derivation of Flux Equation If the light originates from a point source of strength I_0, the element of flux dF emitted in angle $d\theta$ is

$$dF = I_0 \, d\theta = I_0 \frac{dw(1)}{r(1)} = \sigma(1)\, dw(1) \quad (6)$$

where $\sigma(1) = I_0/r(1)$ is the flux density at position $r(1)$ and $dw(1)$ the element of wave front area. When the light originates from an element of length $ds(0)$ radiating in accordance with Lambert's law, then

$$\sigma(1) = B \cos\phi(0)\, ds(0)/r(1) \quad (7)$$

where B is the brightness and $\cos\phi(0) = \mathbf{A}(0) \cdot \mathbf{N}(0)$. Thus the flux incident upon $ds(1)$ is

$$E_{ds(0)-ds(1)} = \sigma(1) \cos\phi(1)\, ds(1). \quad (8a)$$

If the flux is refracted to $ds(2)$ then the flux density over $ds(2)$ is

$$E_{ds(0)-ds(2)} = \sigma(1)\rho_1 \cos\phi(1) \frac{ds(1)}{ds(2)}, \quad (8b)$$

where ρ_1 is the coefficient of absorption or reflection at $ds(1)$. Similarly if the flux

$$E_{ds(1)-ds(2)} \times ds(2)$$

incident upon $ds(2)$ is refracted to $ds(3)$ then the flux density over $ds(3)$ is

$$E_{ds(0)-ds(3)} = \sigma(1)\rho_1\rho_2 \cos\phi(1) \frac{ds(1)}{ds(2)} \frac{ds(2)}{ds(3)} \quad (8c)$$

and so on for any number of surfaces. Putting

$$\begin{aligned} ds(2)\cos\phi(2) &= dw(2), \\ ds(3)\cos\phi(3) &= dw(3), \end{aligned} \quad (9)$$

which expresses continuity of flux across the interface, into Eq. (8c), one obtains

$$E_{ds(1)-ds(3)} = \sigma(1)\rho_1\rho_2 \cos\phi(1)\cos\phi(2) \cdot \cos\phi(3) \frac{ds(1)}{dw(2)} \frac{ds(2)}{dw(3)}. \quad (10)$$

$\phi(1)$, $\phi(2)$, and $\phi(3)$, without subscripts, are angles of incidence at each surface; $\phi_r(1)$ and $\phi_r(2)$ are angles of refraction; $dw(1)$, $dw(2)$, and $dw(3)$, without subscripts, denote the elements of wave front on the incident side of the surfaces 1, 2 and 3; $dw_r(1)$ and $dw_r(2)$ denote the wave front as it leaves surfaces 1 and 2.

Likewise, using

$$\begin{aligned} \cos\phi_r(1)\, ds(1) &= dw_r(1), \\ \cos\phi_r(2)\, ds(2) &= dw_r(2), \end{aligned} \quad (11)$$

in Eq. (10), we have

$$E_{ds(1)-ds(3)} = \sigma(1)\rho_1\rho_2 \cdot \frac{\cos\phi(1)\cos\phi(2)\cos\phi(3)}{\cos\phi_r(1)\cos\phi_r(2)} \cdot \frac{dw_r(1)}{dw(2)} \frac{dw_r(2)}{dw(3)}. \quad (12)$$

The elements of wave front are related to the radii of curvature as follows:

$$dw_r(1) = r_{1c}\, d\theta_1, \qquad dw(2) = r_{1p}\, d\theta_1. \quad (13a)$$

$$dw_r(2) = r_{2c}\, d\theta_2, \qquad dw(3) = r_{2p}\, d\theta_2. \quad (13b)$$

See Fig. 3 for Eq. (13b). A similar figure applies to Eq. (13a) between surfaces 1 and 2. The radius of curvature of the wave front as it leaves

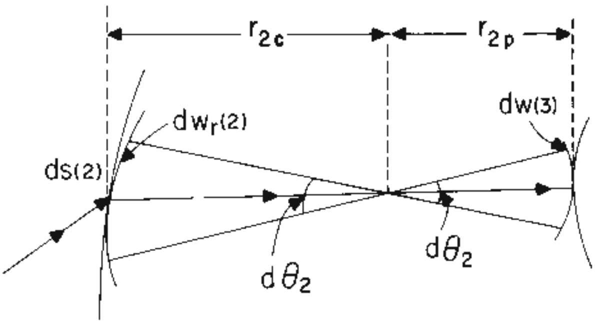

FIG. 3. Ray trace showing various quantities employed in the text.

surface 1 is denoted by r_{1c}. Its radius of curvature as it is incident upon surface 2 is denoted by r_{1p}. Likewise r_{2c} is the radius of curvature of the wave front as it leaves surface 2 at $ds(2)$ and r_{2p} is the radius of curvature of the wave front as it is incident at $ds(3)$. The orthogonality of the ray vector and the wave front is used in writing Eqs. (13,a,b). Putting Eqs. (13a,b) into Eq. (12) one obtains

$$E_{ds(0)-ds(3)} = \sigma(0)\rho_1\rho_2 \cdot \frac{\cos\phi(1)\cos\phi(2)\cos\phi(3)}{\cos\phi_r(1)\cos\phi_r(2)} \cdot \frac{r_{1c}}{r_{1p}}\frac{r_{2c}}{r_{2p}} \qquad (14)$$

where $r_{1p} = r_{12} - r_{1c}$, $r_{2p} = r_{23} - r_{2c}$, with an obvious generalization to n surfaces. Equation (14) is the flux equation for a two-dimensional geometry, and r_{1c}, r_{2c} are the values of $r(r)$ at surfaces 1 and 2, respectively, obtained from Eq. (4b) for refraction and Eq. (4c) for reflection. This completes the derivation of the generalized lens equation and also the flux equation.

A word of caution. If the caustic curve from surface 1 intersects surface 2, then for the particular ray to that point on the caustic we have $r_{1p} = r_{12} - r_{1c} = 0$, since $r_{1p} = r_{12}$. Equation (14) then predicts a singular value for the flux density at $ds(3)$, for this ray, and very large values for the small pencil close to the ray. The singularity is not real, however, and is eliminated by writing

$$\frac{r_{1c}}{r_{1p}}\frac{r_{2c}}{r_{2p}} = r_{1c}\left(\frac{r_{2c}}{r_{1p}}\right)\frac{1}{r_{2p}}$$

and solving for r_{2c}/r_{1p} from Eq. (4b). In Eq. (4b) put $r(r) = r_{2c}$ and $r(i) = r_{1p}$, $\phi(i) = \phi(2)$ and $\phi(r) = \phi_r(2)$. Then

$$\frac{r_{2c}}{r_{1p}} = \frac{R_2\cos^2\phi_r(2)}{\gamma(2)R_2\cos^2\phi(2) + \Omega(2)r_{1p}}. \qquad (15)$$

If $r_{1p} \to 0$, then

$$\frac{r_{2c}}{r_{1p}} = \frac{\cos^2\phi_r(2)}{\gamma(2)\cos^2\phi(2)},$$

which is a finite result. If Eq. (4b) is always written as Eq. (15), this problem is automatically avoided.

IRRADIATION, DISPLACED ATOMS

The word *radiation* originally implied emanation of electromagnetic waves (photons, gamma rays), or alpha or beta rays (helium ions or electrons), and is used in that sense in the entries RADIATION, THERMAL and NUCLEAR RADIATION. It is now commonly accepted in the broader sense of emanation or bombardment by any elementary particle or ion. Indeed, the general subject area of the irradiation of solids is called *radiation effects*. The primary emphasis of the present entry is on irradiation which significantly alters the relative positions of the atoms in a solid, in contrast to cases in which the primary effect is a change in the state of ionization of the atoms (see RADIATION, IONIZING, BASIC INTERACTIONS; RADIATION CHEMISTRY; and COLOR CENTERS): Electron redistribution is sufficiently rapid in metals that ionization effects are not observable and hence the study of ionizing radiation normally is restricted to insulators and semiconductors.

The atoms in the majority of solids are arranged in very specific packing patterns which repeat three-dimensionally for distances large compared to atomic dimensions (see SOLID STATE PHYSICS and CRYSTALLOGRAPHY). This crystalline order is not usually evident: a piece of copper wire is quite flexible and does not look like a "crystal." However, truly amorphous solids (supercooled liquids and glasses) are uncommon, and the copper wire is in fact composed of many crystallites joined by grain boundaries, each "small" by human scale standards, but large enough so that the average copper atom is in a crystalline environment. Thus, the title of this entry refers to the decrease in this atomistic order caused by irradiation.

The simplest defects in the crystal lattice order of solids are *point defects* such as vacant atomic sites (vacancies) and extra atoms crammed into locations where they should not be (interstitials), and *line defects*, effectively wrinkles in the crystal structure (dislocations). Although there is still some controversy, it is generally acknowledged that self interstitials (i.e., not impurity interstitials) migrate freely in the lattice at very low temperatures ($< 100^\circ$K), while vacancies typically might become thermally mobile at 100°C. Self interstitials and vacancies are defined as the disturbance in the lattice order. Thus, interstitial migration does not involve a specific atom moving through the lattice, but the interstitial configuration, similar to a traveling wave, and the motion of a vacancy occurs by a neighboring atom hopping into the vacancy, leaving its site vacant.

The practical significance of the study of irradiation processes in solids is related, for example, to the degradation of mechanical properties of materials in nuclear reactors or electronic properties of semiconductors. To explain these gross effects, details of the structure and properties of solids must be understood, and so irradiation can be used as a probe to study many fundamentals of solid state physics and of defects in the crystalline order of solids.

As an energetic particle traverses a solid, it interacts with and transfers its energy to the crystal in a variety of ways. Much of the emphasis here will be on elastic collisions which impart kinetic energy to the lattice atoms. The probability of significant elastic interaction, called the scattering cross section, is sufficiently small under most circumstances that elastic collisions are spatially well separated, and can be treated theoretically as isolated events using nuclear collison theory. If, during a collision, a lattice atom recoils with kinetic energy above a threshold value, it is called a *primary knock-on*.

The theory for the creation of a primary knock-on is dependent on the irradiating particle. Photons, or gamma rays, first impart energy to electrons via the photoelectric effect or by Compton scattering, or transform to an electron and a positron by pair production (see PHOTOELECTRICITY, COMPTON EFFECT, and POSITRON). These charged particles then travel through the lattice like incident electrons to create primary knock-ons. To reach threshold, photon energies of the order of 1 MeV are required for the two electron processes and of 5 MeV for pair production.

Electrons are so light compared to nuclei that they can only transfer a small fraction of their energy to a lattice atom in an elastic collision. For example, energies of the order of 1 MeV (and relativistic corrections in the theory) are required to reach threshold recoil energies in the 3d transition metals (e.g., Fe and Ni). High-voltage electron microscopes operate with electrons in this energy range and can be used both to create and observe the effects of radiation damage. With electron bombardment, the primary knock-on atoms normally do not have sufficient energy to create a significant number of additional knock-ons.

With ion bombardment, much of the incident particle energy can be transferred to a single lattice atom. At high energies, often in the tens of MeV range, there is a coulombic interaction between the incident ion and the lattice atom cores, and the scattering is approximated by Rutherford theory. Here the primary knock-on can have sufficient energy to act like an incident particle, which can lead to a cascade effect. However, most of the energy loss in this range is due to electronic excitation which, because it is less than 1 MeV, does not yield displaced atoms. As energies decrease, the interactions become more like hard-sphere collisions between atoms. The changeover from Rutherford to hard-sphere scattering occurs in the A-keV range, with A the atomic weight of the moving ion. Although most of the energy loss is in the Rutherford range, the majority of the displaced atoms are produced by hard-sphere scattering.

Neutrons can produce lattice atom displacements either by scattering processes which leave the atom unchanged or by nuclear reactions. For nuclear reactions, a lattice atom can absorb a thermal neutron and then undergo a radioactive transformation, such as $\mathrm{Fe}^{58}(n, \gamma)\,\mathrm{Fe}^{59}$ The iron atom recoils to conserve momentum as the γ is emitted, with energy, for example, somewhat less than a keV, but well above threshold to become a primary knock-on and act to produce a small cascade. Other reactions with thermal neutrons, such as (n, α), (n, β), and (n, f) (fission) also produce primary knock-ons.

Neutron scattering generally involves "fast" neutrons, i.e., with energies in the keV and MeV range. As in the thermal neutron case, lattice atoms generally receive kinetic energies well above the primary knock-on threshold. At the low energy end of neutron scattering, the interaction is primarily elastic, but as energies increase, lattice atom nuclei can become excited. leading to inelastic scattering.

The discussion so far has been concerned with the process by which a primary knock-on is created, and the concept of a threshold energy was presented as intuitively reasonable. It is similarly clear that, given the highly ordered crystal structure, the threshold energy must vary with direction, i.e., the threshold energy is a function of orientation. A minimum value of 25 eV is commonly accepted as typical, with 4.5 times the sublimation energy yielding a rough correlation with the experimental data. Minima tend to occur near high symmetry directions, with the sequence from most to least favorable being, for example, ⟨110⟩, ⟨100⟩, ⟨111⟩ in fcc copper and ⟨100⟩, ⟨110⟩, ⟨111⟩ in bcc iron.

If a knock-on atom only travels a short distance in the lattice, say several interatomic spacings, it momentarily becomes an interstitial, leaving a vacancy at its initial lattice site, but then this interstitial may spontaneously recombine with its vacancy to yield no net damage. As noted above, interstitials of this type move through the lattice as a disturbance in the order, not as a specific atom. The atom which returns to the knock-on site is generally not the atom initially there, so that this subthreshold event can, for instance, yield mixing of ordered alloys.

If the interstitial is somewhat further removed from the knock-on site, a stable interstitial-vacancy complex, called a *close Frankel pair*, is created. There is a binding energy between the two defects so that they preferentially recombine when one becomes mobile. At greater separations yet, the interstitial and vacancy do not interact, are called a *separated Frankel pair*, and migrate in a random path upon becoming mobile.

For primary knock-on energies above but not too much greater than threshold, the interstitial is formed at a distance from the knock-on site by a replacement chain process, which occurs most readily near high symmetry directions. The primary knock-on hits a neighbor almost head on, and, because they have the same mass, transfers most of its energy to that atom. The primary knock-on atom then remains in that neighboring position while the atom which has been there hits one of its neighbors, etc. While a highly energetic particle may have a long path in a solid, the majority of defects created in a cascade occur through this mechanism, often yielding a depleted zone surrounded by a shell rich in interstitials. This configuration, called a *displacement spike*, is raised to a very high temperature for a short duration of time because so much energy is deposited in a small region. The hot spot only lasts for perhaps 100 lattice vibrations before cooling below the melting temperature. Subthreshold collision chains similar to replacement chains are considered to be the primary means by which energy is rapidly removed from a displacement spike event. Experience with billiard balls would indicate that replacement chains or subthreshold collision chains would rapidly defocus, but the combined effects of the lattice structure and scattering theory more realistic than hard spheres indicates that conditions for focusing should be quite common.

Another focusing type of phenomenon is called ***channeling***, whereby a particle (incident or knock-on) travels with little energy loss per unit length down an open channel in the crystal structure. Such channels are easily seen in ball-and-stick lattice models. Under careful laboratory conditions with properly oriented single crystals, incident particles which normally would be stopped can readily pass through a foil by such channeling.

Much of the interest in radiation damage theory is concerned with the estimation of the amount and spatial distribution of the disorder caused by a given irradiation. The ideas discussed above have been incorporated into complex formulations which give good estimates of the formation of damage but normally require numerical methods to solve. However, even if the disorder created was accurately known, direct comparison with experiment is extremely difficult because the defects are so small. Also, at all but very low temperatures, some if not all of the defects are mobile so that annealing takes place continuously. The irradiation drives the solid away from thermal equilibrium, but, if any kinetic pathways are available, the solid will adjust to thermodynamically lower its free energy.

The simplest annealing process is interstitial-vacancy recombination, called ***annihilation***. The defects can also disappear at sinks such as surfaces, grain boundaries and dislocations, or clusters of a given type may form. These clusters can transform into dislocation loops, changing the effective sink concentration by orders of magnitude. The migrating defects can interact with alloying elements leading to solute segregation. The net effect of these, and many additional effects, is a continuous evolution of the microstructure of a solid under irradiation.

The initial defects created in a solid are too small to be observed directly, although strides have been made with field ion microscopy (see FIELD EMISSION). Electrical resistivity is probably the most standard experimental technique used to study the amount of disorder in a solid. A problem is that resistivity, and most other procedures, are not specific: vacancies and interstitials have about the same electron scattering strength, and, for example, a divacancy has about twice the scattering strength of a single vacancy. Sophisticated experimental methods such as positron annihilation spectroscopy in which different defects give different signals, are not without their own ambiguities.

The most significant practical effects in metals are related to mechanical properties. For example, an increase in the dislocation content produces a loss of ductility, dislocation climb leads to high-temperature creep, clustering of vacancies into voids yields bulk swelling, and segregation of impurities at grain boundaries can decrease fracture strength. The creation of damage in semiconductors (see SEMICONDUCTORS) is similar to that in metals, but here the electronic effects are most significant. The disorder gives rise to additional electronic states in the band gap which can act as donors, acceptors, or trapping sites, which in turn can completely alter the sensitive electronic properties built into a particular device.

IRREVERSIBILITY

Physical systems commonly display a tendency to change spontaneously from one state to another, but not to change in the opposite direction. Examples are the tendency of heat to pass from regions of high temperature to regions of low temperature, the tendency of mechanical or electrical energy to be transformed into heat by friction or resistance, and the mixing or diffusion of different substances. While irreversibility appears to be an obvious feature of macroscopic natural phenomena, so much so that violations of this tendency are scarcely conceivable, it is not yet established whether it should be considered a general law applicable on both the atomic and the cosmological scales. Most physicists accept the "statistical" explanation of irreversibility, according to which complex systems with many degrees of freedom tend to spread out among more and more diverse states in the "phase space" of possible configurations (see STATISTICAL MECHANICS). Scientific discussions of this question go back to the time of Newton and continue up to the present day. A brief review of these earlier discussions is necessary in order to illustrate how the problem of irreversibility is related to our general view of the world. We shall be concerned here mainly with the qualitative aspects of irreversibility as distinct from quantitative theories of particular processes (see, e.g., the articles on DIFFUSION, HEAT TRANSFER, THERMOELECTRICITY, and VISCOSITY).

In the seventeenth century, the "clockwork universe" theory was popularized by the French philosopher René Descartes and the British scientist Robert Boyle. According to Descartes and Boyle, the physical world is like a perfect machine which, once created and set in motion by God, can run forever without any further need for divine intervention. This mechanistic view of nature dominated much scientific work (and conditioned many of the influences of physics on biology, psychology, philosophy, and political thought) up to the nineteenth century. Since its most striking successes were attained in the Newtonian theory of the solar system, it has often been attributed to Newton in such phrases as "the Newtonian world-machine." But Newton himself rejected it, pointing to the importance of irreversibility in phenomena such as the viscosity of fluids and the imperfect elasticity of solids; in his *Opticks* he stated that "motion is much more apt to be lost than got, and is always upon the decay." He also thought that mutual gravitational perturbations of planets in the solar system would accumulate over long periods of time, producing instabilities that could be corrected only by divine intervention.

In 1715 the German philosopher G. W. Leibniz attacked Newton's opinion, arguing that the suggestion that "God almighty needs to wind up his watch from time to time; otherwise it would cease to move" (as Leibniz put it) was a slur on God's ability to make a perfect world-machine. Newton retorted that the clockwork metaphor was too materialistic, and was likely to encourage the notion that God has no active role in the world at all. Newton's suspicions were well-founded; later improvements on his calculations of gravitational perturbations indicated that a solar system governed only by Newton's laws is stable, so that all changes in planetary orbits merely oscillate between fixed limits. Thus when Napoleon asked the French mathematician P. S. de Laplace why he had not mentioned God in his treatise on celestial mechanics, Laplace could reply: "Sir, I have no need of that hypothesis."

When Newton asserted that motion tends to be lost in processes such as friction or inelastic collisions, he was refusing to accept the suggestion (already well-known at that time) that it is simply transformed into invisible molecular motion, perceptible only as heat. The modern concept of irreversibility is different from Newton's because it involves a *dissipation* but not a *destruction* of energy. One might therefore expect that the modern theory of irreversibility could be established only after the law of conservation of energy had been accepted (around 1850); in a sense this is true, but it is somewhat misleading historically, as we shall see.

In 1852 the British physicist William Thomson (later known as Lord Kelvin) published a short paper, "On a Universal Tendency in Nature to the Dissipation of Mechanical Energy." The immediate stimulus for this pronouncement was Thomson's reflections on the consequences of Carnot's theory of steam engines, which he and the German physicist Rudolf Clausius had recently used as a basis for the second law of thermodynamics. In formulating the second law, Clausius and Thomson argued that it must be impossible to transfer heat from a cold body to a warm body without some kind of compensating process equivalent to the transfer of at least the same amount of heat in the opposite direction; or, as Thomson phrased it, it is impossible to obtain mechanical work by cooling a body below the temperature of its surroundings. But these "impossibility" or "impotency" statements of the second law were closely associated with the conviction that the forbidden processes were forbidden because they contravened a *natural tendency* for heat to flow from high temperatures to low. Thus, in the development of theories of energy dissipation, the simple flow of heat from hot to cold was the first irreversible process to be recognized; other processes were subsequently said to be irreversible, in part because they were equivalent or analogous to the equalization of temperature differences.

Although Thomson's explicit statement of the principle of dissipation of energy occurred in a thermodynamic context involving transformations of heat and mechanical work, it is evident from his own writings that he was equally concerned with an irreversible process that involved no change in the total quantity of heat: namely, the cooling of the earth from a hypothetical initial molten state to its present state (moderate surface temperature with residual internal heat), ultimately reaching the desolate cold of interplanetary space. This was the predicted "heat death" of the earth (and perhaps of the entire universe) that attracted the attention of popular science writers in the late nineteenth century, and was publicized further by the British astrophysicists J. H. Jeans and A. S. Eddington in the 1920s. But Thomson was not the first to discuss the cooling of the earth; indeed, this had been a favorite topic of debate among scientists in the eighteenth and early nineteenth centuries, and provided the occasion for several assertions that there is a natural tendency for heat to flow from hot to cold. Even the threat of a heat death as a fate common to all bodies in the universe had been hinted as early as 1777 by the French astronomer Jean-Sylvain Bailly. Fourier's theory of heat conduction (whose development was motivated in part by the problem of terrestrial temperatures) was the first major physical theory in modern times to incorporate irreversibility in its basic postulates.

With the advent of thermodynamics in the 1850s, the concept of irreversibility could be extended to processes involving transformations among different forms of energy. Thomson's use of the word "dissipation" introduced a moral connotation based on the observation that whenever heat flows through a finite temperature difference a certain amount of mechanical work *could* be obtained by appropriate use of a heat engine; the maximum work is obtained when each temperature difference in the cycle of operations is made infinitesimally small so that the direction of heat flow could be reversed by a slight alteration of the temperatures (see CARNOT CYCLES AND CARNOT ENGINES). Whenever that is not done, heat flows irreversibly and the chance of doing mechanical work has been missed, hence the energy involved has been "dissipated."

In 1854, Clausius formulated his thermodynamic theory in terms of the "equivalence-value of a transformation," defined as the amount of heat transferred at a certain temperature divided by that temperature. For a cyclic process the total equivalence-value would be determined by an integral over the path of this ratio,

$$\int \frac{dQ}{T}.$$

For a reversible process the value of this integral would be zero, according to Clausius's statement of the second law; whereas for an irreversible process it would be positive. Since this particular mathematical expression proved to be useful in developing his theory, Clausius finally gave it the name *entropy* in 1865; more precisely, the *change* in entropy in a process is defined as

$$dS = dQ/T.$$

Thus entropy provided an indicator of irreversibility, and Clausius could state the second law in the generalized form, "the entropy of the world tends toward a maximum." It is in this form, or simply the phrase "entropy tends to increase," that the principle of irreversibility or principle of dissipation of energy is now ordinarily stated. Eddington asserted that this principle "holds the supreme position among the laws of Nature" because it determines the direction of time itself—"time's arrow."

Although one could simply accept the principle of irreversible entropy increase as a fundamental law of physics without further explanation (as is sometimes done in texts on thermodynamics), there is widespread sentiment among scientists that it must be possible to reduce the law to a more basic postulate about atomic behavior (or about the universe as a whole). This reduction seemed an urgent necessity for those physicists in the nineteenth century who believed that all properties of matter and energy were ultimately explicable by mechanical models, using Newton's laws of motion. Since the kinetic theory of gases was being developed during the same period when entropy was being introduced into thermodynamics, that theory offered a natural starting point. The following conclusions were reached as a result of analyses by Thomson, James Clerk Maxwell, and Ludwig Boltzmann (see KINETIC THEORY):

(1) It is reasonable to assume that the principle of irreversibility is *not* an absolute law of nature and that all processes involving individual atoms are perfectly reversible, since Newton's second law of motion is unchanged when $-t$ is substituted for t, and there is no direct evidence that interatomic forces are dissipative. In that case irreversibility can appear only when large numbers of atoms are involved, and is connected with the fact that observable macroscopic states (specified by parameters such as temperature and pressure) of a system correspond in general to enormously large collections of microscopic states, the latter being specified by values of the positions and velocities of all the atoms. In a typical irreversible process, a system passes from macroscopic state A corresponding to a small number of microscopic states, to another macroscopic state B corresponding to a much larger number of microscopic states. The process could be reversed only if there were some way to pick out the special microscopic states in B that had evolved from microscopic states in A, and then to reverse the directions of all atomic velocities.

(2) In this view irreversibility is a *statistical* property, which appears to be a general law of nature only because the probability of reversal (e.g., the probability that entropy will spontaneously decrease) is extremely small. There is some room for philosophical or methodological debate as to whether a statement that is always true in practice but *may* be wrong once in a billion years "in principle" (according to a theory of atomic behavior) should be considered a law of nature.

(3) The use of statistical terminology in explaining the principle of irreversibility nevertheless suggested that this principle may depend on *randomness at the atomic level.* In 1894, S. H. Burbury pointed out that the proof of Boltzmann's "H theorem" involved the assumption that two colliding molecules are uncorrelated *after* as well as *before* they collide, and argued that this assumption could be justified if the system were subjected to continuous random external disturbance. Boltzmann, and later Max Planck, agreed that such an assumption could be used to derive irreversibility. Yet it was not until the advent of quantum mechanics in the 1920s that most scientists were ready to accept the idea that atomic behavior may involve an inherent element of randomness or indeterminacy. While the late-nineteenth-century debates on irreversibility thus foreshadowed the breakdown of determinism in physics, it has not yet been established that irreversibility should be attributed to atomic randomness.

The statistical theory developed by Maxwell, Thomson, and Boltzmann achieved a substantial clarification by describing irreversible processes in terms of the *mixing* of atoms with different properties; the flow of heat, or the transformation of mechanical energy into heat, can be seen as special cases in which the relevant atomic property is velocity. Thus entropy increases whenever one goes from an ordered state to a disordered state, and entropy itself can be regarded as a measure of disorder. That terminology also suggests that entropy is a measure of the amount of *information* (or rather *lack* of information) which we have about the system (see ENTROPY). An extreme interpretation based on this idea is that irreversibility is not an inherent property of physical systems but is merely a necessary feature of any human description of them.

There have been numerous attempts to construct or imagine devices that would permit a violation of the second law of thermodynamics, i.e., to accomplish "perpetual motion of the second kind" by arranging for heat to flow from cold to hot regions, or by extracting mechanical work from an isothermal heat reservoir. Brownian movement has sometimes been considered an example of the latter kind. Nevertheless there are no generally accepted instances of violations of irreversibility. On the other hand, scientists hesitate to accept the view of Clausius that irreversible entropy increase leads to a final state in which "no further change could evermore take place, and the universe would be in a state of unchanging death."

In addition to the statistical explanation of irreversibility, there have been attempts to discover violations of "time-reversal invariance" in the interactions of elementary particles (see PARITY) and to associate the "direction of time" with the expansion of the universe (see the article by Gal-Or cited below). The persistent philosophical interest in the nature of time ensures that debates about irreversibility will continue to enliven discussions of the foundations of physics for many years to come.

It is sometimes suggested that there is a conflict between biological evolution and the principle of irreversibility, since the former involves the transformation of simple forms of life into more complex ones while the latter involves the transformation from order to disorder. However, there is no conflict if it is recognized that the principle predicts an increase of entropy only in a closed system taken as a whole, and that the statistical nature of irreversibility leads one to expect local decreases in entropy which are compensated by larger increases elsewhere. In the case of biological evolution the system must include the sun; the entropy increase associated with the transfer of energy from the sun to the earth ($dS = dQ/T_{\text{sun}} - dQ/T_{\text{earth}}$) is enormous compared to the decrease in biological processes that utilize a small part of this energy.

As Boltzmann himself pointed out in a lecture in 1904, Darwin's theory of natural selection can be derived qualitatively from statistical thermodynamics. The equilibrium state of a molecular system is not simply the one of greatest entropy or disorder, but involves a balance between disorder and the forces that favor an ordered state; thus at sufficiently low temperatures water molecules will spontaneously form complex crystals. Such an ordered state, initially formed by chance, will be "selected" to survive under certain conditions. The chemical reactions that occur in living systems are quite consistent with thermodynamics, as Harold Blum showed in his classic monograph "Time's Arrow and Evolution (Princeton University Press, 1951).

During the past two decades several scientists have developed more detailed theories of the irreversible processes in biological systems. One of the best known is that of Ilya Prigogine and his collaborators. Their theory shows how a system driven far away from equilibrium may acquire a new kind of order, just as a fluid heated from below will develop a regular pattern of convection cells. Prigogine received the 1977 Nobel Prize in Chemistry for his theory of "dissipative structures," including its application to biology.

ISOSPIN

Isospin (also called *isobaric spin* and *isotopic spin*) is an attribute ascribed to particles in a mathematical formalism introduced originally to simplify calculations involving the interactions among protons and neutrons through nuclear forces. In the isospin formalism, the neutron and proton are treated as though they were two different quantum-mechanical states of the same entity, the nucleon. A neutron is distinguished from a proton by the value of its isospin projection quantum number, t_z: the value $t_z = \frac{1}{2}$ is arbitrarily assigned to the neutron and $t_z = -\frac{1}{2}$ to the proton. (This convention is common in nuclear structure literature, but the opposite assignments for t_z are found in particle physics literature.)

The idea of using such a formalism for treating neutrons and protons was first suggested by Heisenberg,[1] who used the Pauli spin matrices to represent the attribute that we call isospin. Wigner[2] later named the concept *isotopic spin*. Subsequent authors pointed out that the attribute, when extended to nuclei, is relevant not to isotopes but to nuclei with the same mass, hence the name *isobaric spin* replaced *isotopic spin*. In recent literature the name has been shortened to *isospin*. In spite of the name, the concept has nothing to do with mechanical angular momentum. (See MATHEMATICAL PRINCIPLES OF QUANTUM MECHANICS for a discussion of quantum-mechanical angular momentum.)

The mathematical apparatus of the isospin formalism belongs to the general subject of group theory and is identical to that used for treating electron spin in atomic physics (see ELECTRON SPIN). Four quantum-mechanical operators, $\mathbf{t}_z$, $\mathbf{t}^+ \cdot \mathbf{t}^-$, and $\mathbf{t}^2$, constitute the basic elements of the formalism. The number t_z that distinguishes neutrons from protons is the eigenvalue of the operator $\mathbf{t}_z$, analogous to the operator $\mathbf{s}_z$ that gives the projection of the electron spin on the quantum axis. The operator $\mathbf{t}^+$ operating on the representation of a proton changes it into the representation of a neutron and $\mathbf{t}^-$ changes the representation of a neutron into that of a proton. The effects of these operators can be written symbolically as

$$\mathbf{t}_z R(p) = \tfrac{1}{2} R(p); \qquad \mathbf{t}_z R(n) = \tfrac{1}{2} R(n)$$

$$\mathbf{t}^+ R(p) = R(n); \qquad \mathbf{t}^- R(n) = R(p)$$

$$\mathbf{t}^+ R(n) = 0; \qquad \mathbf{t}^- R(p) = 0.$$

The letter R is used to indicate a representation of the entity specified in the parentheses. The representation can be a matrix, a wave function, a diagram, or any other representation appropriate to the method being employed in the calculation. The operator $\mathbf{t}^2$ is related to the other operators by the equation $\mathbf{t}^2 = \tfrac{1}{2}(\mathbf{t}^+\mathbf{t}^- + \mathbf{t}^-\mathbf{t}^+) + \mathbf{t}_z{}^2$. (Note that $\mathbf{t}^+$ and $\mathbf{t}^-$ do not commute. Therefore $\mathbf{t}^+\mathbf{t}^-$ does not equal $\mathbf{t}^-\mathbf{t}^+$.) For the case of the nucleon, where we have set up the defining equations to include only two states, $\mathbf{t}^2$ has the eigenvalue $\tfrac{3}{4}$. The formalism may be applied also to other kinds of particles, and the generalized operator $\mathbf{t}^2$ has eigenvalues of the form $t(t + 1)$, where t is either a half-integral or an integral number, and $2t + 1$ is the number of possible states. The value of t is called the *isospin of the particle*. Thus, it may be said that the nucleon is a particle of isospin $\tfrac{1}{2}$. From a general point of view, the relationships stated above may be viewed in terms of a vector operator $\mathbf{t}$ in a fictitious three-dimensional space where

$$\mathbf{t} = \mathbf{t}_x + \mathbf{t}_y + \mathbf{t}_z$$

$$\mathbf{t}^+ = \mathbf{t}_x + i\mathbf{t}_y$$

$$\mathbf{t}^- = \mathbf{t}_x - i\mathbf{t}_y.$$

This space, which we call *isospace*, is mathematically analogous to ordinary coordinate space but represents attributes of electrical charge rather than ordinary positions and lengths. If we represent an object by a vector $|R\rangle$ in isospace, we can determine the length of the vector by forming the scalar product $\langle R\mathbf{t}|\mathbf{t}R\rangle$, which is equivalent in meaning to $\langle R\mathbf{t}^2 R\rangle$. If R is normalized so that $\langle R|R\rangle = 1$ and is an eigenfunction of $\mathbf{t}^2$, we find that

$$\langle R\mathbf{t}^2 R\rangle = t(t + 1)$$

where t may be thought of as the length of the vector. The values that t may have are integers for bosons and half-integers for fermions.

The isospin representations are members of a rotational group in isospace. Starting with a vector $|R\rangle$ one can generate new orthogonal vectors in isospace through the application of the raising and lowering operators $\mathbf{t}^+$ and $\mathbf{t}^-$. The newly created vectors are characterized by the same eigenvalue of $\mathbf{t}^2$ as the original vector but different eigenvalues of $\mathbf{t}_z$. The operations may be pictured as rotations of the vector in isospace, and the set of vectors created in this way are the possible orientations of the vector $|R\rangle$ in isospace that can be generated through rotation alone. There are $2t + 1$ possible orientations. We say that $|R\rangle$ is a member of an *isospin multiplet* of multiplicity $2t + 1$.

The concept of isospin is especially useful whenever one wants to describe a set of particles differing in electrical charge but similar in other attributes. For example, positive, neutral, and negative pi mesons (or pions) may be described as an isospin triplet. To achieve multiplicity three, t must be 1 and the particle must be a boson.

At the time Heisenberg introduced this method of manipulating neutron and proton representations, it might well have looked like a contrived device of questionable utility. However, later in the 1930s, as evidence began to mount that the forces between nucleons were the same whether they were protons or neutrons, except for the additional electrical repulsion between protons, the concept of isospin gained in apparent utility. Eventually, the formalism evolved into something that could be applied to aggregate systems in which the constituents possessed the attribute of isospin, for example, to nuclei.

To gain insight into the physics underlying the concept of isospin one might note that part of the evidence for the charge independence of the nuclear force came from a study of the energy-level structure for mirror nuclei. Mirror nuclei are related to each other by an interchange of their neutron and proton numbers. For example, the nuclei ^{7}Li (3 protons and 4 neutrons) and ^{7}Be (4 protons and 3 neutrons) are a mirror pair and their energy levels accurately match each other except for an overall displacement. This correspondence suggests that it might be useful to view ^{7}Li and ^{7}Be as though one were related to the other as the neutron is related to the proton. The concept of total isospin in a many-nucleon system is defined in a way that is consistent with the single-nucleon formalism and gives meaning to statements of the type $\mathbf{T}^+R(^7\text{Be}) = R(^7\text{Li})$. The concept of total isospin together with a structure model can provide the relationship between the isospin of the nucleus and the arrangement of the constituent nucleons in the nucleus.

In the nuclear shell model, one pictures the nucleus as though it contains a set of single-particle quantum states that result from the sum of the interactions among the nucleons. The different energy levels of the nucleus are then pictured as different combinations of occupancy by the nucleons of the available single-particle states. The similarity of level structure for mirror nuclei suggests that similar sets of single-particle states exist for protons and neutrons.

In an isospin formalism each single-particle state occurs twice, once with $t_z = \frac{1}{2}$ and once with $t_z = -\frac{1}{2}$, and the states are occupied by nucleons. We can define a set of total isospin operators for the aggregate system as follows: The total isospin projection operator $\mathbf{T}_Z$ is the sum of the individual nucleon isospin projection operators, $\mathbf{T}_z = \Sigma_i t_z$. To find its eigenvalue we need only to sum the isospin projection quantum numbers for all the occupied states. We find that the eigenvalue of $\mathbf{T}_Z$ is $T_Z = \frac{1}{2}(N - Z)$, where N is the number of neutrons and Z the number of protons in the nucleus. We can also define total operators corresponding to the other single-nucleon operators that we discussed previously:

$$\mathbf{T}^{+} = \sum \mathbf{t}^{+}; \quad \mathbf{T}^{-} = \sum \mathbf{t}^{-};$$

$$\mathbf{T}^{2} = \tfrac{1}{2}(\mathbf{T}^{+}\mathbf{T}^{-} + \mathbf{T}^{-}\mathbf{T}^{+}) + \mathbf{T}_Z{}^{2}.$$

The operator $\mathbf{T}^{+}$ when applied to a representation of a many-nucleon system changes it to a representation with $T_Z + 1$, if T_Z is the original value. Similarly $\mathbf{T}^{-}$ changes the representation to a new one with $T_Z - 1$. (Certain numerical factors have been omitted for simplicity. Refer to a textbook on quantum mechanics for a more complete treatment of raising and lowering operators.) The operator $\mathbf{T}^2$ has eigenvalues of the form $T(T + 1)$, where T is a number that is referred to as the *total isospin of the system*. (For a definition of eigenvalue, see MATHEMATICAL PRINCIPLES OF QUANTUM MECHANICS). The value of T is always greater than or equal to the absolute value of T_Z and is an integer for nuclei with an even number of nucleons and a half-integer for nuclei with an odd number of nucleons. An arbitrary representation of a many-nucleon system is not necessarily an eigenfunction of $\mathbf{T}^2$, but it can be reexpressed as a linear combination of representations that are eigenfunctions of $\mathbf{T}^2$.

Before the 1960s the concept of total isospin was used in formal classifications of shell model states, but it was not generally believed that the simple eigenfunctions of $\mathbf{T}^2$ would provide useful descriptions of real nuclear states except with respect to mirror nuclei and very light nuclei. It was thought that in a nucleus with a large number of protons the Coulomb force would be strong enough to destroy the approximate symmetry between the proton and neutron states and isospin would not be a useful concept.

The discovery of isobaric analog states[3] gave isospin a new importance in nuclear structure physics. Analog states are energy levels of one nucleus that have a special relationship to energy levels in the neighboring nucleus with the same number of nucleons. If we compare the energy levels of a nucleus A(N, Z) with N neutrons and Z protons, to the energy levels of a nucleus B(N - 1, Z + 1), we find in B a set of levels at high excitation energies that match one-for-one the lowest few levels of A with respect to energy spacing and other properties.

In terms of isospin, analog states can be understood as states that differ only in their isospin projection T_Z. That is, all quantum numbers except T_Z of the state in nucleus A are the same as those of its analog in B. The ground state of a stable nucleus with more neutrons than protons is always characterized by $T = T_Z = (N - Z)/2$. Its analog is characterized by the same value of T, but T_Z is one unit lower, i.e., $T_Z = T - 1$. That state may in turn have an analog in its neighboring isobar with $T_Z = T - 2$, and so on until $T_Z = -T$. States in mirror nuclei are simply analog states with T_Z (for nucleus A) = $-T_Z$ (for nucleus B).

The binding energy of an analog state differs from that of its parent state, and the energy difference is called the *Coulomb displacement energy*. The approximate value of this energy can be calculated in a rather simple way, if one assumes that the nuclear volume is filled with a uniform charge density. Since both parent and analog nuclei have the same number of nucleons, the volumes are the same. For the parent nucleus, the fraction $Z/(N + Z)$ of the nucleons are charged, while for the analog, $(Z + 1)/(N + Z)$ of the nucleons are charged. The value of the Coulomb displacement energy is approximately the difference in the electrostatic energy for spherical volumes of charge densities implied by those two charge fractions. This has the value of about 12 MeV for nuclei of about 100 atomic mass units, for example. In spite of large differences in absolute binding energies, the analog level spacings match those of the parent accurately for nuclei of all masses that have been studied. It thus appears that the similarity between neutron and proton single-particle states persists even when the Coulomb force produces a large change in the absolute binding energies of the states. The effect of the coulomb force is to introduce an approximately uniform shift in the energy levels of nuclei differing only in T_Z.

Isospin considerations can be a guide to certain features of nuclear reactions. For example, a rule of conservation of isospin may be formulated by analogy with the principle of conservation of angular momentum. The rule states that if the initial system—the projectile plus the target—can be characterized by total isospin quantum numbers T and T_z, then the final system will also be characterized by the same values of T and T_z. The conservation of T_z is equivalent to the statement that the total number of protons and the total number of neutrons does not change in a nuclear reaction. The conservation of T implies restrictions on the rearrangements of the nucleons within the nuclei but is not a very strict rule, since it is based on neglect of the Coulomb force between protons. It has been shown, however, that processes that violate the rule are severely inhibited compared to processes that follow the rule. Some broader implications of isospin conservation have been pointed out by Adair.[4]

ISOTOPES

The word *isotopes*, stemming from the Greek word *isos* (same) and *topos* (place), refers to atoms of the same element which have differing masses. The term *isotope* was first proposed by Soddy (1913) to designate substances having different atomic weights and, at the same time, having chemical properties which were so closely allied as to make chemical methods of producing a separation ineffective. Hence, Soddy suggested that they were chemically identical, i.e., they occupied the same place in the periodic table. The term *nuclide* is, perhaps, a more accurate representation, since it is defined as a particular atomic species with an atomic number Z and a mass number A.

In 1905, Boltwood, studying the decay chains of uranium, identified a new element which he called *ionium* and which, when admixed with thorium, could not be separated by any of the known chemical processes. Similar behavior was observed by Soddy and others in other such mixtures. These studies depended on the detection and identification of minute amounts of a substance by observing the type of radiation and the half-life. Indeed, additional evidence came from the observation of the visible spectrum of a mixture of two of these substances and finding no new lines. Further, Boltwood, in his studies, noted the presence of lead in uranium minerals and suggested that lead might be the end product of the uranium series. As a result of the study of the relation of lead to uranium in a large number of minerals, this view was generally adopted. Soddy concluded that the end products of the uranium and thorium series should be lead with isotopic weights 206 and 208, respectively, whereas ordinary lead as found in nature has an atomic weight of 207.2. Soddy and Hyman reported (1914) that the atomic weight of lead as found in thorite, which consists mainly of thorium with 1–2% uranium and 0.4% lead, indeed had a slightly greater atomic weight than that of ordinary lead. It was not, however, until the development of the mass spectrograph (1919) that a detailed study of the occurrence and relative abundance of such species could be accuately made and it was not until the discovery of the neutron (1932) that a satisfactory explanation could be given.

Of the 81 naturally occurring stable elements, 22 elements are anisotopic, i.e., possess one stable isotope. The largest number of stable isotopes occurs in tin, which has ten. Since the atoms in multinuclidic elements are chemically identical and have the same number of protons in the nucleus, the varying masses are accounted for by the variable number of neutrons in the nucleus ($Z = 50$, $A = 112, 114, 115, 116, 117, 118, 119, 120, 122, 124$). Two of the elements below bismuth ($Z = 83$), technetium ($Z = 43$) and promethium ($Z = 61$), do not have any stable nuclides. Table 1 lists, in order of increasing atomic number Z (the charge or number of protons associated with the nucleus) the 106 known elements, and where available, the relative atomic weights. It should be noted that the conflict regarding the Soviet and United States claims to a discovery of elements 104 and 105 continues. The Berkeley workers have proposed the names of *Rutherfordium* for $Z = 104$ and *Hahnium* for $Z = 105$, while the Soviet workers have proposed *Kurchatovium* and *Nielsbohrium*. The International Union of Pure and Applied Chemistry has proposed *Unnilquadium* (Unq, $Z = 104$), *Unnilpentium* (Unp, $Z = 105$), and *Unnilhexium* (Unh, $Z = 106$). Popular usage, however, involves the direct use of $Z = 104$, 105, and 106.

Isotopes are divided into two groups: stable and radioactive (unstable). The total known isotopes number about 1950, of which 280 are stable and the balance are radioactive, having a transient existence ranging from millionths of a second to millions of years. Radioisotopes undergo transformation, or decay, emitting alpha, beta, gamma, or x-radiations during their

Values are those recommended by the Commission on Atomic Weights and Isotopic Abundances, Inorganic Chemistry Division, International Union of Pure and Applied Chemistry, in *Pure and Applied Chemistry*, 52, 2349–2384 (1980).

Values are considered to be ±1 in the last digit or ±3 in the last digit when followed by an asterisk (*).

return to a stable condition. Elements beyond bismuth ($Z = 83$) are radioactive. A clear graphic presentation of isotopes, both stable and radioactive, can be seen in the General Electric Knolls Atomic Power Laboratory "Chart of the Nuclides," now in its twelfth edition (revised to April 1977), where the nuclides are displayed by plotting nuclides of elements in increasing atomic number (Z) against the neutron number (N). (See RADIOACTIVITY).

Isotopes, both stable and radioactive, have continued to grow in importance to science and technology during the past 50 years. Since atoms can be characterized or marked by their radioactivity, or in some cases by a change in isotopic composition, the elements can be traced, a procedure of great value in physical and biological science, technology, and medical diagnosis. Further, radioisotopes emit particulate and/or electromagnetic radiations that can be used to probe into and through matter, affect it chemically and physically, produce heat and light, kill or alter microorganisms, and perform many other functions useful in today's complex industrial/technological society.

Stable Isotopes By 1900, physicists had found that positively charged particles formed by the passage of an electric discharge through an evacuated tube consisted of molecular ions of the gas present in the tube. Deflection of these positive rays by electric and magnetic fields offered a sensitive tool to study gaseous elements. By allowing the rays from a given element to fall on a photographic plate, a series of parabolic streaks were observed, each corresponding to a definite value of mass-to-charge ratio (m/e). Positive ray photographs of neon (atomic weight 20.2) obtained by Thomson exhibited a heavy neon line at mass 20 and a faint line at 22. In an effort to elucidate the situation, Thomson's assistant, Aston, passed neon gas through a porous pipe-clay tube repeatedly and was able to show a significant alteration in the atomic weight of the two extreme fractions. This alteration was reflected in changes in the relative brightness of the two lines in subsequent positive ray analyses.

Aston proceeded to redesign the positive ray apparatus so that the particles having the same mass were brought to a focus to produce a sharp line rather than a parabola; the resulting instrument was called a *mass spectrograph*. With this instrument, Aston was able to confirm the finding that neon exists in at least two forms (atomic weights of 20 and 22) and that the proportions appeared to be 10:1, giving an average atomic weight of 20.2 to neon. Aston next analyzed chlorine and also found that this gave two lines, corresponding to 35 and 37, and in time examined mercury, nitrogen, and the noble gases.

Independently Dempster, working at the University of Chicago, developed a *mass spectrometer* which he used to examine the isotopes of magnesium, lithium, potassium, calcium, and zinc.

Thus the pioneering work of Aston and Dempster in 1918–19 with the electromagnetic mass spectrometer unequivocally demonstrated the isotopic nature of the stable elements and is the historical starting point for separation and study of the isotopes of the elements. The electromagnetic separation of isotopes is relatively simple in principle (see MASS SPECTROMETRY).

Production of Stable Isotopes. There are a number of possible ways of separating isotopes using electromagnetic principles. However, the large-scale *electromagnetic mass separator*, known as a *calutron*, is the device now used predominantly. Within a tank maintained at high vacuum, ions of an element are produced by vaporization at high temperature, sometimes assisted by a chemical agent such as carbon tetrachloride (chlorination). The ions are accelerated by an electric potential and projected as a beam across a magnetic field. The trajectories of these ions are dependent on their masses; hence the path of the lighter ion has a greater curvature than that of the heavier ion. After traversing a circular path of 180–300°, the divergent particle paths are interrupted by catcher pockets, usually made of slots in graphite or copper water-cooled "receivers." The isotopes are then chemically recovered from the receiver pockets.

Only relatively small amounts of material can be separated in the calutron, since it separates the isotopes literally atom-by-atom. Nevertheless, ion currents up to one ampere can be maintained, allowing kilograms of material to be separated in a machine operating over a year's time. Virtually all of the isotopes of the elements have been separated in relatively high purity at Oak Ridge National Laboratory. The details on separated isotopes available and the procedures to be used in obtaining them are given in the ORNL Research Materials Catalogs.

Large-scale gaseous diffusion separation of ^{235}U is accomplished by diffusing uranium hexafluoride (UF_6) gas through a series of several thousand barriers. Because of the repetitive nature of the process, continuous diffusion through thousands of stages, or cascades, gaseous diffusion plants are extremely large industrial facilities.

More recently, large high-speed centrifuges have been developed for the separation of ^{235}U. Because the desired enrichment is not obtained in a single centrifuge, several machines are connected in a series or cascade. The gas centrifuge enrichment technology is economically superior to the gaseous diffusion enrichment process, requiring only 5% as much electrical energy.

Gaseous thermal diffusion is used to separate the noble gas isotopes (krypton, neon, and argon). Liquid thermal diffusion is currently used to separate the isotopes of chlorine, bromine, and sulfur.

Chemical exchange is used with such isotopes as hydrogen and nitrogen.

Cryogenic distillation is used to separate isotopes of carbon, oxygen, and nitrogen.

Electrolysis is used for deuterium separation and distillation and has been used for the enrichment of mercury isotopes.

Laser isotope separation has been used for ^{235}U separation and offers potential for the separation of other ions.

Other than the well-known uses of ^{235}U and ^{3}H in large-scale nuclear work, separated isotopes have been in the past primarily for fundamental scientific work, such as the measurement of nuclear reaction cross sections. There is now, however, a growing utilization of isotopic materials in all fields of fundamental research and as target materials for radioisotope production.

Radioisotopes Some radioisotopes occur in nature, e.g., uranium, radium, and thorium—ordinarily accompanied by their radioactive daughters (decay products). Radioisotopes that occur in nature have half-lives* greater than about 10^8 years or are the decay products of parent radioisotopes of such long-lived radioisotopes. These primordial radioisotopes were produced when the earth was formed and have not yet decayed away in the ensuing several billion years. Of the naturally occurring isotopes of the elements, roughly 280 are stable, and about 25 may be considered naturally radioactive. Some shorter-lived radioisotopes, such as 5530-year ^{14}C and 12.33-year ^{3}H are normally formed by cosmic ray interactions with atmospheric carbon and hydrogen. Irene Curie observed and identified the first artifically induced radioactivity in 1934 by irradiating targets of aluminum, magnesium, and boron with alpha particles from a 100-mCi† polonium source and noting that the targets continued to emit radiation after the alpha source was removed. This discovery offered the first chemical proof of artifical transmutation. After the introduction of the cyclotron and other particle accelerators, many elements were bombarded with deuterons and protons to produce hundreds of new radioisotopes, including the well-known ^{131}I, ^{32}P, and ^{14}C. Large-scale production of radioisotopes, however, did not come about until nuclear reactors were available after World War II to supply enormous amounts of neutrons. The number of artificially produced isotopes had reached 200 in 1937, and with the nuclear reactor as a source of neutrons in World War II, about 450 artificially radioactive isotopes were identified by 1944, and over 1650 by 1977. Each element has at least one radioactive isotope, and some have as many as 30.

The discovery of the first transuranic element, neptunium ($Z = 93$) in 1940 was followed by the identification of the other members of the actinide series ($Z = 89$–103), which are analogous to the lanthanide series or rare earths ($Z = 57$–71), thus completing the series. It is expected that element 104 and element 105 should demonstrate periodic characteristics of hafnium and tantalum, respectively. Indeed, predictions on both the chemical and nuclear basis have been made on the properties of other "superheavy" elements. For example, islands of stability of the elements are predicted around $Z = 114$, $N = 184$ and elements 117–120 lend themselves to reasonably detailed predictions of their macroscopic properties.

Radioisotopes are produced by disturbing a preferred neutron-proton ratio in the nuclei of elements. This is done by adding or removing neutrons, by adding or removing charged particles such as protons, or by a combination of both. Usually, a nuclear reactor is used as the source of neutrons; a cyclotron or other particle accelerator is used as the source of charged particles. The radionuclides formed by increasing the neutron-proton ratio generally decay (or transform) back to a stable configuration by having a neutron transform to a proton, with the emission of a negative electron (beta particles, β^-) and a neutrino (ν)—an almost undetectable uncharged particle of negligible mass (see NUCLEAR REACTIONS):

$$n \rightarrow p + \beta^- + \nu.$$

For those radionuclides resulting from a decrease in the neutron-proton ratio (i.e., neutron-deficient nuclei), the transformation again tends to reverse the cause of instability, and, where energetically possible, a proton in the nucleus is transformed into a neutron, with the emission of a positive electron (positron, β^+):

$$p \rightarrow n + \beta^+ + \nu.$$

In a competing process, neutron-deficient nuclei will regain stability by the capture of an orbital electron (EC). Indeed, it is the only β-decay mode possible for such nuclei when the decay energy (the mass difference between the decaying and product atom) is less than 2 mc^2:

$$p + e^- \rightarrow n + \nu.$$

The electronic vacancy produced in the K (or L, etc.) shell is filled by an electron from a less tightly bound state with the simultaneous emission of an x-ray (characteristic of the product element) or an electron produced by an

*A half-life ($T_{1/2}$) is defined as the time required for one half of an initially large number of radioactive atoms of a given species to decay.

†A curie (Ci) is defined as 3.70×10^{10} disintegrations/second.

internal photoelectric process (*Auger electrons*). These atomic rearrangements following electron capture, particularly in a heavy atom, may involve many x-ray emissions and Auger processes in successively higher shells. The adjustment can be quite extensive and includes such effects as *Coster-Kronig transitions* (Auger effect in the subshells). The *fluorescence yield* is defined as the fraction of vacancies filled by the emission of x-rays. The *Auger yield* is, in a similar fashion, defined as the fraction of vacancies filled by the emission of Auger electrons.

Many radioactive nuclei decay by two or more modes so that β^-, β^+, and EC decay with associated emissions and x-radiation are not uncommon. The *branching ratio* defines the relative amount of each mode of decay.

For heavy nuclei ($Z > 82$), the transformation to a more stable configuration usually takes place by the emission of an alpha particle (α or ^{4}He). As the nuclei become progressively heavier, the half-lives become shorter and the *fission process* becomes more dominant.

In alpha or beta decay processes the product nucleus may be left in either the ground state or, more frequently, in an excited state. A nucleus in an excited state may de-excite by the emission of electromagnetic radiation or photons (γ-radiation). Frequently the gamma transition does not proceed directly to the ground state, but rather may go in several steps involving intermediate excited states. The *angular correlation* between successive gamma rays depends on the multipole character of the radiations and on the spins of the intermediate states. An alternative to gamma-ray emission is the *internal conversion* process, an electromagnetic interaction between the nucleus and the orbital electrons. Thus, the transition between the two energy states of the nucleus is not evidenced by the emission of a photon. Instead the energy is imparted to an orbital electron which is ejected from the atom. The ratio of the internal conversion process to the rate of gamma emission is known as the internal conversion coefficient, α. The internal conversion process leaves the atom with a vacancy in one of the shells. The subsequent atomic rearrangement process is essentially identical to that following electron capture.

For some nuclei, only gamma radiation is emitted for the deexcitation from a metastable or isomeric state. Such decay is termed *isomeric transition* (IT) and is characterized by no change in mass number or atomic number. Here, too, the internal conversion process is a competing process.

Knowledge of the energies and intensities of the particulate radiation (α, β^-, β^+, and e^-) and the electromagnetic radiation (γ-rays and x-rays) serve to characterize a particular nucleus and as such is the principal means, along with the half-life, of identifying the radioisotope. Indeed, transuranic workers, using *Moseley's law*, have used the coincidence between the alpha particles of the parent and the K x-rays of the daughter to simultaneously establish the parent-daughter genetic relationship and the atomic number independently of other nuclear or chemical information.

Production of Radioisotopes. The bulk of the artificially produced radioisotopes are made by neutron reactions in the high-volume neutron fluxes available in NUCLEAR REACTORS. Neutrons, having no charge, can easily penetrate the coulombic barriers of the nucleus. The atomic nuclei of the elements vary in their ability to capture thermal neutrons (i.e., neutrons slowed down to 2200 meters/second or ~0.025 eV) according to their *cross sections*, a term which expresses the probability of interaction of a neutron of a certain energy or velocity (see CROSS SECTIONS AND STOPPING POWER). When target materials are placed in the reactor and subjected to a flux of neutrons (ϕ, number of neutrons traversing a unit area per unit time), neutrons are captured in proportion to cross sections of the target element atoms present. Cross sections are expressed in *barns* (1 barn = 10^{-24} cm^2, which is approximately equal to the actual cross sectional area of a medium-weight nucleus). Certain materials, such as aluminum and graphite, have such small neutron capture cross sections that few neutrons are captured; others, such as cadmium, have such large cross sections that a thin foil will absorb almost all the thermal neutrons impinging upon it.

Radioisotopes are produced in a nuclear reactor by several different processes. Those processes that produce appreciable quantities of radioisotopes are described below.

(1) (n, γ) Process. In the (n, γ) process, which is most common, a neutron is captured by a target and simultaneously a photon is emitted. Since no change of atomic number Z occurs, the element remains the same as the target material. The (n, γ) reaction is primarily a thermal neutron reaction; cross sections for (n, γ) reactions vary from a few millibarns to many thousands of barns. For example:

$$^{23}\text{Na}(n, \gamma)^{24}\text{Na} \qquad (T_{1/2} = 15.02 \text{ h}).$$

The radioelement cannot be separated chemically unless a recoil collection is used. In the *Szilard-Chalmers process*, the recoil energy of the residual nucleus, resulting from the emission of the photon, is greater than the chemical binding energy of the nucleus in a compound.

Radioisotopes produced sometimes decay by beta emission (β^- or β^+) or electron capture to a radioactive daughter with a higher or lower atomic number. For example:

$$^{144}\text{Sm}(n, \gamma)^{145}\text{Sm}$$

$$^{145}\text{Sm} \xrightarrow[(340\text{ d})]{\text{EC}} {}^{145}\text{Pm} \qquad (T_{1/2} = 17.7 \text{ y}).$$

The daughter can be chemically separated to obtain high-specific-activity* material.

With the availability of thermal neutron fluxes well in excess of $2 \times 10^{15}\, n/\mathrm{cm}^2 \cdot \mathrm{sec}$, the preparation of millicurie amounts of radioisotopes by successive (n, γ) reactions has become feasible. For example:

$$^{64}\mathrm{Ni}(n,\gamma)\,^{65}\mathrm{Ni} \qquad (T_{1/2} = 2.520 \text{ h})$$

$$^{65}\mathrm{Ni}(n,\gamma)\,^{66}\mathrm{Ni} \qquad (T_{1/2} = 54.8 \text{ h}).$$

(2) $(n,\ p)$ Process. In the $(n,\ p)$ process, which requires neutrons of higher-than-thermal energies,† a neutron enters a target nucleus with sufficient energy to cause a proton to be released. The atomic number is reduced by 1, and the affected atom is transmuted into a different element, which can be separated chemically from the target material. Through chemical separation, high-specific-activity material can be obtained. For example:

$$^{32}\mathrm{S}(n,p)\,^{32}\mathrm{P} \qquad (T_{1/2} = 14.28 \text{ d}).$$

Cross sections for such reactions, typically a few millibarns, are orders of magnitude less than those for (n, γ) reactions.

(3) $(n,\ \alpha)$ Process. The (n, α) process, like the $(n,\ p)$ process, requires high-energy neutrons and typically has a cross section of a few millibarns. In the (n, α) process, a neutron of high energy enters a target atom and causes an alpha particle to be emitted. The atomic number of the target atom is reduced by 2, and a chemical separation yielding high-specific-activity material is possible. For example:

$$^{36}\mathrm{Cl}(n,\alpha)\,^{33}\mathrm{P} \qquad (T_{1/2} = 25.3 \text{ d}).$$

(4) Fission. Under normal operating conditions, research reactors have 20–50% burnup of the fissile material. The asymmetric fission process yields fission products of mass ranging between $A = 72$ and $A = 162$. The maximum fission yields of 6.5% occur at $A = 95$ and $A = 138$. Since several isotopes of any one element are often produced, the isotopic purity will not be as high as that of radioisotopes produced by $(n,\ p)$ and $(n,\ \alpha)$ reactions. This isotopic purity will depend somewhat upon the length of time that the uranium was exposed to neutrons and upon the elapsed time between removal from the reactor and the chemical separation. Fission products are routinely chemically separated and purified from high-level waste streams of DOE production facilities and represent an important source of such radioisotopes as ^{90}Sr (thermoelectric generator systems for terrestrial and underwater applications), ^{137}Cs (radiography, teletherapy, and large irradiation units), and ^{147}Pm (thermoelectric power generators).

The basic equation for radioisotope production is

$$\mathrm{A} \xrightarrow[\sigma_\mathrm{A}]{} \mathrm{B} \longrightarrow \xrightarrow[\sigma_\mathrm{B}]{\lambda_\mathrm{B}}$$

The target atom A captures neutrons to produce the product nuclide B, which in turn is transformed by decay or further neutron capture. The effective cross sections σ_A, σ_B and the decay rate constant λ_B enable the rate and equilibrium values for the transformation to be calculated for any particular irradiation conditions. The exact solution for the differential equation describing these rate processes for the number of atoms N of the product formed at time t in neutron flux ϕ is,

$$\lambda_\mathrm{B} N_\mathrm{B} = \frac{\lambda_\mathrm{B}\,\phi\sigma_\mathrm{A} N_\mathrm{A}}{\lambda_\mathrm{B} + \phi[\sigma_\mathrm{B} - \sigma_\mathrm{A}]} \cdot [e^{-\phi\sigma_\mathrm{A} t} - e^{-(\phi\sigma_\mathrm{B} + \lambda_\mathrm{B})t}].$$

In most cases, one can neglect the burnup of the target atoms and the product radioisotope. In such cases, the above equation then reduces to:

$$\lambda_\mathrm{B} N_\mathrm{B} = N_{\mathrm{A}_0}\,\phi\sigma_\mathrm{A}(1 - e^{-\lambda_\mathrm{B} t}).$$

Here N_{A_0} refers to the number of original target atoms at time zero.

For irradiations of sufficient length ($t \gg T_{1/2}$), and again neglecting burnup, the saturation factor $(1 - e^{-\lambda_\mathrm{B} t})$ approaches 1 and the equation further reduces to

$$\lambda_\mathrm{B} N_\mathrm{B} = N_{\mathrm{A}0}\,\phi\sigma_\mathrm{A}.$$

With the introduction of the *cyclotron* in the early 1930s, charged particle reactions started to play a significant role in the preparation of a large variety of neutron-deficient radioisotopes. Indeed, until the advent of nuclear reactors in the mid-1940s, proton-, deuteron-, and alpha-particle accelerators played the major role in supplying radioisotopes for medical, biological, and scientific research. During the period 1950–1970, the ORNL 86-Inch Cyclotron exploiting a 2.6-mA (2×10^{16} particles/sec) beam of 23-MeV protons, supplied the major portion of neutron-deficient radioisotopes. With the development of *compact cyclotrons*, the production and use of short-lived radioisotopes for medical purposes has gained impetus. Both hospitals and radiopharmaceutical and radiochemical organizations have found these cyclotrons extremely useful. Indeed, one organization is utilizing five such

*Specific activity is the amount of radioisotope per unit weight of the total element and is usually expressed as curies or millicuries/gram.

†A few exceptions are found among reactions with the light nuclei in cases where binding energy of a proton or particle is appreciably lower than that of a neutron: the reactions $^{10}\mathrm{B}(n,\ p)\,^{10}\mathrm{Be}$, $^{14}\mathrm{N}(n,\ p)\,^{14}\mathrm{C}$, $^{35}\mathrm{Cl}(n,\ p)\,^{35}\mathrm{S}$, $^{10}\mathrm{B}(n,\ \alpha)\,^{7}\mathrm{Li}$. and $^{6}\mathrm{Li}(n,\ \alpha)\,^{3}\mathrm{H}$ occur with thermal neutrons.

accelerators. Hospitals have found these accelerators particularly useful in producing short-lived radionuclides such as 20.38-m ^{11}C, 9.96-m ^{13}N, 122 s ^{15}O, and 109.8 m ^{18}F for on-site diagnostic procedures. *Heavy-ion accelerators*, developing beams of carbon, nitrogen, oxygen, neon, and argon, have opened additional areas for research. These devices, in conjunction with on-line mass separators, should make possible the production and identification of more of the 5000 or so theoretically possible nuclei. The Brookhaven Linac Isotope Producer (BLIP) and the Los Alamos Scientific Laboratory High Flux Meson Facility (LAMPF) offer the possibility of producing large amounts of neutron-deficient radioisotopes by high-energy proton-induced spallation reactions using 200-MeV and 750-MeV protons, respectively. Most recently, the completion of the Oak Ridge National Laboratory Holifield Heavy Ion Research Facility (HHIRF), a facility utilizing a 25-million-volt tandem electrostatic accelerator and the Oak Ridge Isochronous Cyclotron, makes it possible to accelerate ions up to the mass region of 160, i.e., rare earth elements, to the energies required to produce nuclear reactions, and extends the capability for creating nuclear species far from stability.

A method for preparing short-lived radioisotopes off-site has found widespread use in nuclear medicine. The radioisotope generator employs a relatively long-lived parent which is sorbed onto an ion exchanger; the short-lived daughter may be eluted, as required, with a suitable agent. The most common such system, the ^{99}Mo–^{99m}Tc generator, yielding 6.02-h ^{99}Tc pertechnetate, has been established as a powerful tool for diagnostic scanning and has largely supplanted the use of ^{130}I. Other generators include the ^{87}Y–^{87m}Sr (2.83 h) and the ^{113}Sn–^{113m}In (99.5 m) systems.

Recent advances in *transuranic* isotope technology have made possible the production of large quantities of these radioisotopes. The original neutron irradiations to produce such nuclei were performed in the Oak Ridge and Hanford reactors in the 1940s, in the NRX reactor at Chalk River Laboratory in Canada in the late 1940s, and in the Materials Testing Reactor (MTR) in Idaho, in the 1950s. Both neutron irradiation and charge particle bombardment were used to produce and identify about 50 transplutonium nuclides covering the atomic number range up through $Z = 103$ and mass range up through 257. During the 1960–1970 period, the Savannah River reactors and the High Flux Isotopes Reactor (HFIR) at the Oak Ridge National Laboratory were used for large-scale production of an additional 50 transplutonium isotopes in milligram and gram quantities. Indeed, several grams of ^{252}Cf have been produced since 1966. Milligrams of materials such as ^{252}Cf and ^{241}Am represent excellent fission sources of neutrons presenting peak thermal neutron fluxes of $10^8\,n/\text{cm}^2 \cdot \text{sec}$ (compared to $10^5\,n/\text{cm}^2 \cdot \text{sec}$ for a 1-g radium source mixed with beryllium). (See TRANSURANIUM ELEMENTS.)

Isotope Processing The techniques used for the processing of ultrahigh-purity chemicals are required for isotope work in recovering stable isotopes, preparing target materials, and separating and purifying radioisotopes. Practically every technique from traditional wet chemistry to ion exchange and chromatography is utilized, often with high-purity radioisotopes, at very low concentration levels (e.g., micrograms per liter). Sophisticated analytical methods (e.g., mass and radiation spectral analysis) are also required and make up a significant portion of the cost of isotope preparations.

The size of the radioisotope industry has not changed much during the past decade; about 100 private firms produce radioisotopes, radiopharmaceuticals, sealed sources, and equipment for medical, industrial, and scientific uses of radioisotopes. The magnitude of sales, however, has increased dramatically. Whereas in 1970 the U.S. estimated sales were more than $50 million, now, in 1982, a single firm has gross sales of substantially greater magnitude: New England Nuclear, a major supplier, reports net sales of $66 million for 1979 and $82 million for 1980. It is estimated that the annual sales of ^{99}Mo and associated generators well exceeds $50 million (perhaps as high as $100 million), ^{201}Ti exceeding $30 million, and ^{67}Ga exceeding $10 million. To place it in another perspective, approximately 225,000 thallium doses were administered to patients in the United States in 1980. Sales of stable isotopes at Oak Ridge National Laboratory exceed $4 million annually, that for radioisotopes is $6 million, and that for heavy elements (^{241}Am, ^{234}U, ^{229}Th, and others) exceeds $4 million. The overall market today is in the tens of billions of dollars.

It is estimated that 17 million in vivo and 100 thousand in vitro nuclear studies were made during 1980, a figure which corresponds to one out of every two or three hospitalized patients plus a large number of outpatients (275 thousand/day). There are about 22,000 individuals in the United States practicing nuclear medicine.

KEPLER'S LAWS OF PLANETARY MOTION

The German astronomer and mathematician Johannes Kepler (1571–1630) worked briefly with the Danish astronomer Tycho Brahe, who gathered some of the most accurate observational data on planetary motion in the pretelescope era. When Brahe died in 1601, Kepler inherited his data books and devoted many years of intensive effort to finding a mathematical description for the planetary motion described by the data. Kepler was successful in deriving three laws of planetary motion which led ultimately to our current understanding of the orbital motion of planets, moons, and comets, as well as man-made satellites and spacecraft. The first two laws were published in 1609, about the time Galileo was first making astronomical observations with his telescope; the third law did not appear until a decade later, in 1619.

Briefly stated, these laws are (see Fig. 1):

1. The orbit of each planet is an ellipse with the sun at one focus.
2. The line from the sun to a planet sweeps out equal areas inside the ellipse in equal lengths of time.
3. The squares of the orbital periods of the planets are proportional to the cubes of their mean distances from the sun.

1. The *first law* describes the geometrical shape of the orbit as an ellipse, which correctly accounts for the manner in which the distance from the sun to the planet changes as the planet travels along its orbit. As shown in Fig. 1, the perihelion is the point in the orbit at which the planet is closest to the sun; the aphelion is the point farthest from the sun.

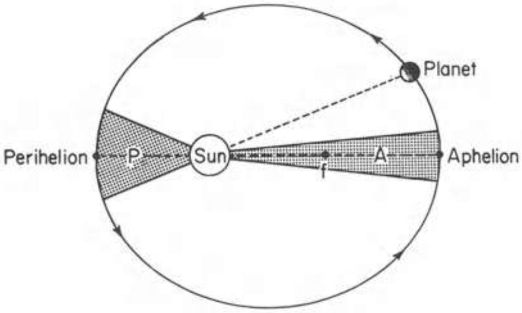

FIG. 1. Elliptical orbit of a planet with the sun at one focus. Equal areas P and A are swept out in equal lengths of time. (Taken from Second Edition article by Richard M. Sutton.)

Prior to Kepler's time, it was assumed that the planetary orbits were concentric circles with the sun at the center, because it was thought that only the perfect geometrical curve of the circle could describe the motion through the heavens of perfect celestial bodies. However, as the accuracy of the observational data increased, it became clear that the distance from the sun to each planet was not constant, as it would be for a circular orbit. Increasingly complicated geometrical constructions using several circles were proposed in an attempt to fit the data for an individual planet orbit. Kepler was the first person to recognize that an ellipse, rather than a circle, is the geometrical curve which describes the shape of a planet orbit in a simple and elegant manner.

2. The *second law* is a concise mathematical description of the observed fact that the rate at which the sun-planet line rotates through space (the angular velocity of the motion) increases as the planet moves closer to the sun and decreases as it moves farther from the sun. As shown in Fig. 1, the distance along the orbit traveled by the planet near perihelion in a given length of time (for example, one month) is greater than the distance travelled near aphelion during the same length of time. This phenomenon is described quantitatively by the statement that equal areas are swept out in equal lengths of time. The time required to sweep out the total area inside the ellipse is the orbit period of the planet.

3. The first two laws describe the motion of an individual planet. By contrast, the *third law* states the manner in which the motions of the various planets are related to each other. It states that the ratio formed by dividing the square of the orbit period of any planet by the cube of its mean distance from the sun is the same value for all planets in the solar system. The term *mean distance*, as used in the third law, is simply the average of the perihelion and aphelion distances. This mean distance is then half the distance between perihelion and aphelion, and is called the *semimajor axis* of the

ellipse. Another way of stating the third law is that the period of a planet is proportional to the 3/2 power of its mean distance from the sun.

Kepler, to his credit, formulated these three laws based entirely on empirical data, without the benefit of a fundamental theory which explained why planetary motion satisfied these laws. The missing ingredient was the concept of gravitational force, which was developed several decades later by Sir Isaac Newton. Newton, starting with Kepler's first law, deduced that a planet whould move in an elliptical orbit with the sun at one focus only if the force exerted on the planet by the sun was proportional to the inverse square of the distance between them. This is the so-called *inverse-square law* of gravitational force. Newton also showed that Kepler's second law was a consequence of the principle of conservation of angular momentum. The angular momentum is conserved because the gravitational force is a central force, that is, it acts along the line from the planet to the central body, the sun. The third law is a natural consequence of the inverse-square gravitational force field of the sun, which exists throughout the solar system. It is interesting to note that the motion of any body orbiting the sun in a closed, periodic orbit is governed by this same force law and must satisfy Kepler's laws. Thus the motion of comets, asteroids, and interplanetary spacecraft, such as the Mariner spacecraft launched to Mars in 1969 and the Voyager spacecraft launched to Jupiter in 1977, are governed by these same laws.

One can easily verify Kepler's third law using modern astronomical data for the planetary orbits. If one plots the orbit periods of the planets against their mean distances from the sun on a log-log graph as shown in Fig. 2, a straight line of slope 3/2 connects the points, indicating that the orbit period T is proportional to the 3/2 power of the mean distance R. The unit of distance used in the figure is the astronomical unit (A.U.), which is approximately 150 million kilometers or 93 million miles.

In the few minutes it takes to plot the graph, one can discover what it took Kepler ten years to find! The data for the planets beyond Saturn (unknown to Kepler) also lie on this same straight line. It is interesting to also note that Halley's comet, which orbits the sun with a period of 76 years at a mean distance from the

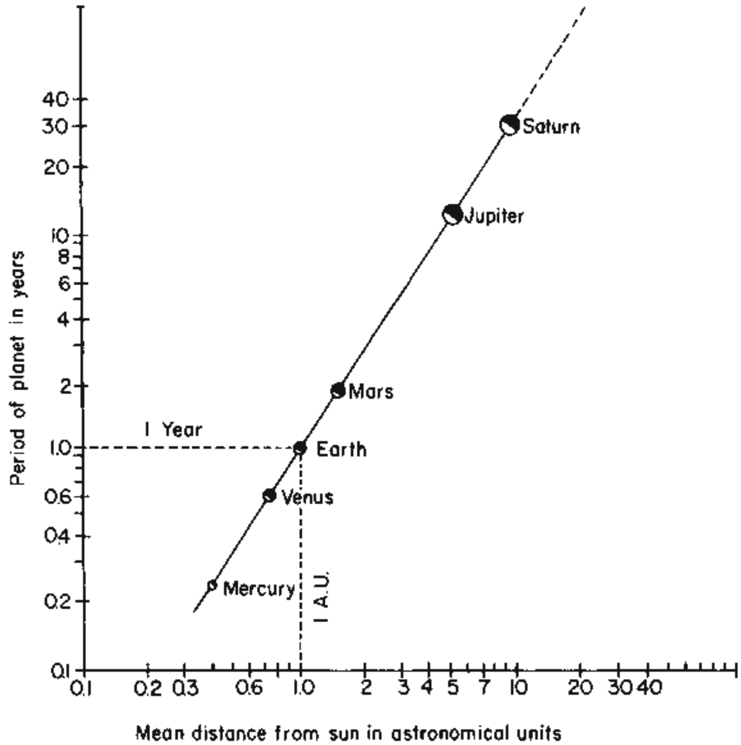

FIG. 2. Graph on log-log paper of periods of planets in years vs mean distance from sun in astronomical units (sun-earth distance is 1 A.U.). (Taken from second edition article by Richard M. Sutton.)

sun of 18 A.U. also falls on the same straight line.

The motion of Halley's comet, which will cross the earth's orbit in 1986, also provides a dramatic example of one consequence of Kepler's second law (the conservation of angular momentum). In order to satisfy this law, the ratio of`the speed of the comet at perihelion to its speed at aphelion must equal the ratio of the aphelion to perihelion distances from the sun. Since the aphelion distance is 35.3 A.U. (outside of Neptune's orbit) and its perihelion distance is 0.6 A.U. (inside the earth's orbit at 1 A.U.), the speed of the comet at perihelion is nearly 60 times its speed at aphelion.

The magnitudes of the speeds of the planets are enormous by earth-based standards. Because the orbit of the earth is very nearly a circular orbit of radius 1 A.U., the distance travelled by the earth in one year is approximately 2π A.U. (the circumference of the circular orbit). Dividing this distance by the elapsed time of one year gives the value of the unit of speed called the EMOS, for *earth-mean-orbital-speed.* One EMOS is equal to about 30 kilometers per second or 67,000 miles per hour. Thus the reader, sitting motionless relative to his or her surroundings, is actually traveling at this enormous speed around the sun. The EMOS is a convenient unit of speed used in mission planning for interplanetary spacecraft.

Kepler's laws also apply in the case of man-made or natural satellite orbital motion about a planet, such as the earth. In this application, the central body is the planet rather than the sun. If the satellite is close to the planet in relation to the distance from the sun to the satellite, the planet's gravitational force on the satellite is much greater than the gravitational force due to the sun. The satellite is then said to be *inside the sphere of influence of the planet.* The earth's moon and all artificial satellites closer to the earth are well within the earth's sphere of the influence because the sun is 400 times farther from the moon than is the earth. (Recall that the gravitational force is inversely proportional to the *square* of the distance).

Figure 3 illustrates on a log-log graph the periods in hours of satellites orbiting the earth plotted against their mean distances from the center of the earth, measured in units of earth radii. As in the case of the planetary orbits about the sun shown in Fig. 1, the graph is a straight line of slope 3/2, illustrating Kepler's

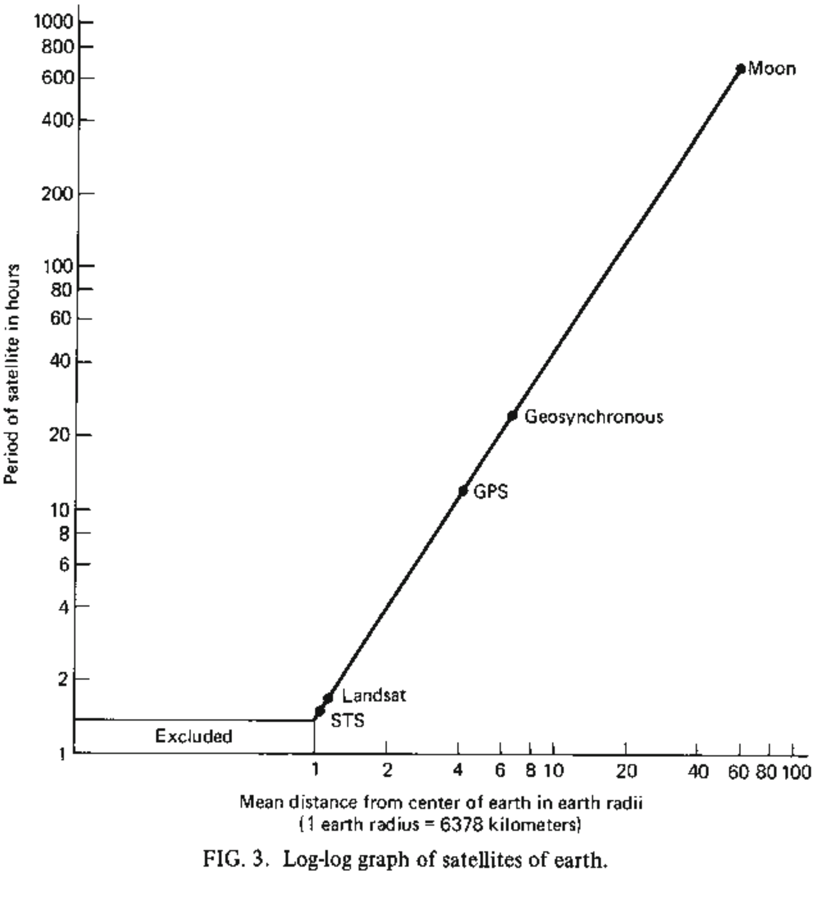

FIG. 3. Log-log graph of satellites of earth.

third law. The sphere of influence of the earth is located at approximately 150 earth radii from the center of the earth.

The lower left-hand region of the graph is excluded because no satellite can continually orbit the earth if its mean distance from the center of the earth is less than one earth radius, equal to 6378 kilometers, or approximately 4000 miles. In fact, the minimum mean distance is slightly greater than this value by a hundred kilometers or so because of the layer of atmosphere surrounding the earth. Satellites entering the atmosphere burn up due to the heat caused by atmospheric drag. However, if one for a moment imagines a fictitious satellite orbiting the earth at tree-top level and ignores the effect of atmospheric drag, the orbit period would be approximately 84 minutes or 1.4 hours, at an orbit speed of approximately 8 kilometers per second (about 18,000 miles per hour). This enormous speed is necessary in order to overcome the gravitational force attempting to pull the satellite down to the surface of the earth.

The satellites shown in Fig. 3 include the STS-1, the first orbital flight of the Space Transportation System, (the Space Shuttle), which was in orbit April 12–14, 1981. The Space Shuttle orbited the earth at an *altitude* of approximately 278 kilometers with an orbit period of 90 minutes. The altitude of a satellite is defined as the distance above the surface of the earth. The distance from the center of the earth is calculated by simply adding the altitude of the satellite to the radius of the earth. The Landsat satellites, which photograph the earth's surface, have an altitude of 920 km and a period of 1.7 hours.

Another satellite shown is a NAVSTAR GPS (Global Positioning System) satellite. A collection of these satellites are in orbits having 12-hour periods, and provide precision navigation information for ships and aircraft on or near the surface of the earth. Also shown is a geosynchronous satellite, which has an orbit period of one sidereal day, equal to 23 hours, 56 minutes, and 4 seconds (the period of the daily rotation of the earth relative to the distant stars). The orbital motion of geosynchronous satellites is synchronized with the daily rotation of the earth, causing these satellites to remain directly over fixed points on the surface of the earth at the equator. Geosynchronous satellites are used for radio, television, and other forms of communication over large distances on the earth. An example is the satellite WESTAR I, which is located above the equator at 99° west longitude. The earth's moon is also shown on the same straight line on the graph with its sidereal period of 27.3 days.

For a satellite in an elliptical orbit about the earth, the points in orbit nearest and farthest from the center of the earth are termed *perigee* and *apogee*, respectively. Data for satellite orbits is usually given in terms of perigee and apogee altitudes. To calculate the mean distance from the center of the earth for use in Fig. 3 to determine the orbit period, one simply adds the radius of the earth (6378 km) to the mean altitude (the average of the perigee and apogee altitudes). For example, a satellite having a perigee altitude of 1548 kilometers and an apogee altitude of 1800 kilometers has a mean altitude of 1674 km and a mean distance from the center of the earth of 8052 km, or about 1.3 earth radii. Referring to the graph of Fig. 3, this corresponds to an orbit period of 2 hours.

Other types of orbits besides ellipses are possible in an inverse-square gravitational force field, namely ***parabolic*** and ***hyperbolic*** orbits. These were entirely unknown to Kepler, who was only aware of closed, periodic orbits. Parabolic and hyperbolic orbits are open, in the sense that they do not close on themselves, but instead extend to infinity on either side of the central body. The motion along these orbits does not periodically repeat and Kepler's first and third laws do not apply in this case. However, Kepler's second law is still valid because angular momentum is conserved. Thus, Kepler derived a law which applies to orbits which he did not even know existed! Parabolic and hyperbolic orbits occur when the speed of the orbiting body is too great for the body to be captured by the central body. For this reason these types of orbits are also termed *escape orbits.*

Figure 4 shows an example of a hyperbolic orbit, the flyby of the planet Jupiter by the

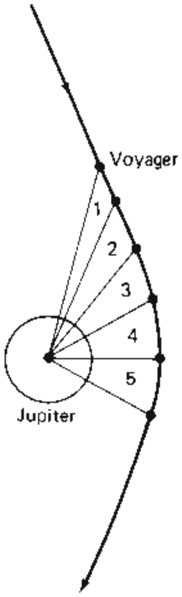

FIG. 4. Hyperbolic flyby of Jupiter by Voyager spacecraft. Numbered areas are equal and are swept out in equal lengths of time.

Voyager I spacecraft in March 1979. The spacecraft made a single high-speed passage by the planet and proceeded on to the next destination, the planet Saturn. The orbit is curved toward the planet due to the gravitational force of the planet pulling on the spacecraft.

Other examples of hyperbolic orbits are the orbits of the two Voyager spacecraft about the sun after their encounters with Jupiter in March and July of 1979. During their Jupiter flybys, the spacecraft were accelerated by the gravitational force of the massive planet to speeds which placed them on escape orbits from the solar system. After their subsequent encounters with the other planets, they will proceed out of the solar system into our galaxy never to return. As they escape the solar system on hyperbolic orbits, which were unknown to Kepler, their motion satisfies Kepler's second law, derived almost 400 years ago.

KERR EFFECTS

In electrooptics and nonlinear optics, a change in the index of refraction of a medium that is proportional to the square of an electric field or to the product of two electric fields is termed a *Kerr effect.*[1] In magnetooptics, various field-dependent changes in the polarization of a light beam reflected from the surface of a magnetized material are also called Kerr effects.[2] The details of the physics underlying each of these classes of phenomena depend upon the experimental conditions and the medium.

The electrooptic Kerr effect is intrinsically anisotropic; the index of refraction for light polarized along the direction of the field is altered by an amount different from that for light polarized perpendicular to the applied field. In a typical experiment a dc field is applied at 45° to the polarization of the incident light and the field-induced birefringence $\delta n_\parallel - \delta n_\perp$ causes the output beam to become elliptically polarized.[3] This change in polarization can be readily measured; the phase retardation due to the Kerr effect is proportional to a constant characteristic of the material and the length of the sample and inversely proportional to the wavelength.

In liquids and other optically isotropic media a dc Kerr constant is usually defined as:

$$B = \frac{\delta n_\parallel - \delta n_\perp}{\lambda |E|^2}$$

where λ is the wavelength in vacuum. The individual molecules of such media are often highly anisotropic with dipole moments μ oriented along a definite molecular axis as well as (frequency-dependent) dielectric polarizability tensors $\alpha_{ij}(\omega)$ with different values along each of three orthogonal directions. The overall isotropy of the medium results from the random orientations of the individual molecules. If the molecules are free to rotate, an applied electric field can perturb the initial random distribution of molecular orientations, causing more molecules to align parallel to the field than perpendicular to it. This realignment causes the majority of the birefringence detected in the Kerr effect.[1] Even when the molecular orientations are fixed, the applied field can perturb electronic energy levels. The change in energy of electronic transitions is called the *Stark effect*, and can often be detected as a shift or splitting of an absorption band. Since every absorption band causes dispersion in the index of refraction that extends to wavelengths beyond the absorption itself, the shift in energy levels implies a change in the index of refraction that contributes to the Kerr effect and is characterized by an electronic hyperpolarizability tensor γ_{ijkl}. The dc Kerr constant for a liquid composed of uniaxial molecules where the three components of the molecular polarizability tensor at zero frequency are $\alpha_{11}(0)$ and $\alpha_{22}(0) = \alpha_{33}(0) = \alpha_{11}(0) + \Delta\alpha(0)$ and the corresponding polarizabilities at optical frequencies are $\alpha_{11}(\omega)$ and $\alpha_{11}(\omega) + \Delta\alpha(\omega)$ and where the dipole moment is along α_{11} can be expressed as:

$$B = \frac{\pi N}{n\lambda}\left(\frac{n^2+2}{3}\right)^2\left(\frac{\epsilon+2}{3}\right)^2 \cdot \left[2\langle\gamma_{xyyx}\rangle + \frac{\Delta\alpha(0)\,\Delta\alpha(\omega)}{15kT} + \frac{\mu^2\,\Delta\alpha(\omega)}{15k^2T^2}\right].$$

In this equation N is the number density per unit volume, ϵ is the dc dielectric constant, $\langle\gamma_{xyyx}\rangle$ is the orientationally averaged molecular hyperpolarizability, k is Boltzmann's constant, and T is the absolute temperature. When $\mu \neq 0$ the term proportional to μ^2 usually dominates, while $\langle\gamma_{xyyx}\rangle$ is significant only for highly symmetric molecules such as CCl_4. The dc Kerr constant of nitrobenzene is 3.26×10^{-5} cm/statvolt^2 at $\lambda = 589$ nm, which is an order of magnitude larger than the constants for other simple molecules.[4] Nematic liquid crystals can show even larger effect, however.

In crystals, the polarization subscripts of the nonlinear susceptibility tensor must be referred to crystallographic axes. A quadratic field dependence of the index of refraction ellipsoid results from the Kerr effect, but is often called the *quadratic electrooptic effect*. It is smaller and less important technologically than the *linear electrooptic* or *Pockels effect*, which only occurs in noncentrosymmetric crystals.[5]

The optical Kerr effect occurs when the applied or orienting field is at optical frequency ω_1. The definition of the dc Kerr constant above can be modified to describe some effects expected in the optical case. The direction of a static dipole moment cannot reverse fast enough to follow a rapidly oscillating optical field so the third term in the equation for B vanishes. Also the dielectric constant ϵ must be replaced with the square of the index of refraction at the frequency of the applied field and the dc molecular anisotropy $\Delta\alpha(0)$ must be replaced by the optical frequency value $\Delta\alpha(\omega_1)$.[6] Additional complexities, however, result from the presence of resonances in the optical Kerr constant at a variety of optical frequencies.

The optical Kerr effect and its many variations are best discussed in terms of a third order nonlinear susceptibility tensor $\chi^{(3)}_{ijkl}(\omega_2, -\omega_1, \omega_1, -\omega_2)$ where the components of the dielectric polarization density is written as $P_i = \Sigma_j\, \chi_{ij}E_j \;+\; \Sigma_{kj}\, \chi^{(2)}_{ijk}E_jE_k \;+\; \Sigma_{jkl}\, \chi^{(3)}_{ijkl}E_jE_kE_l$.[7] In the Maker-Terhune convention, the frequency ω_2 is that of the optical probe, while the frequency ω_1 (which may be zero) describes the applied field. The subscripts relate to the polarization directions of the field, and each of the four subscripts is paired with the frequency at the corresponding position in the argument. Thus an applied field at frequency ω_1 in the x direction causes a change in the index of refraction in the direction parallel to the field:

$$\begin{aligned}\delta n_x &= \delta n_{\parallel}\\ &= \frac{24\pi}{n}\, \chi^{(3)}_{xxxx}(\omega_2, -\omega_1, \omega_1, -\,\omega_2)\,|E_x|^2,\end{aligned}$$

while, perpendicular to the field,

$$\begin{aligned}\delta n_y &= \delta n_{\perp}\\ &= \frac{24\pi}{n}\, \chi^{(3)}_{yxxy}(\omega_2, -\omega_1, \omega_1, -\omega_2)\,|E_x|^2\end{aligned}$$

in cgs units. These index of refraction changes cause self-focusing of high-power laser beams in most media.

Coherent beams crossing in a Kerr medium create an interference pattern of bright and dark fringes. The optical Kerr effect makes the index of refraction in the region of the dark fringes different from that in the bright fringes, creating a grating which can Bragg scatter other beams. The scattered beam contains information carried by the initial beams; the overall process has been widely studied and is generally termed *real-time holography*.

The tensor nature of the nonlinear susceptibility complicates the description of many technologically important applications of the optical Kerr effect. If the applied field at frequency ω_1 has projections $E_x(\omega_1)$ and $E_y(\omega_1)$ along the x and y axes, the field alters the polarization of a probe beam at frequency ω_2 in an otherwise optically isotropic medium. If the probing field is initially polarized along x, the birefringence of a sample of length l creates a component polarized along y with amplitude

$$\begin{aligned}E_y(\omega_2) = \frac{-12il}{n(\omega_2)\lambda_2}\, \{\chi^{(3)}_{yxyx}(\omega_2, -\omega_1,\\ \omega_1, -\omega_2)E^*_x(\omega_1)E_y(\omega_1)\\ +\chi^{(3)}_{yyxx}(\omega_2, -\omega_1, \omega_1, -\omega_2)\\ \cdot\, E_x(\omega_1)E^*_y(\omega_1)\}\, E^*_x(\omega_2)\end{aligned}$$

where $i = \sqrt{-1}$ and an asterisk denotes the complex conjugate.

Because the molecular reorientations can occur on a picosecond time scale, the optical Kerr effect can be used as a high-speed shutter. A cell filled with a Kerr liquid such as CS_2 is placed between crossed polarizers. A powerful 10-picosecond-long laser pulse, linearly polarized at 45° to the axes of the polarizers and incident from the side, can induce sufficient birefringence to permit rapidly occurring processes to be photographed.[8]

The nonlinear susceptibilities describing the optical Kerr effect show resonances and dispersion similar to the index of refraction, but often depending on more than one frequency. These effects have been exploited in "polarization spectroscopy," Raman induced Kerr effect spectroscopy, and other laser spectroscopy techniques.[9] These techniques benefit from the sensitivity with which polarization changes can be detected. In the polarization spectroscopy version of saturation spectroscopy, all the fields have the same frequency, but propagate in opposite directions through an absorbing vapor. When the laser frequency approaches that of a transition in the vapor, a field-dependent birefringence (and dichroism) can often be induced. In vapors at low density, the widths of the nonlinear resonances can be much less than that of the absorption itself.

In Raman induced Kerr effect spectroscopy, the difference of the input frequencies $\omega_1 - \omega_2$ must approach that of a Raman active vibration of the medium. Again a resonant Kerr effect occurs—accompanied by dichroism at exact resonance. The nonresonant part of the Kerr effect can be suppressed by using circularly polarized light for the applied field (i.e., $E_x(\omega_1) = \pm iE_y(\omega_1)$). Two-photon-absorption-induced birefringence occurs when the sum of the input frequencies approaches a two-photon transition. Dramatic polarization rotations occur when the applied field is circularly polarized.

The magnetooptic Kerr effects result from the different phase velocities of left and right circularly polarized light propagating along a magnetic field (see FARADAY EFFECT). This difference in phase velocity can be interpreted as a difference in the indices of refraction for the two polarization states. Fresnel's laws of reflection then imply that right and left circularly (or elliptically) polarized light will be reflected with different amplitudes and phases at the surface of a magnetized medium. Since linearly polarized light can be decomposed into circular (or elliptical) components, the difference in Fresnel coefficients implies that the reflected light will be elliptically polarized with major axis rotated from the initial polarization plane.[2]

If linearly polarized light is normally incident upon the surface, and if the magnetization is perpendicular to the surface, the rotation angle of the major axis of the ellipse is

$$\theta_K = -\text{Im}\left\{\frac{n_+ - n_-}{n_+ n_- - 1}\right\}$$

and the ellipticity of the reflected light is

$$\epsilon_K = -\text{Re}\left\{\frac{n_+ - n_-}{n_+ n_- - 1}\right\}$$

where $n_\pm = N_\pm - iK_\pm$ is the complex index of refraction for right (+) or left (−) circularly polarized light and Re and Im denote the real and imaginary parts, respectively. Both θ_K and ϵ_K are typically very small with θ_K less than 10 minutes of arc for the ferromagnetic metals.

If the light is not normally incident, there are three cases. (1) In the *polar Kerr effect*, the magnetization is normal to the surface, and the complex Fresnel reflection coefficients for *s* and *p* polarized incident light result in elliptically polarized reflected light. (2) In the *longitudinal Kerr effect*, the magnetization is parallel to the surface and lies within the plane of incidence. Again, linearly polarized incident light becomes elliptically polarized upon reflection. (3) In the *equatorial Kerr effect*, the magnetization is parallel to the surface and perpendicular to the plane of incidence. Light polarized along the magnetization (*s*-polarization) is *unaffected* by the magnetic field, while *p* polarized light has a reflection coefficient that contains a term *linear* in the magnetization. In absorbing materials the intensity of the reflected light will depend upon the sign of the magnetization. The equatorial Kerr effect has been an important tool for studying absorbing magnetic materials such as ferromagnetic metals.[10]

The polar Kerr effect has been exploited in magneto-optical memories for computer and video applications. A film of magnetic material can be magnetized with small domains having magnetic fields either up or down. An incident plane wave is reflected with polarization detectably rotated one way or the other by different domains. Up magnetization can be interpreted as a binary 1 while down magnetization would be binary 0. Such domains can be produced with dimensions as small as a wavelength of light by heating the film with a focused laser beam in a magnetizing field and allowing it to cool through a curie or compensation temperature. The calculated information density would be greater than 10^8 bits/cm^2.

KINETIC THEORY

The kinetic theory is a branch of THEORETICAL PHYSICS developed in the nineteenth century to explain and calculate the properties of fluids. It is most useful for studying the physical properties of gases, but it can also be applied to liquids, electrons in metals, and neutrons passing through solids. The word "kinetic" means "pertaining to motion," in this case the motion of molecules or subatomic particles.

Historical Development The first attempt to develop a kinetic theory of gases was made in 1738 by the Swiss mathematician Daniel Bernoulli. Bernoulli began with the idea that matter consists of tiny atoms moving about rapidly in all directions, which the Greek philosopher Democritus had presented, but was unable to prove. Bernoulli showed that the collisions of atoms against the walls of a container would produce a pressure which would be inversely proportional to the total volume of the container; he assumed that the space occupied by the atoms themselves is negligible compared to the total volume of the container and that the rest of the space is empty. He also found that the pressure would be directly proportional to the kinetic energy of motion of the atoms if the velocities of the atoms are changed while the volume is kept fixed. (The kinetic energy of an atom is half its mass multiplied by the square of its velocity.)

The British scientist Robert Boyle had already shown in 1662 that the pressure of air varies inversely as its volume if the temperature is held constant (see GAS LAWS). Thus Bernoulli's theory was able to explain a well-known fundamental property of air and other gases, It was also known that the pressure of a gas confined in a fixed volume increases with temperature. However, it was not until about 1800 that there was enough experimental evidence, and an accurate enough temperature scale, for Gay-Lussac (French) and others to establish a quantitative relation between pressure and temperature. This relation can be expressed by saying that pressure is proportional to the temperature measured from "absolute zero" (though it was not until later in the nineteenth century that the idea of absolute zero temperature was generally accepted). According to the kinetic theory, the absolute temperature is proportional to the kinetic energy of motion of molecules in a gas.

The kinetic theory was proposed again in the first half of the nineteenth century by two British scientists, John Herapath and J. J. Waterston. Neither of them was familiar with Bernoulli's theory, which had not made much impression on the world of science. Waterston obtained one important new result, which is now known as the "equipartition theorem": in a mixture of two or more different gases at the same temperature, the average kinetic energy of each kind of molecule will be the same. This means that heavy molecules will tend to move more slowly than light molecules, since when the mass of a molecule is greater, its velocity must be less in order to keep the kinetic energy the same.

In 1858, the German physicist Rudolf Clausius showed how the kinetic theory could be used to explain the rate of mixing of two gases and the rate of heat conduction. His work was extended by James Clerk Maxwell (British), who calculated the viscosity coefficient by the kinetic theory. He found that theoretically the VISCOSITY of a gas should be the same at different pressures, and should increase with temperature. This seemed to go against common sense, but later experiments by Maxwell himself and other physicists showed that the theory is correct. Soon afterward several scientists, starting with Josef Loschmidt (Austrian) in 1865, used the kinetic theory to calculate the diameter of an atom. At this time it began to appear that the atom is something that really exists in nature, since it can be measured, weighed, and counted, and is not merely a philosophical speculation. By then the atomic theory had already been accepted in chemistry as a basis for explaining chemical reactions, but it was the kinetic theory of gases that established the place of atoms in physics.

Starting from the foundations laid by Clausius and Maxwell, Ludwig Boltzmann (Austrian) and J. Willard Gibbs (American) worked out systematic methods for calculating all the properties of gases from kinetic theory (see STATISTICAL MECHANICS). Sydney Chapman (British) and David Enskog (Swedish) completed the theory, insofar as it pertains to the transport properties (diffusion, viscosity, and heat conduction) of gases at ordinary densities, although there are still some unsolved problems in the area of high-density gases and liquids, on the one hand, and rarefied (very low density) gases on the other. In the course of working out this theory, Chapman and Enskog discovered that it should be possible to separate the components of a mixture of a gas by making one side of the container hotter than the other. This effect—known as "thermal diffusion"—was soon afterwards established experimentally by Chapman and Dootson (British), thus confirming the prediction based on kinetic theory. (Thermal diffusion was used as one of the methods of separating isotopes of uranium during the development of the atomic bomb in World War II).

Although the kinetic theory was founded on the principles of classical Newtonian mechanics and led to some incorrect results because those principles are not valid on the molecular level, it is now generally agreed that the kinetic theory is valid for calculating the statistical properties of large numbers of molecules, provided that the properties of the individual molecules themselves are determined experimentally, or from the quantum theory. It is only when one tries to apply the kinetic theory to matter in extreme conditions (very low temperatures or very high densities) that he must take account of quantum-mechanical modifications of the statistical method itself (see QUANTUM THEORY and STATISTICAL MECHANICS).

Main Features of the Theory By assuming that the major part of the heat energy of a gas consists of kinetic energy of motion of the molecules, one finds that the average velocity of a molecule is several hundred meters per second under ordinary conditions. However, it is a fact of common observation that gases do not actually move as a whole at such speeds; a gas will eventually spread throughout any container in which it is placed, but it may be several seconds or minutes, for example, before chlorine gas generated at one end of a large laboratory is noticed at the other end. According to the kinetic theory, the reason for the relative slowness of gaseous diffusion, in contrast to the high average velocities of individual molecules, is that a molecule can travel on the average only a very short distance (its "mean free path") before it collides with another molecule and changes its direction of motion. In particular, at atmospheric pressure, if the molecular diameter is assumed to be about 0.00000001 cm (which is approximately true for most molecules), the mean free path would be approximately 0.00001 cm. At the same time, the average distance between neighboring molecules would be somewhat more than 0.0000001 cm, so that the fraction of the total volume occupied by the molecules themselves is less than 1 part in 1000. The average molecular velocity in air at 15°C is about 460 m/sec, so that a molecule will have about 4 600 000 000 collisions per second.

To simplify their calculations, Maxwell and Boltzmann made the following assumptions:

(1) Instead of trying to compute the exact path followed by every molecule, they assumed that, because of the enormous frequency of collisions, the velocities and postions of molecules in a gas are distributed at random over all possible values consistent with the known physical state of the gas. For example, it is assumed that the average total velocity is known, as is the temperature (which fixes the mean square velocity). If variations of temperature and density from one place to another can be ignored, then the molecular velocities can be described by a statistical distribution—the "Maxwell distribution"—which is similar to the normal "bell-shaped curve" or law of errors in statistics.

It should be noted that the effect of a large number of collisions is *not* to make all the velocities equal, but rather to produce a wide range of velocities from zero up to very large values—though the probability of large deviations from the average is quite small. The existence of this "spread" of molecular velocities has been verified directly by various experiments.

(2) The diameter of a molecule is so small, compared to the average distance between molecules, that simultaneous collisions of three or more molecules may be ignored. The validity of this assumption for low-density gases makes it possible to develop a very accurate theory of gas properties, since these properties can be related to the interactions of molecules taken two at a time, and the mathematical description of such two-particle interactions is relatively simple. The corresponding kinetic theory of dense gases and liquids, on the other hand, involves the solution of difficult many-particle problems, and reliable results have been obtained only within the last few years.

(3) In treating the collision of two molecules, one supposes that there is no correlation between their velocities before the collision. In the elementary kinetic theory, one assumes that each molecule has the average velocity characteristic of the region of the gas in which it has most recently undergone a collision. It thus "forgets" its past history every time it collides with another molecule. This is obviously not strictly true for each individual molecule, but it is a useful approximation for dealing with average properties of large number of molecules.

In modern physics research, it is usual to distinguish between "equilibrium theory" and "transport theory," both of which grew out of the elementary kinetic theory. Equilibrium theory is described in the article on STATISTICAL MECHANICS (see also EQUILIBRIUM); it is used to study such properties as the heat capacity (amount of heat needed to raise the temperature by a certain amount) and the compressibility (change in volume produced by a small change in pressure). Equilibrium theory also tries to explain the existence of phase transitions, such as the condensation of gases to liquids, or the appearance of magnetic ordering in solids. From the theoretical viewpoint, the calculation of equilibrium properties is simpler than that of transport properties such as viscosity, because one merely averages over all the possible states of the system (i.e., over all possible combinations of velocities and positions of the molecules) without having to worry about how one state follows another in time. TRANSPORT THEORY involves a detailed analysis of molecular collisions in order to determine how changes in the state of the system are related to external forces or nonuniform conditions imposed on it.

One of the most fruitful techniques in transport theory is the use of "Boltzmann's equation." This equation describes how the velocity distribution changes as a result of external forces and collisions between molecules. Unfortunately the equation is rather difficult to solve, because the term that expresses the effect of collisions on the velocity distribution is an integral over the values of the (unknown) velocity distribution itself for two colliding molecules. In order to calculate the transport properties it is necessary to resort to tedious computations with infinite series, except for certain artificial force laws (such as repulsive forces inversely proportional to the fifth power of the distance between two molecules) for which the integral can be simplified. In most cases, the results (as worked out by Chapman and Enskog) do not differ greatly from the ones obtained from the approximate elementary theory. However, the important phenomenon of thermal diffusion was discovered only because of a theoretical prediction by Enskog and Chapman; since the existence of this effect had not even been suggested by the earlier theories, this discovery must be regarded as one of the triumphs of mathematical analysis.

Irreversibility As indicated above, the kinetic theory assumes that the velocity of a molecule may depend on the conditions in the region where it has just suffered a collision, but is otherwise random—in other words, independent of its previous history. This assumption permits one to use the methods of probability theory even though, in classical mechanics, the actual motions of the molecules are regarded as completely determined by their initial configurations. As long as one uses the theory only to calculate properties of a gas that can actually be measured during a relatively short time, the assumption of randomness leads to no serious errors. However, it introduces an element of irreversibility which is inconsistent with the reversibility of the laws of classical mechanics. (A reversible process is one that can go equally well forwards or backwards, in contrast to an irreversible process, like scrambling an egg, which cannot be undone without a great expenditure of energy. The British physicist William Thomson, later Lord Kelvin, had pointed out the importance of irreversible processes in his "Principle of the Dissipation of Energy," in 1852.) The irreversible aspect of the kinetic theory is shown most clearly by Boltzmann's "*H*-theorem," which has led to a considerable amount of controversy about the foundations of kinetic theory. Boltzmann showed in 1872 that a certain quantity, later called *H*, which depends on the velocity distribution, must always decrease with time, unless the velocity distribution is Maxwell's distribution, in which case *H* remains constant. In the latter case, which corresponds to the equilibrium state, *H* is proportional to the negative of the entropy (see article on THERMODYNAMICS). Thus the *H*-theorem provides a molecular interpretation of the second law of thermodynamics or, in particular, the principle that the entropy of an isolated system must always increase or remain constant. Irreversible processes are those in which entropy increases. The entropy itself can be regarded as a measure of the degree of randomness or disorder of the gas, although it must be recognized that disorder really means just our own lack of knowledge about the details of molecular configurations. The equilibrium state represents the maximum possible disorder; the *H*-theorem implies that a gas which is initially in a nonequilibrium (partly ordered) state will eventually reach equilibrium and then stay there forever if it is not disturbed.

If the long-term consequences of the *H*-theorem were applicable to all matter in the universe, one might expect that the universe would eventually "run down"; although the total energy might always remain the same, no useful work could be done with this energy because all matter would be at the same temperature (see THERMODYNAMICS). This final state has been called the "heat death" of the universe.

The contradiction between the *H*-theorem and the laws of classical mechanics is shown by two famous criticisms of the kinetic theory, the "reversibility paradox" and the "recurrence paradox." The first paradox is based on the fact that Newton's laws of motion are unchanged if one reverses the time direction, so that it would seem to be impossible to deduce from these equations a theorem that predicts irreversible behavior. Kelvin discussed this paradox in 1874, and concluded that while any single sequence of molecular motions could be reversed, leading to an ordered state, the number of disordered states is so much greater than the number of ordered states that it is virtually impossible to stay in an ordered state for any period of time. Thus irreversibility is a statistical but not an absolute consequence of kinetic theory. Boltzmann gave a similar answer when the problem was pointed out to him by Loschmidt a few years later. The second paradox is based on a theorem of Henri Poincaré (French): if a mechanical system is enclosed in a finite volume, then after a sufficiently long time it will return as closely as one likes to its initial state. Hence *H* must return to its original value; if it has decreased during some period of time, it must increase during some other period. The time between successive recurrences of the same state for the molecules in 1 cc of air is much longer than the present age of the universe, so one does not have to worry about recurrences in any actual experiment. In his attempt to resolve the recurrence paradox, Boltzmann was finally led to a remarkable psycho-cosmological speculation: he suggested that the "direction of time" as perceived by an animate being is *determined* by the direction of irreversible processes in his environment and in his body. Thus when the time comes for a recurrence, entropy will decrease but subjective time will flow in the opposite direction; thus the law "entropy increases with time" is a tautology! This idea of alternating time-directions in cosmic history was further explored by H. Reichenbach (*The Direction of Time*, Berkeley, 1956) and has been proposed again in recent theories of the expanding (and contracting) universe.

Some other aspects of this problem and its connection with atomic randomness are discussed in the article on IRREVERSIBILITY.

Recent Developments Since World War II there has been a revival of interest in the "classical" kinetic theory of gases, based on the assumptions of Clausius, Maxwell and Boltzmann and ignoring quantum effects except insofar as these may determine the intermolecular force law. In part this interest is due to applications involving high-speed aerodynamics and plasma physics, in part to renewed attempts to construct reliable theories of liquids as well as dense gases. New methods for obtaining accurate solutions of the Boltzmann equation have been developed by H. Grad, C. L. Pekeris, E. Ikenberry and C. Truesdell, and many others. These solutions have been used to describe the behavior of gases in many circumstances more complicated than those treated in the nineteenth century (including the interactions of charged particles and magnetic fields). Problems such as the propagation and dispersion of sound waves have also been treated by G. E. Uhlenbeck and his collaborators.

In 1946, three general formulations of kinetic theory were published, by M. Born and H. S. Green, by J. G. Kirkwood, and by N. N. Bogoliubov. In each case the goal was to derive a generalized Boltzmann equation in a form that would be valid when simultaneous interactions among more than two molecules have to be taken into account, and thence to obtain solutions of the equation from which transport properties of dense gases and liquids could be calculated. In each formulation certain approximations had to be made in order to obtain practical results; because of the difficulty in estimating the error involved in these approximations, and the great complexity of the equations involved, there was no clear evidence that the results for properties such as the viscosity coefficient would be significantly more accurate than those obtained by Enskog from his modified kinetic theory for dense gases published in 1922. Eventually, in the early 1960s, attention was centered on the systematic derivation of series expansions for the transport coefficients in ascending powers of the density, together with attempts to calculate the first few terms in such series for special molecular models such as elastic spheres. In the meantime, an alternative and apparently more rigorous method for deriving theoretical expressions for transport coefficients, based on the "fluctuation-dissipation theorem" introduced in 1928 by H. Nyquist in electrical engineering problems, was developed by M. S. Green, H. Mori, and R. Kubo. This method had the heuristic advantage of bringing out clearly the connection between transport theory and the description of fluctuations in equilibrium statistical mechanics. Later it was proved that the Green-Mori-Kubo method gives results precisely equivalent to those that would be obtained from the Born-Green, Kirkwood, and Bogoliubov methods, and also those of yet another method developed by I. Prigogine, if in each case the calculations are done without approximation. Thus, just as in the case of quantum mechanics, several alternative approaches are equally valid in modern kinetic theory.

After intensive efforts to calculate terms in the density expansion of transport coefficients, it was finally discovered in 1965 that such a density expansion does not actually exist, for mathematical reasons associated with the persistence of weak correlations between colliding particles over very long times. The divergence of the expansion (and thus the inadequacy of the approximations on which most earlier theories had been based) was established almost simultaneously by J. R. Dorfman and E. G. D. Cohen, J. Weinstock, and R. Goldman and E. Frieman. The result has been a flurry of activity in kinetic theory, in which many of the intuitively plausible ideas about "relaxation" of initial states to steady nonequilibrium states, and destruction of correlations by intermolecular collisions, have been revised.

In spite of the impressive success of kinetic theory in solving numerous problems of both practical and theoretical interest, many scientists are not satisfied that the theory of nonequilibrium processes rests on a solid foundation comparable to that of equilibrium statistical mechanics. There is no single fundamental postulate analogous to the Gibbs canonical distribution from which everything can be deduced. Perhaps as a result of this gap in fundamental principles, there remains considerable disagreement about how to formulate some of the major outstanding problems which involve the connection between the atomic and the macroscopic levels, such as the nature of turbulence.

Other applications of the kinetic theory are discussed in the articles on AERODYNAMICS, BOLTZMANN'S DISTRIBUTION LAW, ELECTRICAL CONDUCTIVITY, LIQUID STATE, NUCLEAR REACTORS and PLASMA. See especially IRREVERSIBILITY.

LAPLACE TRANSFORM

Introduction The Laplace transform $\bar{f}(s)$ of a function $f(t)$ is defined to be the integral

$$\bar{f}(s) = \int_0^\infty e^{-st} f(t)\,dt$$

if the integral exists. It will certainly exist if $f(t)$ is itself integrable between zero and an arbitrary upper limit, and if, for a large enough real value of k, $e^{-kt}f(t) \to 0$ as $t \to \infty$. Then if it exists for one complex value of s it exists also for all complex s of greater real part, and so the integral "transforms" the function $f(t)$ into a function $\bar{f}(s)$ defined on a half-plane of the complex Argand plane.[10,6]

Operational Methods The Laplace transform is perhaps the best known and most useful of a number of integral transforms, whose application is that province of applied mathematics usually called operational methods.

The essential idea is to exploit the analogy between certain differential and algebraic operators. Historically, the idea goes back to Leibnitz, and has been employed by a number of mathematicians including Laplace, Lagrange and Riemann.[2] It was treated extensively by Boole, and Oliver Heaviside developed it to the point where he could apply it, particularly to circuit theory in electricity. In his D-notation, given the ordinary differential equation with constant coefficients

$$a_0 \frac{d^n y}{dt^n} + a_1 \frac{d^{n-1} y}{dt^{n-1}} + \cdots + a_{n-1} \frac{dy}{dt} + a_n y = F(t),$$

we introduce the operator $P(D) = \sum_{k=0}^{n} a_k D^{n-k}$ and so write the equation as

$$P(D)y = F(t).$$

Then it is formally solved as

$$y = \frac{1}{P(D)} F(t),$$

and one is left to interpret this result. The key to this interpretation lies in the three operational relations

$$D \equiv \frac{d}{dt}, \qquad D^{-1} = \int^t dt,$$

and

$$(1 - D)^{-1} = \sum_{k=0}^{\infty} D^k = \sum_{k=0}^{\infty} D^{-k-1}.$$

In these, D^{-1} is an indefinite integral and hence one of the major faults was that D and D^{-1} were not commutative, as $D^{-1}D - DD^{-1}$ would in general be a constant. Heaviside does not seem to have been clear which interpretation of $(1 - D)^{-1}$ to take, preferring the first but recognizing the difficulties of convergence implied. The method also fails to take account of the initial values under which the equation is to be solved.

Now it follows by successive integrations by parts that if $d^k y/dt^k$ has a Laplace transform it is

$$s^k \bar{y}(s) - \sum_{j=0}^{k-1} y_{k-j-1} s^j$$

where $\bar{y}$ is the Laplace transform of y, and $y_r = \lim_{t\to 0} d^r y/dt^r$. Thus the Laplace transform has the algebraic property of the D-operator, but the initial values are now included in the operation. If this is then applied to the differential equation above, the term to be interpreted becomes

$$\bar{y}(s) = \{\bar{F}(s) + Q(s)\}/P(s),$$

where $\bar{F}(s)$ is the Laplace transform of $F(t)$, and $Q(t)$ is a polynomial of degree $n - 1$ with coefficients depending on the constants y_r.

It can easily be verified that the Laplace transforms of $t^n e^{at}$, $e^{at} \cos bt$ and $e^{at} \sin bt$ are respectively $n!(s - a)^{-1-n}$, $(s - a)/\{(s - a)^2 + b^2\}$ and $b/\{(s - a)^2 + b^2\}$. If, then, the forcing function $F(t)$ is a finite sum of terms which are products of powers of t, exponentials, and trigonometric functions, the equation can be solved by resolving $\bar{y}(s)$ into partial fractions and interpreting separately the individual terms.

The Inversion Integral The justification for the procedure above involves an assumption that the relation between a function and its Laplace transform is unique. This would follow from a corresponding result for the Fourier transform, as we will show that the relationship for the Laplace transform can be deduced from the Fourier Integral Theorem. In fact, functions which differ on a set of points of zero measure will have the same Fourier or Laplace transform; but in most practical problems such an equivalence class of functions would not be distinguished in any case, so that effectively there is a uniqueness theorem. The Fourier integral theorem establishes, for a restricted class of functions, which vanish sufficiently strongly for large values of t, a unique reciprocal relation between a function $F(t)$ and its Fourier transform $\hat{F}(p)$,

$$(2\pi)^{1/2}\hat{F}(p) = \int_{-\infty}^{\infty} e^{ipt}F(t)dt,$$

$$(2\pi)^{1/2}F(t) = \lim_{X\to\infty}\int_{-X+ic}^{X+ic} e^{-ipt}\hat{F}(p)dp,$$

where c is chosen so that the integral is meaningful.

If we introduce the unit function $H(t)$, which is one for positive t, and zero for negative t, a function often associated with the name of Heaviside, and we also write $p = is$, $F(t) = (2\pi)^{1/2}f(t)H(t)$, then $\hat{F}(is)$ is the Laplace transform $\bar{f}(s)$. We therefore obtain the uniqueness theorem we desire, and in addition obtain an inversion formula for the Laplace transform, often known as the Bromwich integral

$$2\pi i f(t)H(t) = \lim_{X\to\infty}\int_{c-iX}^{c+iX} e^{st}\bar{f}(s)ds,$$

where c must be greater than the real part of any singularity of $\bar{f}(s)$.

We may use the method of residues to evaluate the inversion integral for a wide class of transforms,[6] and so with its use we can relax the restriction we had to place on the forcing function above.

An alternative form of the inversion formula can be given by[11]

$$f(t) = \lim_{n\to\infty}\frac{(-1)^n}{n!}\left(\frac{n}{t}\right)^{n+1}\bar{f}^{(n)}\left(\frac{n}{t}\right)$$

where $\bar{f}^{(n)}(s)$ is the nth derivative of $\bar{f}(s)$.

The Convolution Theorem We may also show that, for a suitably restricted class of functions, the Fourier transform has a convolution or Faltung theorem associated with it. This takes the form that if $\hat{F}(p)$ and $\hat{G}(p)$ are respectively the Fourier transforms of $F(t)$ and $G(t)$, then $(2\pi)^{1/2}\hat{F}(p)\hat{G}(p)$ is the Fourier transform of

$$\int_{-\infty}^{\infty} F(u)G(t-u)du.$$

If we interpret this as a theorem for the Laplace transform we obtain the result that if $\bar{f}(s)$ and $\bar{g}(s)$ are respectively the Laplace transforms of $f(t)$ and $g(t)$, then $\bar{f}(s)\bar{g}(s)$ is the Laplace transform of the function

$$\int_0^t f(u)g(t-u)du.$$

This theorem has an immediate application to the solution of the differential equation we have introduced above, for we can assert that if $Y(t)$ is the function whose Laplace transform is $1/P(s)$, then $\bar{F}(s)/P(s)$ is the Laplace transform of

$$\int_0^t F(u)Y(t-u)du.$$

Now $P(s)$ is a polynomial in s, and so we can write

$$P(s) = a_0\prod_{k=1}^{m}(s-\alpha_k)^{N_R}$$

where the α_k are in general complex, and $\sum_{k=1}^{m} N_k = n$. We can then resolve $1/P(s)$ into partial fractions

$$\sum_{k=1}^{m}\sum_{j=1}^{Nk}\frac{A_{kj}}{(s-\alpha_k)^j}$$

(see Refs. 5 and 6) and so

$$Y(t) = \sum_{k=1}^{m}\sum_{j=1}^{Nk}\frac{A_{kj}}{(j-1)!}t^{j-1}e^{\alpha_k t}.$$

This is equivalent to solving the differential equation by the method of variation of parameters.

The convolution theorem is also of great assistance in the solution of integral equations with difference kernels, i.e., with kernels of the form $K(t, u) = K(t-u)$. In particular we see that the Volterra equation

$$f(t) = g(t) + \lambda\int_0^t K(t-u)f(u)du$$

leads directly to

$$\bar{f}(s) = \bar{g}(s)/\{1-\lambda\bar{K}(s)\}.$$

The corresponding Fredholm integral equation with a different kernel may also be solved using a transform. In this case, however, another integral equation is obtained which may be solved by the Wiener-Hopf technique.[6]

Other Properties of the Laplace Transform It can be proved quite easily[6] that within the half-plane in which it converges, $\bar{f}(s)$ is an analytic function of s, and so has derivatives of all orders with respect to s. It then follows that

$$\frac{d^k\bar{f}(s)}{ds^k} = (-1)^k \int_0^\infty e^{-st}t^k f(t)dt.$$

We may apply this relation to ordinary differential equations whose coefficients are polynomials in t. If we combine this formula with the relation for the transform of a derivative we have used before, the equation

$$\sum_{k=0}^{n} \sum_{j=0}^{m_k} a_{kj} t^j \frac{d^{n-k}y}{dt^{n-k}} = F(t)$$

is transformed into

$$\sum_{k=0}^{n} \sum_{j=0}^{m_k} (-1)^j a_{kj} \left\{ \frac{d^j}{ds^j}(s^{n-k}\bar{y}) - \sum_{i=j}^{n-k-1} \frac{i!y_{n-k-i-1}}{(i-j)!} s^{i-j} \right\} = \bar{F}(s).$$

Hence an ordinary linear differential equation of order n whose coefficients are polynomials in t of maximum degree m, becomes an ordinary linear differential equation for the transform which is of order m and whose coefficients are polynomials of degree n. This is exactly the same situation as arises if we attempt to solve the original equation by a contour integral of Laplace type.[7]

In fact the Laplace transform is only a special case of this more general technique, which is in consequence rather more useful.

One advantage does, however, remain for the use of the Laplace transform in this context. It has asymptotic properties which can allow the deduction of certain properties of a function from its transform without explicitly inverting it. It is an immediate deduction from Watson's lemma[7] that if, for small t,

$$f(t) = t^\nu \sum_{n=0}^{\infty} a_n t^n, \qquad \nu > -1,$$

then for $|s|$ large

$$\bar{f}(s) \sim s^{-1-\nu} \sum_{n=0}^{\infty} \Gamma(n+\nu+1) a_n s^{-n}.$$

To deduce an expression for $f(t)$ for small t from the transform, a converse theorem is required and the conditions under which this is valid may be found in Ref. 4. The same text establishes conditions for the validity of another useful relation, which is that if a is the singularity of $\bar{f}(s)$ of greatest real part, and near it $\bar{f}(s)$ has an expansion

$$\bar{f}(s) = (s-a)^{-\nu-1} \sum_{n=0}^{\infty} A_n (s-a)^n,$$

then for large positive values of t

$$f(t) \sim t^\nu e^{at} \sum_{n=0}^{\infty} \frac{A_n}{\Gamma(\nu+1-n)t^n}.$$

Partial Differential Equations and Other Transforms Possibly the most useful application is to the solution of initial value problems for some of the linear partial differential equations of mathematical physics. This is exploited to the full in Ref. 1 and to a lesser extent in Refs. 5 and 6. In a number of these equations time derivatives appear with constant coefficients, so the use of the transform effectively reduces by one the number of independent variables. In particular, if there is only one other independent variable than the time, it produces an ordinary differential equation. The method has great flexibility since the asymptotic properties can often be used to extract information which conventional solutions in eigenvalue expansions conceal. It can be shown that if the Laplace transform of $f(t)H(t)$ is $\bar{f}(s)$, then the Laplace transform of $f(t-a)H(t-a)$ is $e^{-sa}\bar{f}(s)$. In problems involving wave propagation this can be exploited to analyze the solution into the components arising from multiple reflections.

It is clear from the way that the initial conditions appear in the Laplace transform of a derivative, that it can be used primarily for the solution of initial value problems, and hence for partial differential equations of hyperbolic or parabolic type only. In treating the solution of equations of elliptic type on infinite domains, in which the boundary conditions are given at both ends of the range, we require other integral transforms, the conditions at infinity being usually of a form which will ensure the convergence of the defining integral. The question of which transform to use is usually decided by the equation, the coordinate system, and the form in which the boundary conditions are given. It is convenient to illustrate some of the most commonly used transforms by reference to the Laplace equation $\nabla^2\phi = 0$.

In Cartesian coordinates this has the form

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} = 0.$$

If the region in which a solution is sought extends over $(-\infty, \infty)$ in one coordinate, say x, and the boundary conditions are that $\phi \to 0$ as $|x| \to \infty$, we would use a Fourier transform, whose inversion formula and convolution integral have already been given. Like the Laplace transform, an asymptotic expansion of the transform is equivalent to the expansion of the function near the origin. The expansion of the transform near the singularity of least negative imaginary part gives the asymptotic expansion of the function near $x = \infty$, and of least positive imaginary part near $x = -\infty$.

If the range in x is only semi-infinite, we may use either a Fourier cosine transform, with the reciprocal relations

$$\bar{f}(s) = \left(\frac{2}{\pi}\right)^{1/2} \int_0^\infty f(x) \cos sx \, dx;$$

$$f(x) = \left(\frac{2}{\pi}\right)^{1/2} \int_0^\infty f(s) \cos sx \, dx$$

or the Fourier sine transform with the reciprocal relations

$$\bar{f}(s) = \left(\frac{2}{\pi}\right)^{1/2} \int_0^\infty f(x) \sin sx \, dx;$$

$$f(x) = \left(\frac{2}{\pi}\right)^{1/2} \int_0^\infty \bar{f}(s) \sin sx \, dx.$$

Both transforms require the boundary condition $\phi(x) \to 0$ as $x \to \infty$, but the choice between them is decided by whether ϕ or $\partial\phi/\partial x$ is given on $x = 0$, for if $\phi(x) \to 0$ as $x \to \infty$, and the integrals exist,

$$\int_0^\infty \frac{\partial^2\phi}{\partial x^2} \cos sx \, dx = -\left(\frac{\partial\phi}{\partial x}\right)_{x=0} - s^2 \int_0^\infty \phi(x) \cos sx \, dx,$$

while

$$\int_0^\infty \frac{\partial^2\phi}{\partial x^2} \sin sx \, dx = s\phi_{x=0} - s^2 \int_0^\infty \phi(x) \sin sx \, dx.$$

Convolution theorems and the asymptotic properties can be deduced by noting that if ϕ is continued for $x < 0$ as an even function, the cosine transform is the Fourier transform of the continued function, and if ϕ is continued as an odd function we relate the sine transform to the Fourier.

In spherical polar coordinates the Laplace equation has solutions like $R^\nu S_\nu$ where S_ν is a spherical harmonic of degree ν. This suggests that to solve problems in conical regions of infinite extent we use the Mellin transform and its inverse

$$\bar{f}(s) = \int_0^\infty R^{s-1} f(R) dR;$$

$$f(R) = \lim_{X\to\infty} \frac{1}{2\pi i} \int_{c-iX}^{c+iX} R^{-s} \bar{f}(s) \, ds.$$

This can be derived from the Fourier transform by substituting $R = e^x$, which also gives the convolution theorem that $\bar{f}(s)\bar{g}(s)$ is the transform of

$$\int_0^\infty f(\rho) g\left(\frac{R}{\rho}\right) \frac{d\rho}{\rho}.$$

To apply this transform to the equation it is necessary, but not sufficient, that $R^s\phi$ vanish at infinity and at $R = 0$. These conditions will also dictate what choice of c in the inversion integral will be needed for convergence. The singularity of $\bar{f}(s)$ whose real part is less than c but nearest to it will dominate the behavior of $f(R)$ for small R, and the singularity with real part greater than c but closest to it will dominate the behavior of $f(R)$ for large R.

If the Laplace equation is expressed in terms of cylindrical polar coordinates (r, θ, z) it has solutions of the form $\Phi_\nu(r, z)e^{i\nu\theta}$, and to determine the form of Φ_ν we may use a Hankel transform of order ν, defined by

$$\bar{f}_\nu(s) = \int_0^\infty r f(r) J_\nu(sr) dr,$$

$$f(r) = \int_0^\infty s\bar{f}_\nu(s) J_\nu(sr) dr$$

where $J_\nu(sr)$ is the Bessel function of first kind and of order $\nu \geqslant 0$.

For integer order this can be derived from applying simultaneous Fourier transforms to the x and y variables and then converting to polar coordinates by $x = r \cos\theta$, $y = r \sin\theta$. For noninteger order it is better to derive the result directly using a modified version of the method needed for the Fourier theorem and exploiting the analogy between the Bessel and circular functions. There is no convenient convolution theorem, though convolution theorems can be deduced. Once again the behavior of $f(r)$ for small r is deducible from the values of $\bar{f}_\nu(s)$ for large s, and the properties of $f(r)$ for large values of r follow essentially from the singularity of $\bar{f}_\nu(s)$ nearest the real axis. Any of these transforms can be applied simultaneously with other ones.

All these transforms and also the Hilbert transform

$$\bar{f}(s) = \frac{P}{\pi} \int_{-\infty}^\infty \frac{f(t)dt}{t - s}, \quad f(t) = \frac{1}{\pi} P \int_{-\infty}^\infty \frac{\bar{f}(s)ds}{s - t}$$

where $P\int$ is a Cauchy principal value, are treated rigorously in Ref. 8.

An alternative to the Fourier transform, provided $f(t)$ vanishes strongly enough at $t = \pm\infty$, is the so-called two-sided Laplace transform

$$\int_{-\infty}^{\infty} e^{-st} f(t)dt,$$

which is really a complex Fourier transform. An extended account of this and its application can be found in Ref. 9. Very many other integral transforms have appeared in the literature, and tables of them with some theory can be found in Ref. 3. A more general transform which embraces a number of those above is described in Ref. 11.

More Recent Work The introduction of the concept of generalized functions has considerably increased the class of functions whose transforms can be utilized. Thus, for example, the Fourier transform of t^k exists as a generalized function and is $(-i)^k(2\pi)^{1/2}\delta^{(k)}(s)$, where $\delta^{(k)}(s)$ is the kth distribution derivative of the Dirac delta function. In particular the growth condition for a generalized Laplace transform is relaxed to become one that is bounded above by a polynomial in $|s|$.

A treatment of a number of these generalized integral transforms can be found in Ref. 12.

A number of authors have made use of the transforms of generalized functions, and most notably the Fourier transform, in the rapid development in the theory of Linear Partial Differential Equations which has taken place in the last twenty years.[13, 14]

There is also quite a lot of interest in developing both new integral transforms, such as are published periodically in mathematical journals, and a general operational calculus not limited specifically to any particular transform.[15]

LASER

"Laser" is an acronym for *l*(ight) *a*(mplification by) *s*(timulated) *e*(mission of) *r*(adiation). This device is identical in theory of operation to the MASER except that it operates at frequencies in the optical region of the electromagnetic spectrum, rather than in the microwave. Laser operation has been demonstrated at wavelengths from 1500 to over 1 000 000 Å or from 0.15 to 100μm. By common usage, these devices are all called lasers, although more descriptive terminology utilizes ultraviolet maser, optical maser, infrared maser, etc. Although the original microwave maser offers an extremely stable frequency source, its main use is as an amplifier with extremely low noise output. In contrast, the main significance of the laser is its ability to produce a single frequency at high intensity in the optical region, a feat heretofore impossible at these frequencies. Not only may the output be a single monochromatic wave, but the wave may be coherent, or in phase, over the whole surface of the radiator. In this mode of operation, the laser is actually an oscillator whose output depends upon the selective amplification of one of the single frequency modes of the resonant cavity containing the active laser medium.

Following the development of the microwave maser, Schawlow and Townes in 1958 proposed that optical maser action could be obtained by placing an active medium in an optical cavity. The medium would be a gas or solid which was excited electrically or by light in such a manner that any optical wave present would be amplified as it moved through the material. The cavity was proposed to be a Fabry-Perot resonator—two plane, parallel reflecting plates with a small transmission through which the radiation might escape. Upon excitation of the material, light will be emitted with a band of frequencies determined by the particular material. In addition, the direction of emission will be nominally random. In the presence of the cavity, some of the waves will escape after several back and forth reflections from the parallel plates, "walking off" the edge of the reflectors. Those waves which travel normal to the walls will remain in the cavity and be amplified provided they reinforce each other after each round-trip reflection at the two surfaces. This reinforcement or resonance is only satisfied if the spacing of the plates is an integral multiple of one-half the wavelength in the medium. Thus, after a short time, only that frequency which satisfies the resonant condition and those waves traveling normal to the reflector will build up to an appreciable intensity. The resultant light which is partially transmitted through one of the reflectors will thus be a single frequency or several discrete frequencies if there is more than one cavity resonance within the band of frequencies emitted by the laser material. In addition, the wave front will be in phase across the surface of the reflector since waves striking the surface at normal incidence are amplified most strongly. The resultant beam will then be diffraction limited, i.e., the beam will spread by an angle in radians given approximately by the ratio of the wavelength to the diameter of the beam. In actual practice, single-mode operation is obtained only under special conditions. Generally, several frequency modes are present due to the multiple resonances of the cavity and numerous "off-axis" modes are found which correspond to resonant waves which travel at small angles from the normal to reflectors. These waves "walk off" so slowly that they still are amplified appreciably. Refinements of the simple cavity proposed by Schawlow and Townes consist of concave reflectors which decrease the diffraction losses, or several parallel reflectors which limit the oscillation to a frequency common to each pair in the set.

The key to successful laser operation is of course the active medium which amplifies the wave. Qualitatively, a material which fluoresces or exhibits luminescence is an obvious candidate. In fluorescence, electrons are excited to an upper-energy state by short-wavelength light such as ultraviolet, while luminescence is produced by passing an electron current through the medium, such as in a gaseous discharge. In either process, stimulated emission can occur only if more electrons are produced in the upper-energy state than in the lower or terminal state for the radiating transition. In this case, an incident photon will stimulate further transitions and amplification will result. If the final state were more heavily populated, then the photon would cause more upward or absorbing transitions and the net effect would be absorption.

Solid-State Lasers The first optical maser was demonstrated by Maiman of Hughes Research Laboratories in 1960 using ruby, which is single-crystal aluminum oxide "doped" with chromium impurities. By applying semitransparent reflective coatings on the ends of a rod about 2 inches long, he made the cavity and the crystal an integral unit. Then, exposure to an intense exciting light from a xenon flashtube was found to invert the population between the red-emitting level and the ground or lowest-energy state of the electrons. The result was a burst of intense red light emanating in a beam through the end reflectors. This was the first and is still one of the most powerful lasers. Advances in the art since that time have resulted in energies per pulse of the order of 1000 joules or watt-seconds. Peak powers are as high as 500 000 kW in short pulses of the order of 10^{-8} sec. Because of "off-axis" modes and multiple resonances, the output is not a single-frequency, single plane-wave mode, but generally consists of the order of 100 separate modes. The beam is still quite narrow, being the order of 1 milliradian or 0.05 degrees. As a comparison with conventional light sources, the energy radiated from 1 cm^2 of the brightest flash lamp is less than 10 kW and is distributed over the entire visible spectrum. In addition, the radiation is incoherent and is spread out uniformly in all angles from the source. Thus, the directivity and spectral purity of the laser source are many orders of magnitude superior to that of an incandescent source. The ruby laser suffers from a low efficiency, about 1 per cent, and except with elaborate cooling systems, only operates on a pulsed basis. Other crystalline or glass systems with impurity ions have been developed, which yield wavelengths from the ultraviolet to approximately 3μm wavelength in the infrared. Some, such as neodymium-doped yttrium aluminum garnet (YAG), operate in a continuous mode at the one-watt level while peak powers have reached values as high as 10^{14} W in pulses of the order of 10^{-12} sec. These ultrahigh powers are obtained in neodymium-doped glass systems using several stages of amplification and novel pulse-forming techniques.

Gas Lasers Historically, the next development came in 1961 when Javan, Bennett and Herriott demonstrated laser action in a gaseous discharge of helium and neon. Again, the parallel-plate reflector cavity was used but this time with a spacing of several feet. Later, concave mirrors were used to decrease the loss of energy out the sides of the cavity. This device operates continuously and delivers power at levels up to one watt. Pulsing the gas discharge yields peak powers as high as 100 W. The first laser radiated at 1.15 μm in the infrared, while further development with different gases has yielded outputs from the ultraviolet to 1000μm or 1 mm in the far infrared. In contrast to the ruby laser, the gaseous laser beam may be diffraction limited and the frequency is pure, i.e., oscillation may be limited to one mode. By careful design, the frequency may be stabilized to a few thousand cycles per second or approximately one part in 10^{13}. Although the original gas laser utilized electrical excitation of electronic transitions, later versions use vibrational transitions in molecules such as carbon dioxide, and the excitation mechanism may be electrical, chemical, or thermal. In the chemical laser, atomic species such as hydrogen and fluorine can be reacted to produce molecules in an excited vibrational state which in turn yields amplification or oscillation. Recent electrically excited lasers, particularly those using carbon dioxide at 10 μm, have been operated at atmospheric pressure using spark discharges or pre-ionization by voltages in the 100-kV range. The high pressure and the powerful electrical excitation result in peak powers in the 10 to 100-MW region. For continuous laser operation, the gas may be circulated rapidly to avoid excessive heating, and using an electrical discharge, powers from 1 to 10 kW have been obtained. An entirely new excitation process, essentially thermal, was announced by Gerry in 1970. In this, the gas dynamic laser, an appropriate fuel is burned to produce carbon dioxide and nitrogen at high temperature and pressure. When released through a nozzle into the optical resonator region, the gas cools rapidly in terms of its kinetic or translational energy, but the population of the vibrational energy levels of the carbon dioxide molecules becomes inverted since the lower level of the laser transition relaxes much more rapidly. In addition, the vibrationally excited nitrogen molecules are in near resonance with the upper laser state of the carbon dioxide and transfer energy with high efficiency to maintain the inversion. This type of laser has produced continuous powers as high as 60 kW.

Semiconductor Lasers The third main type of laser utilizes a solid material, in this case a semiconductor. Here the electron current flowing across a junction between *p*- and *n*-type material produces extra electrons in the conduction band. These radiate upon making a transition back to the valence band or lower-energy states. If the junction current is large enough, there will be more electrons near the edge of the conduction band than there are at the edge of the valence band and a population inversion may occur. To utilize this effect, the semiconductor crystal is polished with two parallel faces perpendicular to the junction plane. The amplified waves may then propagate along the plane of the junction and are reflected back and forth at the surfaces. The gain in the material is high enough so that the reflection at the semiconductor-air interface is sufficient to produce oscillation without special reflective coatings. The first such device used gallium arsenide and radiated at 8400Å or just beyond the visible region in the infrared. This laser was developed by groups at General Electric, International Business Machines, and Lincoln Laboratory in 1962. The efficiency is high, about 40 per cent, and the power source is low-voltage direct current. One shortcoming is the requirement of liquid nitrogen cooling (77 K) to maintain power output and efficiency. Powers as high as 3 W continuous have been produced. The cavity in this case is extremely small, the reflector spacing being less than a millimeter. As a result, it is fairly easy to limit the oscillation to one frequency mode although small irregularities in the junction prevent coherence over the full width of the narrow radiating junction strip. The compactness and efficiency of the semiconductor laser make it particularly attractive for systems use. Wavelengths as long as 30μm and as short as 6300Å have been generated using different semiconductors such as indium arsenide, indium phosphide, indium antimonide, or alloys such as gallium arsenide-phosphide. In addition, these lasers may be tuned over several percent of their nominal frequency of operation by varying the current flow through the device. The tuning results from the variation in temperature with current which in turn changes the index of refraction and the resultant resonant frequency of the cavity. Since the linewidth of the radiation is only about 1 MHz the tunable semiconductor laser is an excellent tool for high resolution spectroscopy.

Liquid Lasers Laser action may also be obtained in liquids using either a flash tube or another laser as the pump. Early versions used rare earths in an organic liquid, while more recently organic dyes have been found to be more efficient but require a separate laser for the exciting radiation. The dye laser has the special attraction that one laser may be tuned over a significant fraction of the visible spectrum by using a reflection grating as one of the cavity mirrors. Another type of liquid laser utilizes a different principle than those above, depending upon stimulated Raman scattering. Raman laser action was discovered by Woodbury in 1962 using a ruby laser and nitrobenzene. Here the laser excites the nitrobenzene, which in turn shows amplification at a frequency displaced from the ruby line by the vibrational frequency of the molecule. There is no true inverted population in this case. The incident photon is scattered by the molecule which absorbs an amount of energy determined by its vibrational energy. The molecule is left in an excited state and the scattered photon is frequency shifted by the energy loss. This process may be stimulated, since the rate at which the scattered photons are produced is proportional to the number of photons already present in the cavity at the scattering wavelength. As in the normal stimulated emission case, the frequency and phase of the output wave are identical with the wave which stimulates the scattering. The Raman laser normally operates using the Stokes line, or the wavelength corresponding to the loss of one vibrational quantum. Other modes of operation utilize the second or third Stokes lines corresponding to double or triple vibrational absorptions. Similarly, higher-order effects in the medium may produce a series of anti-Stokes lines which correspond to vibrational energy being added to the initial energy of the photons from the driving laser. The wavelength range of Raman lasers using different liquids is from the visible to the near infrared.

Q-Switching The high instantaneous powers quoted for ruby are obtained by using the "Q-switched" mode of laser operation. This technique, due to Hellwarth and McClung, uses a cavity resonator whose reflectivity or "Q" may be controlled externally. The laser, usually ruby, is first excited by the flash lamp while the cavity is in a state of low reflectivity and thus low feedback. As a result, the inverted population reaches an extreme value before oscillation occurs. At the peak of inversion, the reflectivity is "switched on," and the resultant high reflectivity produces an intense burst of energy which almost completely depopulates the high-energy states in a time of the order of 10^{-8} sec. The switching is accomplished either by a Kerr electro-optic shutter in the cavity or by rotating one of the mirrors so that it is lined up parallel with the opposite reflector at the optimum time during the flash lamp pulse.

Mode-Locked Pulses An alternative method for generating extremely short pulses utilizes the technique of mode-locking. Since a laser resonator has frequency modes equally spaced at a separation of $c/2L$, where L is the cavity length, oscillation can occur in any mode as long as it is within the natural emission linewidth of the laser transition. Many lasers oscillate in only one mode, since that with the highest gain takes over from any modes away from the line center. Now, if the cavity is modulated internally at a frequency equal to the mode spacing, all modes within the natural linewidth become coherently coupled and the result is a train of pulses at the modulation frequency with a pulse width roughly the inverse of the natural linewidth. An alternative way of looking at the process is to assume random noise pulses propagating back and forth between the cavity mirrors. Since the round-trip time is the same as the modulation period, a noise pulse which passes through the modulator at its maximum transmission will receive the most net gain in a round trip. Although the differential gain among differentially phased pulses is small, the cumulative effect after many round trips singles out the in-phase pulse train. The width of the pulse is determined by the amplifier bandwidth, which is the natural linewidth as mentioned above. After demonstration of this technique of pulse generation, it was discovered that a laser could be mode-locked by a saturable filter in the cavity, i.e., a material whose transmission loss decreased with increasing light intensity. In this case, a random pulse increases the transmission in the filter on each passage and produces its own transmission modulation. This so-called self-mode locking was soon discovered to exist in some lasers without the addition of a special saturable filter material. The measurement and discovery of these effects depends upon newly developed techniques of measuring short pulse lengths. In particular, the pulse train may be passed into a reflecting cell containing a material whose fluorescence is proportional to the square of the light intensity. Upon reflection

TABLE 1. LASERS CLASSIFIED BY TYPE, WAVELENGTH, AND PUMPING SOURCE.

Type	Wavelength Range	Example	Pump	Comments
Solid (Insulating)	0.17–3.9 μm	Al_2O_3:Cr Glass: Nd	optical	highest pulse powers

Gas	0.15 μm–1 mm	He-Ne
		Argon
		HF
		CO_2
			electrical;
			gas dynamic;
			laser*
				highest continuous powers

Semiconductor	0.6–30 μm	GaAs PbSnTe	electrical	electrically tunable over narrow bandwidth
Liquid	0.2–1.3 μm	organic dye	optical; laser	wide tuning range; picosecond pulses
Free electron	0.6 μm–3 mm	e^-	high-energy accelerator	requires relativistic electron beam

*Wavelengths from 50 to 500 μm usually require CO_2 laser pumping of an organic molecular gas.

back through the fluorescent material, the light output increases where one returning pulse passes an incoming pulse. In this manner, the physical width of the light pattern measures the pulse length. Using a laser material with a broad emission band has yielded pulse trains with widths of the order of 10^{-12} sec or a picosecond. This corresponds to physical lengths of the order of one millimeter.

Other Sources of Coherent Light In addition to the lasers described above and summarized in Table 1, there are several other techniques for generating coherent infrared and optical radiation. Stimulated Raman scattering, the basis of the original liquid Raman laser, is now used to generate frequencies throughout the visible and infrared region. Harmonic generation, utilizing the nonlinear index of refraction of solids, liquids, and gases at high intensities, has produced radiation out to the extreme ultraviolet at wavelengths below 0.1 μm. Similarly, these same nonlinear materials may be used for parametric oscillators, which are tunable devices producing two output frequencies whose sum is equal to the driving laser frequency. An excellent review of laser principles and a description of these latter systems may be found in Ref. 1. The last entry in Table 1, the free electron laser, is included for completeness, although the radiation generation process is describable by relativistic electron dynamics and does not necessarily invoke the stimulated emission mechanism. The radiation in this case arises from the interaction of an electron beam near the velocity of light with a spatially periodic magnetic field. A description of this device and a detailed review of the complete laser field may be found in Ref. 2.

LASER FUSION

The object of laser fusion research is to use laser radiation to heat small pellets of deuterium/tritium mixture to produce the nuclear fusion reaction

$$D + T = {}^4He + n + 3 \times 10^{14}\ J/Kg.$$

The reaction is exothermic with about one-fifth of the energy in the ^{4}He particles. Eventually it is hoped to find ways of using the excess energy for economic electricity generation. The idea was first reported in 1972.

To produce a significant reaction rate, a temperature of $\sim 10^8$ K is required and the corresponding pressure causes a rapid expansion of the deuterium-tritium fuel. The aim is to complete the nuclear fusion burn before the expansion can cool and extinguish the reaction. Since inertia limits the expansion velocity the approach is sometimes called *inertial confinement*, in contrast to magnetic confinement (see the article on FUSION POWER). Although other heating methods for inertial confinement (e.g., electron, light-ion, or heavy-ion beam bombardment) are being considered, laser heating is attracting most attention because focusing is easier, there is probably less undesirable core preheat, and it is possibly more economic.

The burn condition for a sphere of fuel of radius r, is that the number of particles burnt before significant expansion must be approximately equal to the total number of particles, i.e.,

$$n^2 \langle \sigma v \rangle t \approx n.$$

where t is the burn time ($\approx$expansion timescale r/v), v is the ion thermal velocity, and σ is the fusion cross section. It happens that $\langle \sigma v \rangle / v$ is approximately independent of v in the temperature range important for fusion, so the condition is equivalent to $nr \approx$ constant or, since n is proportional to the final density ρ, $\rho r \approx$ constant. Numerically $\rho r > 30$ kg/m^2 is required, determined by the need to keep the dimensions greater than the ^{4}He particle range so that the ^{4}He energy can make up for heat radiated and thereby maintain the burn. The fusion energy is produced as a miniature thermonuclear explosion. It is estimated that the maximum energy of each explosion that can be handled is ~ 15 kg TNT, equivalent to $\sim 10^8$ J, and about 30 explosions per second would be required for a 1-GW(e) power station. The laser energy required to heat the fuel would be $\sim 10^6$ J. Each explosion would burn about 3×10^{-7} Kg of D/T mixture, corresponding to a small pellet of only $\sim 10^{-3}$ m radius. The burn time is $\sim 5 \times 10^{-10}$ s, and the pressure in the burning fuel would be $\sim 10^{12}$ atmospheres. The burn condition and the fuel radius correspond to $\rho \approx 3 \times 10^5$ kg/m^3 and a compression of ~ 1500 times the density of liquid D/T mixture. The feasibility of laser fusion depends on developing a way of getting this high compression.

The compression is produced by laser radiation, which exerts pressure on the pellet by heating and evaporating the surface material. In moving away, the ablated material carries momentum and, by Newton's Third Law, a corresponding pressure is exerted on the remaining material (the ablation pressure is, under the required conditions, much greater than the ponderomotive pressure of laser photons). However the simple application of an arbitrary pressure pulse of laser radiation to a sphere of fuel will not produce the required temperature and pressure. In plane geometry, conventional strong shock theory gives a compression of 4 because of preheating by the shock, and spherical convergence only increases the compression to ~30 because of the outward-going shock reflected at the fuel center. To obtain high compression, shocks must be avoided so that the compression is effectively isentropic and the temperature kept low until after the compression has been achieved. One method that has been proposed is continuously to increase the driving pressure while the implosion proceeds to that the shock and piston do not part, thereby avoiding shock preheating and the final compression limit due to the reflected shock from the center. This is not easy to achieve because of two factors: the high power required at the end of the implosion and the difficulty in getting the correct pressure variation in the short time available. These problems may be reduced by using a hollow shell target. A pressure p will accelerate a fuel shell of thickness δ to a final velocity $(2rp/\rho_s\delta)^{1/2}$, where ρ_s is the initial density, so the final pressure produced at the centre is a function of r/δ. This is further increased by convergence. For example, calculations show that with $r/\delta = 10$ the ratio of the final pressure to the driving pressure is ~600. The sensitivity to the pressure variation can be reduced by using a heavy "pusher" shell of another material which may be accelerated by a pressure more uniform in time. A further increase in energy may be obtained by surrounding the pusher with another massive shell with an intervening vacuum space. The massive shell is accelerated by the driving pressure and collides with the pusher/fuel shells which, by conservation of momentum (allowing for shocks in the shell thickness) move away with velocity $\sqrt{2}$ times the massive shell velocity. The use of massive shells to tailor the implosion velocity would reduce the overall efficiency because of the energy required to move the pusher/massive shells. Another important factor is the cost of complicated shell pellets.

The absorption of the laser radiation occurs at a critical radius where the radiation frequency equals the natural frequency of the electrons, called the *electron plasma frequency*, at a density $10^{15}/\lambda^2$ m^{-3}, where λ is the radiation wavelength in meters. About 20% of the incident radiation is absorbed. Heat is transported from the absorption to the ablation radius by electron thermal conduction; at high power the heat transport is restricted by the finite flow velocity of free streaming electrons, reducing the pressure available as a function of power. This limits the overall efficiency. Also, the faster electrons may have sufficient mean free path to penetrate the ablation radius to preheat fuel at smaller radii, so the resultant pressure reduces the final compression. The preheating is wavelength dependent and is a severe limit to target design.

Another limit to the compression may be Rayleigh-Taylor instabilities which occur when the low density ablated material exerts acceleration pressure on the heavy shell. These become more restrictive with increasing ratio of instability wavelength (λ_R) to shell thickness: when $\lambda_R < \delta$ the ripples cause some turbulent heating of the shell; when $\lambda_R \sim \delta$ the shell is strongly turbulently mixed and preheated; and when $\lambda_R > \delta$ the instability disturbs the implosion symmetry. Although Rayleigh-Taylor instabilities cause heating and are a fairly severe limit on the symmetry of the implosion, it is possible that the problem may be reduced by damping due to viscosity and thermal conduction around the shell. Such damping occurs when the distance between the absorption and ablation fronts exceed about one-half the initial fuel radius.

Present experiments test laser fusion principles using glass microballoons of ~10^{-4} m in diameter and ~10^{-6} m wall thickness, containing D/T gas at a pressure of ~100 atmospheres. The laser pulse energy is a few kJ and power ~10^{13} W, produced in a number of beams (~10) arranged to exert pressure from all directions. In contrast to the ideal laser compression described above, the energy is delivered in a time short compared to the collapse time: so the thin, dense glass wall suddenly vaporizes and exerts pressure on the D/T gas; this is called an *exploding pusher*. A disadvantage of this method of operation is that considerable electron preheat can develop, but an advantage is that the preheat tends to inhibit Rayleigh-Taylor instabilities. The absorption of the laser light has been found to be complicated, involving such processes as inverse bremsstrahlung, stimulated Brillouin scattering, parametric instabilities, stimulated Raman scattering, and nonlinear density profile steepening. Compressions of a few times 100 are obtained and temperatures up to ~10^7 K. A fraction of up to 10^{-8} of the fuel is burnt, giving a neutron yield of ~10^{11} per pellet.

In conceptual laser fusion reactors, a reaction chamber of ~10 m diameter is envisaged. A heat exchanger/tritium breeder blanket surrounds the chamber in a way similar to magnetic confinement systems. The heat from the blanket would be used to generate electricity, some of which is used to drive the laser. The overall efficiency (the laser efficiency times the electrical generation efficiency) must exceed the inverse of the energy gain in the fusion reaction (~10^3) for net energy production. Since the generating efficiency is ~20%, the laser efficiency must >~0.5%, including coupling to the plasma. Short laser wavelengths favor good plasma coupling and reduce preheat, but the lasers are inefficient. A $\lambda = 1$ μm Nd glass laser has an efficiency of only 0.1%, whereas a $\lambda = 10\ \mu m$ CO_2 laser has an efficiency of 1%. Attempts are being made to increase the coupling efficiency of Nd glass lasers by using short wavelength harmonics. However, glass lasers are probably unsuitable for the continuous high repetition rates required in a reactor, and so short wavelength gas lasers (e.g., using KrF) are being developed.

A proposal to increase the overall reactor efficiency is to use a liquid lithium wall in the reacting chamber, which will absorb the fusion energy pulse by evaporation and will be continuously replaced: this may give an order of magnitude increase in the power that can be handled. Among technical problems to be overcome in obtaining power from laser fusion are launching the pellets, laser beam or pellet steering, pumping gaseous debris so that it does not scatter the laser beam, production of cheap multilayer pellets ($<\sim 7$¢/pellet, 1982 value) and disposal of ~100 metric tons/year of radioactive pellet debris.

It is hoped to demonstrate scientific breakeven in the mid-1980s by using multibeam lasers of energy $\sim 10^5$ J.

Support for inertial confinement research comes from its application in the areas of fusion power generation, the basic physics of matter at extreme densities and pressures. Indeed, confidence in the application to produce power derives from the knowledge that ignition may be achieved by compressional heating in thermonuclear weapons. The main countries interested in inertial confinement research are USA, USSR, Japan, UK, and France. In the last 10 years the US has spent ~\$10 billion on laser fusion research; in 1982 the spend was ~\$200 million, which was about 50% of the spend on the magnetic confinement approach to fusion power. However the US laser fusion spend is expected to decrease to ~\$100 million in 1983, corresponding to about 25% of the spend on magnetic confinement.

LATTICE DEFECTS

The crystal consists of a regular array of atoms (or molecules) (see CRYSTALLOGRAPHY). But the perfect crystal, in which all atoms are on precisely defined lattice points, is nonexistent. Real crystals contain more or less *lattice defects* or *lattice imperfections*. Even a small amount of lattice defects can affect properties of crystals remarkably, so that the understanding of the behavior of lattice defects is very important in modern solid-state physics.

Lattice defects are classified into three classes from the point of view of the dimensional extension. These are the *point defect*, the *line defect*, and the *plane defect*. Vacancies (atomic or ionic) and interstitials (atoms or ions) are the most elementary point defects. A dislocation is a line defect. Twin boundaries and extended dislocations are some examples of plane defects.

Dislocations Dislocations are lattice defects quite unique in that their movement produces the plastic deformation of crystals, and that mechanical properties of crystals are largely determined by the behavior of dislocations in crystals. The presence of dislocations, however, affects also various physical properties of crystals other than plastic and mechanical properties.

Figure 1 shows an edge dislocation in a simple cubic crystal, the dislocation line being perpendicular to the plane of the paper. The same atomic arrangement is repeated in the direction of the dislocation line. The edge dislocation is formed at the edge A of the inserted extra atomic half-plane AB. The edge dislocation A can also be formed by a partial slip of the crystal along a slip plane CAD by a shear stress shown by arrows in Fig. 1. The part CA of the slip plane has already slipped, but the part AD has not yet slipped. Therefore, the dislocation line A, which penetrates the plane of the paper perpendicularly at A, is defined as the boundary between the slipped and unslipped parts of the slip plane. When a dislocation sweeps the whole slip plane from C to D, the upper and lower half-crystals are sheared along the slip plane by an amount and in a direction shown in Fig. 1 by a vector b, which is called the Burgers vector. The slip produced by the movement of a dislocation is the elementary process of plastic deformation of crystals.

The Burgers vector of an edge dislocation is perpendicular to the line of dislocation as can be seen from Fig. 1. This is not the case in dislocations other than the edge dislocation. In the case of screw dislocation the Burgers vector is parallel to the line of dislocation. Atomic planes perpendicular to a screw dislocation form a continuous helicoid around the screw dislocation (AD) as shown in Fig. 2. In the case of a mixed dislocation, which consists of the edge component and the screw component, the Burgers vector and the dislocation line make an angle between 0° and 90°.

The stress and the strain around a dislocation can be accurately calculated by the theory of elasticity except in the region called the dislocation core which is within a few atomic distances of the center of a dislocation (broken circle in Fig. 1), as the crystal regions outside the core can be treated as an elastic continuum, because the strain there is sufficiently small. The following are some of the important results

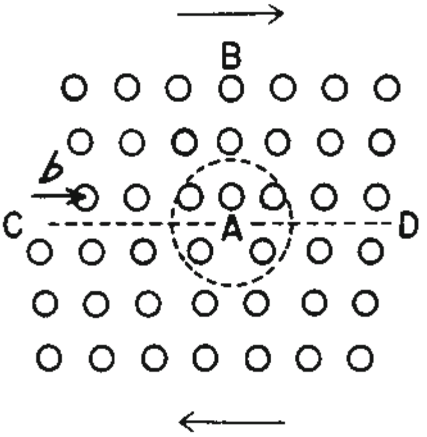

FIG. 1. An edge dislocation in a simple cubic crystal. A: center of a dislocation; AB: extra half-plane; CAD: slip plane; *b*: Burgers vector.

of the elasticity theory of dislocations. The stress around a dislocation decreases inversely proportionally to the distance from the dislocation axis. The total strain energy integrated over the entire crystal outside the core is proportional to the square of the magnitude of the Burgers vector, and is of the order of magnitude of μb^2 for a unit length of a dislocation, where μ is the shear modulus and b is the magnitude of the Burgers vector. Two or more dislocations interact with one another through the stress field. Two parallel screw dislocations attract each other if their helicoidal windings are in opposite directions (i.e., a left-handed screw and a right-handed screw), and repel each other if their windings are in the same direction. Two parallel edge dislocations with parallel Burgers vectors attract or repel in a somewhat complicated way (for details, see any textbook of dislocation theory, e.g., Refs. 1, 2, and 3).

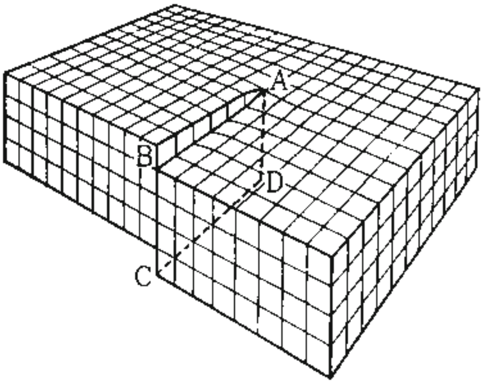

FIG. 2. A screw dislocation AD in a simple cubic crystal.

The stress, the strain, and the energy in a dislocation core can be computed if the discrete structure of the crystal is considered. The core energy of a dislocation in copper, for example, is of the order of 1 eV per dislocation length of an atomic spacing. This is considerably smaller than the elastic strain energy outside the core.

Another important property of dislocations which can be understood by considering the discrete and periodic structure of the crystal is the so-called Peierls potential. When an edge dislocation is located, e.g., at position A in Fig. 1, the atomic arrangement around the dislocation has a mirror symmetry so that the energy of the dislocation is at a minimum. When the dislocation has moved a distance b, the atomic arrangement around the dislocation resumes the same configuration as before and the energy is again at a minimum. Between these two positions with minimum energy the atomic configuration of the dislocation is not necessarily mirror symmetrical and the dislocation energy increases. Thus the potential energy of the dislocation changes periodically with the period b, when the dislocation moves along the slip plane. This potential barrier is called the Peierls potential. The Peierls potential is the intrinsic resistance to the movement of dislocations in crystals. It is relatively small in most metals, and is relatively large in such crystals as diamond, refractory oxides, and so on.

Incidentally, there are many extrinsic origins of resistance to the movement of dislocations, i.e., impurity atoms, point defects, plane defects, other dislocations, etc. These impurities and defects interact with the moving dislocations concerned, and act as obstacles to the movement of these dislocations. A larger resistance to the movement of dislocations means a larger resistance to the plastic deformation and accordingly a higher mechanical strength of crystals.

Properties of dislocations discussed so far are general ones and are not restricted to any specific crystal. But there are some properties which directly reflect specific crystal structures (e.g., extended dislocations) or specific physical characteristics of crystals (e.g., a space charge around a dislocation in semiconductors).

Now in discussing an extended dislocation, it would be more convenient to refer to a specific crystal structure, in which a dislocation is known to extend. The face-centered cubic (fcc) lattice gives a good example. In fcc metals a total dislocation, whose Burgers vector is a lattice vector $(a/2)\{110\}$, dissociates into two partial dislocations, whose Burgers vectors are of the type $(a/6)\{112\}$ and are smaller in magnitude than a lattice vector. An example of dissociative reaction is:

$$(a/2)[10\bar{1}] \rightarrow (a/6)[11\bar{2}] + (a/6)[2\bar{1}\bar{1}],$$

where a is the lattice constant. The passage of the first partial dislocation $(a/6)[11\bar{2}]$ along a

(111) slip plane in a perfect fcc lattice leaves behind it a fault of stacking of (111) atomic layers, which is a plane defect called a stacking fault. By the passage of the second partial dislocation $(a/6)[2\bar{1}\bar{1}]$ along the same slip plane, the faulted plane resumes its original perfect lattice. Thus between the two partial dislocation lines there is a strip of stacking fault. This dislocation configuration as a whole is called an extended dislocation. The width of the extended dislocation is determined by the balance of two forces, namely the repulsive force between two partial dislocations and the contractive force of the stacking fault. In copper and copper alloys, for example, the width is fairly large and is from 10 to 100 Å, while in aluminum, which has a large stacking-fault energy, the total dislocation practically does not extend. The extension of dislocations greatly affects the plastic and mechanical behaviors of crystals.

In elemental semiconductors with the diamond lattice, an edge dislocation has unpaired valence bonds or dangling bonds along the edge of the extra half-plane. In *n*-type germanium, for example, a dangling bond, which acts as an acceptor, traps an electron, so that an edge dislocation line is negatively charged. This negative line charge is shielded by a surrounding cylindrical positive space charge. This electrical structure of dislocations affects the electrical and other properties of semiconductors.

Dislocations are introduced into crystals by plastic deformation, and by precipitation of point defects such as vacancies or interstitials. They are also introduced during crystal growth to relax various internal stresses.

Point Defects Atomic or ionic vacancies and interstitial atoms or ions are the most elementary point defects. Di-vacancies, tri-vacancies, and higher clusters of vacancies, and di-interstitials, tri-interstitials, and higher clusters of interstitials can exist. Complexes of these point defects with impurity atoms are formed according to circumstances.

The most fundamental physical properties of point defects are the formation energy, the migration energy, the binding energy, and the atomic configuration around the point defect. These properties are widely different in different crystal structures and in different types of crystalline solids. In most metals and elemental semiconductors the formation energy of a single vacancy E_{fV} is smaller than the formation energy of a single interstitial E_{fI}, while the migration energy of a single vacancy E_{mV} is larger than the migration energy of a single interstitial E_{mI}. Typical examples of energy values are: $E_{fV} \approx 1$ eV and $E_{mV} \approx 1$ eV for copper; $E_{mV} \approx 0.2$ eV for *p*-type silicon and $E_{mV} \approx 0.3$ eV for *n*-type silicon; the binding energies between two single vacancies to form a di-vacancy are a few tenths of an eV in noble metals.

The relaxation of atoms around a single vacancy in most metals has a simple symmetry which is related to the symmetry of the crystal structure. But the atomic configuration around a single vacancy in covalent semiconductors is somewhat distorted because of the quantum-mechanical Jahn-Teller distortion. The atomic configuration of a single interstitial is rather complicated, because different configurations for an interstitial are possible in some cases, and because the configuration often shows a lower symmetry than the host crystal. In cubic metals, for example, the so-called split interstitial or dumbbell-form interstitial is the most stable one because of the lowest formation energy (for details, see any textbook of point defects, e.g., Refs. 1 and 4).

In ionic crystals one or more of the following point defects are considered according to respective circumstances, i.e., vacancies of positive ions and of negative ions, and interstitials of positive ions and of negative ions. Some of them form complexes with impurity ions. Point defects in alkali halides and similar ionic crystals have been extensively investigated in connection with their optical properties, and many color centers are well analyzed in terms of point defects (see COLOR CENTER; for details, see, e.g., Ref. 5). In alkali halides, for example, the *F* center is a negative ion vacancy with a trapped electron, the *M* center is a pair of negative ion vacancies with two trapped electrons, and the *H* center is an interstitial negative ion with a considerably distorted configuration, having captured a positive hole.

The migration of point defects results in the transport of materials in crystals, i.e., self-diffusion, mutual diffusion, ionic conduction, etc. In most metals and covalent semiconductors the self-diffusion and the substitutional impurity diffusion occur by means of the migration of vacancies. The diffusion and the ionic conduction in ionic crystals take place by means of the migration of ionic vacancies and/or ionic interstitials.

Point defects are produced in crystals in thermal equilibrium, their concentration being approximately equal to $\exp(-E_f/kT)$ at the absolute temperature T, if the formation energy is E_f. Here k is Boltzmann's constant. Point defects are also introduced into crystals in excess of thermal equilibrium by irradiation of energetic radiation or by plastic deformation. Excess point defects are annihilated by annealing, the kinetics of which is well investigated under various conditions (Ref. 4).

LENS

A lens is any element that focuses light to form images. Many lenses are found in nature. Ice crystals, waves on the surface of water, and all the eyes of humans and animals are examples of lenses. These lenses have one or more curved surfaces and are made of a transparent material. Manufactured lenses are usually made out of glass, plastic or crystal material. The simplest lens consists of two ground and polished spherical surfaces. A line connecting the centers of the two spheres is called the optical axis of the lens. The lens is edged to form a cylindrical surface centered on the optical axis. The spherical surfaces may be convex or concave, resulting in lenses which are positive refracting or negative refracting. A positive lens collects the light from a distant object and focuses it to a real image. The negative lens disperses the light and causes it to diverge from a virtual image. Positive and negative elements are used in combinations to form optical lens systems. The optical axes of each of the lens elements usually coincide to form centered optical systems. Most optical systems are designed to be centered optical systems, but in manufacture the centering is seldom perfect, so the system will have various degrees of defective performance.

Spherical surfaces are usually used in optical systems because of stringent requirements on the manufacture of optical elements. In order to perform properly, a given surface in an optical system often has to coincide with the prescribed surface to within a few millionths of an inch. Such extreme tolerances can be achieved on spherical surfaces because spheres may be ground and polished with self-correcting techniques.

A few lenses have been made using nonspherical surfaces, but they usually have rotational symmetry around the optical axis. These surfaces are called rotationally symmetric aspheric surfaces. Aspheric surfaces of this type are difficult to generate so they are used infrequently.

Some lenses are made with cylindrical and toric surfaces. Spectacle lenses often have surfaces of this type. It is practical to use aspherics in spectacle lenses because the beam of light entering a person's eye is small in diameter. The performance requirements are therefore not great. Cylindrical or toric surfaces are seldom used in telescopes, or microscopes of high performance.

There are many types of glass used in optical lenses. Some glasses are more dispersive (see REFRACTION) than others. By combining positive and negative lenses of different glass it is possible to correct for chromatic aberrations.

Theory of the Lens Most of the performance of a lens or lens system may be understood by considering that light travels as rays in straight lines until it encounters a change of index of refraction. The light is then refracted according to Snell's law (see REFRACTION). Light is emitted from a point source of light in the object as a diverging beam of rays. A lens is able to collect these rays and refocus them to an image point (see Fig. 1).

With analytical geometry, one may derive equations for calculating the path of any ray as it passes through the optical system. The procedure is called ray tracing. The mathematical equations used to trace rays are long and complicated, and have to be computed with many significant figures. Prior to the use of modern digital computers, the design and analysis of lens systems was a long tedious job. An average lens design required many months of calculation. Today most of these calculations are done on large computers, and few people need to be concerned about being able to ray trace.

Paraxial Rays Paraxial rays pass through the center portion of the lens and the assumption is made that the object points are close to the optical axis. The ray-tracing equations for paraxial rays are simple, and by using the paraxial approximation, many useful theorems for lens performance may be worked out.

In the paraxial region, any optical system may be described by locating six cardinal points along the optical axis. Once these cardinal points are known, the position and size of the image of any object may be computed from the following formulas (see Fig. 2).

$$m = \frac{\bar{y}_k}{\bar{y}_0} = -\frac{z'}{f} = -\frac{f'}{z} \qquad (1)$$

$$zz' = ff' \text{ and } \frac{f}{s} + \frac{f'}{s'} = 1 \qquad (2)$$

$$f/n_0 = f'/n_k \qquad (3)$$

$$P_1N_1 = P_2N_2 \qquad (4)$$

$$P_1P_2 = N_1N_2 \qquad (5)$$

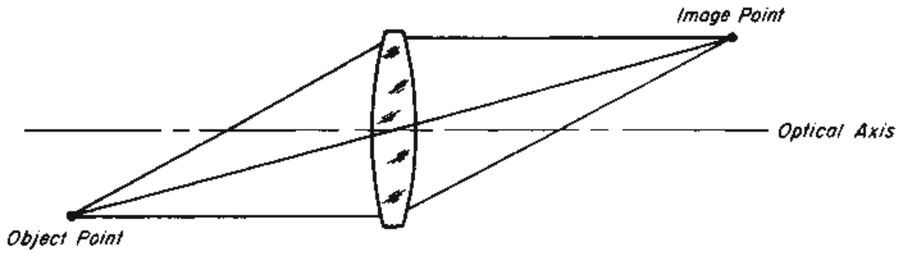

FIG. 1. A diagram showing how a lens collects diverging rays and focuses them at an image point.

$$F_1N_1 = f' \tag{6}$$

$$N_2F_2 = f \tag{7}$$

P_1 and P_2 are called the first and second principal points. N_1 and N_2 are called the first and second nodal points. F_1 and F_2 are the first and second focal points. f and f' are the front and back focal lengths. n_0 and n_k are the indices of refraction in the object and image space.

The following terms are commonly used in connection with lenses:

Field of View. The field of view usually refers to the half angle subtended by the object as seen from the first principal point P_1. For example, it would be $\tan^{-1}(\bar{y}_0/S)$ in Fig. 2. When specified for a lens, it usually refers to the maximum size of object which may be imaged by the lens. Optical designers tend to describe the field of view by its half angle, as shown in Fig. 2. Marketing firms often refer to the full field which is twice the half angle. If not clearly stated, confusion over this term may result.

Relative Aperture. This refers to the half angle of the cone of rays converging to the axial image point. The sine of this angle is often called the numerical aperture and is written *NA*. If *NA* is large, the lens collects a large cone of light and focuses it on the image. Another way to describe this *NA* is to use the term f-number. The f-number of a lens and the *NA* of a lens are related by the following equation

$$f\text{-number} = \frac{0.5}{NA}$$

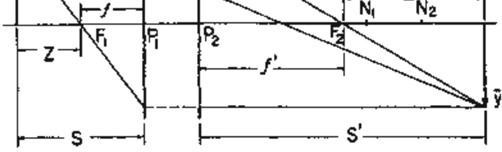

FIG. 2. Diagram showing the location of the six cardinal points in a lens system.

Aperture Stop. The aperture stop in a lens system is a diaphragm which determines the *NA* of the lens.

Lens Aberrations Lens designers attempt to combine elements and glass types to reduce the lens aberrations. All points in the object should be imaged as points in the image and should be located at or very near the position predicted by the paraxial rays. In lenses of large relative aperture and field of view, there are usually several residual aberrations that designers are unable to eliminate. There are the following types of aberrations:

(1) Spherical
(2) Coma
(3) Astigmatic
(4) Field curvature
(5) Distortion
(6) Axial chromatic aberrations
(7) Lateral chromatic aberrations.

These aberrations are corrected by using combinations of positive and negative elements. There are two general principles one may use as guide lines in correcting optical systems. (1) A closely spaced positive and negative lens with the aperture stop in contact may be corrected for spherical aberration, coma, axial and lateral chromatic aberration and distortion. (2) It is necessary to use positive and negative lenses with appreciable air space between them to correct field curvature and astigmatism.

There are many conflicting requirements in lens systems. Lenses of large relative aperture usually are designed to cover small fields of view. A large field of view normally dictates a small relative aperture. Wide fields and large aperture may be realized by using many elements or by compromising some of the image quality. For example, lenses of 140° total field working at $f/2$ are available, but they are complex and have large amounts of distortion. Periscopes allow one to look through a long pipe and see a wide field at high magnification, but there is always some residual chromatic aberration and field curvature left in the design.

Lenses are usually designed for specific applications, and the designer has made a careful balance between conflicting requirements. It is seldom that a lens designed for one application will perform optically in another. In the past there was a tendency to misuse lenses, because it was difficult to design a new system. Today it is easy to obtain a new design. It is, however, expensive to build a prototype of a new lens design. This is because the optical shop has to make the lenses without adequate tooling. It takes a skilled optician to make a prototype lens accurately enough to perform as designed. When production runs are large, modern tooling can ease the burden on the skilled optician and the cost per lens can be drastically reduced.

Lens Testing A designer specifies a set of curvatures, thicknesses and optical glasses for a nominal design. The work shop makes the lens to these specifications within certain tolerances. The final lens must then be tested to make sure that the over-all performance is as expected. It is rare indeed that a lens performs exactly as computed. It is then necessary to determine if the difference is negligible and, if not, what to do about it. First, one tests the complete assembled lens and attempts to predict the performance. By studying the defective image, it may be possible to locate the sources of error. The tests consist of studying the light distribution in the image of a point source. This is done on a lens bench or testing interferometer. Sometimes it is possible to locate the source of error by testing the over-all system, but usually the lens system is disassembled and all the lens surfaces, spaces and centering are checked separately.

The invention of the laser (1960), the astonishing progress in computing equipment (1950–1980), the development of small detectors, and the associated transistor technology have brought about major changes in lens testing. Interferometers are used more extensively, tolerances are held better in the optical shop and mounting techniques have improved. The trend now is to use better quality control at every step of the manufacturing process. The objective is to manufacture and mount the lenses to achieve a high yield of acceptable lenses. The disassembly of lenses as described above is seldom done beyond the prototype stage. In large production runs the rejected lenses are few and seldom are they repaired.

Lens Types There are several optical systems which may be classified as types. There is considerable overlap between the types, but there is some value in the following classification.

Microscope Objectives. Microscope objectives are used to magnify small objects. They are usually used with a microscope eyepiece. Microscope objectives range in focal lengths from 2 to 48 mm and are used at magnifications ranging from 1000 to 5×. The high-power objectives are made up of many small elements. Some of the lenses are only a few millimeters in diameter. The lens making and mounting procedures for such small lenses are quite different from larger elements.

Telescope Objectives. Telescope objectives are used to view distant objects. Telescope objectives have a wide variety of focal lengths and diameters. They are usually corrected precisely for spherical aberration, coma and axial chromatic aberration. Since telescope objectives cover small fields of view, astigmatism and field curvature usually are not corrected. Telescope lenses of large diameter (20 inches or more) become afflicted with chromatic aberration which cannot be corrected, so many of the large telescopes used by astronomers are mirrors instead of lenses.

Telescope objectives are used in binoculars, opera glasses, surveying instruments, gunsights, and many laboratory instruments.

Periscopes. Periscopes are used to enable one to look through a long tube. The submarine periscope is one well-known example, but there are many other types used in industrial and medical instruments. Gastroscopes and cystoscopes are examples of periscopes used in medical instruments. Periscopes are made up of a train of telescope objectives and eyepieces.

Camera Objectives. By far the largest class of optical lens systems would be classified as camera lenses. They are used to record images on films as in common landscape cameras, but today they are also used with many other types of image recording systems such as television image tubes, electrostatic plates, etc. The distinguishing features of camera lenses are wide field and large aperture. Usually the image is located on a flat image plane. Camera lenses range in complexity from a single meniscus lens to systems with more than ten elements. Camera lenses cover such a wide range of uses that one could claim all lenses to be a form of camera lens. For example, a long focal length lens used on a 35-mm camera may actually be very similar to a telescope objective.

Zoom Lenses. Zoom lenses are in common use on cameras and a wide variety of instruments. A zoom lens has a variable focal length, which is achieved by changing the spaces between elements. The lenses are positioned accurately with precision cams, which have become practical to manufacture since the introduction of numerically controlled machines. Zoom lenses first appeared on 8 mm and 16 mm movie and TV cameras. They were originally too large for the popular 35 mm still cameras. The latest designs and manufacturing methods have improved so much that the sizes are much reduced and 35 mm zoom lenses are now popular.

Photolithographic Lenses. Some of the most precise lenses made are used in the making of modern integrated circuits. These lenses are used to project images of precision masks onto silicon wafers. The devices on the silicon wafers have dimensions as small as one micrometer. The lenses have to form these minute images over large areas. Some of these lenses are capable of imaging several million independent image spots in a single exposure.

Satellite Lenses. Since the development of earth satellites, camera lenses have been made to photograph the cloud patterns covering the earth. These lenses are short focal length and wide field. Lenses of long focal length have been able to photograph lines less than 6 inches wide on the ground from a satellite in orbit 200 miles from the earth. Many spectacular pictures have been taken of planets and stars from satellite cameras.

Laser Scanning Lenses. The wide variety of gas and solid state diode lasers along with modern modulating systems has lead to many applications using laser scanners. The extremely intense small diameter beams from lasers may be reflected from oscillating mirrors to provide a rapidly scanning line of light similar to that generated in a cathode ray oscilloscope. The advantage is that the material to be scanned does not have to be in a vacuum. Nearly any material may be scanned with a laser beam. Laser scanners can be used to scan printed material and convert the light reflected into an electrical signal. The electrical signal may then be stored in a computer memory, and image processed. Finally, it can be read back through a similar laser scanner and be printed out on a light sensitive material of which there are now many kinds. Since these scanning lenses work with lasers the light is monochromatic, making it easier to design high quality lenses. Some of the scanning lenses can surpass the image quality of lithographic lenses because the light used is monochromatic.

Eyepieces. Eyepieces are quite clearly a distinctive class of optical lens system. Eyepieces are designed to match the sensitivity and physical requirements of the human eye. For example, the eye is sensitive in the visual part of the spectrum so eyepieces are designed for this range of wavelengths. An eyepiece must also be located with its aperture stop in an external position so that the observer's eye may be located within it. This requirement imposes serious limitations on eyepieces, and they are seldom useful in any other applications.

Magnifiers are essentially eyepieces except they are designed to view opaque material while an eyepiece is designed to view an aerial image formed by an objective.

Condensers. Condensers are used to collect and focus large amounts of light. They are found in projectors and substages of microscopes. A searchlight mirror is a form of a condenser. The numerical aperture of a condenser is usually very large, and for many applications, the image-forming properties are not important. Condensers are often made, therefore, with low-quality surfaces. Some condenser lenses are molded. Condensers are usually placed close to an intense light source which heats and cracks the lenses if made of glass. Condensers are often made out of quartz because of its ability to withstand heat. Aspheric condenser lenses are common in condensers. With some of the modern high-intensity light sources, it is necessary to correct for the image errors in order to obtain uniform illumination.

LIGHT

Light is a form of electromagnetic energy. It has a physical character similar to that of radiowaves. In order that the human eye may get the sensory perception of light, the electromagnetic waves entering the pupil should have a wavelength λ between 4000 and 7000Å (1Å = 10^{-8}cm). The wavelength of a wave is inversely proportional to its frequency ν. The product of the two quantities equals the velocity of propagation. For light in vacuum one has $c = \nu\lambda = 3 \times 10^{10}$ cm/sec. The frequency of light waves is therefore almost a billion times higher, their wavelength a billion times shorter, than the waves of standard radio broadcast bands. The perception of color depends on the distribution of the electromagnetic energy over the visible wavelengths. White light is a superposition of waves at many frequencies. It can be decomposed into its monochromatic spectral components by a prism or other spectral apparatus. The violet end of the spectrum is near 4000Å, the red end near 7000Å. Whereas light in its narrow definition should be confined to this relatively narrow portion of the electromagnetic spectrum, it is customary to extend the definition to the ultraviolet and infrared portion of the spectrum. One sometimes speaks loosely of ultraviolet and infrared "light," although electromagnetic waves at these frequencies are not detected by the eye. The human mind and hands have, however, devised a large variety of instruments by which such invisible radiation can be detected and measured. Photographic plates can be made sensitive to x-rays, with a wavelength shorter than the ultraviolet, or to the much longer wavelengths of the infrared. Geiger counters can detect electromagnetic radiation of very short wavelength (λ-rays and x-rays). Photoelectric cells are sensitive in the ultra-violet and visible portion of the spectrum. Photoconductivity can be used to detect infrared radiation. At still longer wavelengths, the microwaves and radiowaves are detected by diode detectors in appropriately arranged microwave and radioreceivers. All these types of radiation can also be converted into heat by absorption in a blackbody, i.e., a material that can absorb radiation at all wavelengths. The radiation can be felt as heat, if it is absorbed by the human skin.

The study of the human eye as a detector of light is the task of *physiological optics.* The impression of light is not necessarily always connected with the simultaneous presence of electromagnetic energy at the retina. We see "stars" from a heavy mechanical blow in the dark. The impression of light is retained for about 0.1 second after the light source is shut off. This fact is made use of in the movies to create the impression of motion by a series of still images. The eye is a detector with a relatively long response time. Photoelectric cells can react more than a million times faster. Color vision is also subject to physiological peculiarities which are quite complex (see COLOR and VISION AND THE EYE).

The property of light which is most immediately accessible to observation is its propagation along straight lines (shadows). If light rays pass from one medium to another, their direction is changed according to the law of REFRACTION. If the light in medium 1 propagates with a velocity v_1 and makes an angle ϑ_1 with the normal to the boundary between media 1 and 2, the direction ϑ_2 in medium 2, with a velocity of propagation v_2 is given by Snell's law, $\sin \vartheta_1/\sin \vartheta_2 = v_1/v_2 = n$. The constant n is called the relative index of refraction of medium 2 with respect to medium 1. These three laws are the basis of *geometrical optics.* This branch of the science of light describes the paths of light rays, the formation of images by mirrors and lenses, the action of telescopes, microscopes, prisms and other optical instruments.

The wave character of light becomes apparent by more refined observations. The phenomena of diffraction, interference and polarization are the subjects of *physical optics.* Diffraction describes how waves are bent around obstacles. They represent corrections to and deviations from the laws of geometrical optics. These effects become pronounced only when the material has a characteristic dimension comparable to the wavelength of the wave. When light waves reach the same point along different paths, the resulting intensity may be smaller than that produced by each individual wave separately. The relative phases of the waves may be such that they interfere destructively, when the arrival of one wave with maximum positive deflection coincides with that of another wave with maximum negative deflection. Observations of light in crystals of calcite (iceland spar) first showed that there are two different modes of vibrations for each direction of propagation. These are called the two transverse modes of polarization.

All phenomena of geometrical and physical optics are described consistently by Maxwell's equations of electromagnetic theory. Optical phenomena are, therefore, closely related to other electric and magnetic phenomena. Around 1900 the prevailing opinion was that the wave character of light was unambigously established and the nature of light well understood.

There was, however, a mathematical difficulty with the intensity of radiation of ultraviolet and higher frequencies. The photoelectric effect could also be interpreted only by considering light to have a quality of particles. The number of electrons emitted from a photosensitive surface is proportional to the intensity of the light. The energy of the individual electrons is, however, determined by the light frequency. This led to the postulate of light quanta with energy $h\nu$, where h is Planck's constant. This duality in nature, in which "wave-like" and "particle-like" properties are combined, is described without internal contradiction by quantum mechanics. The combined "particle and wave" character of light is revealed by the combination of properties of the light sources, the electromagnetic field describing the light waves, and the detectors.

The study of the interaction of light waves with matter in the sources and in the detectors is the subject of SPECTROSCOPY. This is a wide field which encompases atomic and molecular spectroscopy, parts of solid-state physics and photochemistry. The quantum theory was largely developed on the basis of spectroscopic data. A light quantum is emitted by an excited atom, molecule or other material system, when an electron in such a particle makes a transition or "quantum jump" from a state with higher energy to a state with lower energy. The energy difference between these states is equal to the quantum energy $h\nu$. Similarly, the absorption of light quanta is accompanied by an electronic transition from a state with a lower energy to a state with an energy higher by an amount $h\nu$. In this manner, the frequencies of spectral lines are characteristic for the electronic energy levels in each material. The frequency of the light may be said to correspond to the frequencies of the vibrating charges or oscillators, which are represented by the electrons.

Light sources are thus bodies with a sizeable population of electrons in excited states. This may be accomplished by raising the temperature of the material. The most important source of light is the sun. The moon and other planets are visible only because they reflect sunlight, just as all other objects on the earth which we can see by daylight, but not at night. The sun is a star. In stars, the temperature is maintained at a very high temperature by nuclear reactions.

Man-made light sources range from the primitive fire, candles, and oil and kerosene lamps to the electric light bulb, fluorescent gas-discharge tubes, arcs, etc. In early sources, the material particles of smoke or wick were heated by the chemical reaction of oxidation or burning; in the incandescent electric lamps, a wire is heated to a very high temperature by an electric current. There are so many energy levels in these luminous solid materials or gases at high pressures that the emitted light is white and contains essentially all frequencies. The higher the temperature, the more radiation is emitted and the higher the average frequency of radiation. It should be realized that most of the energy is emitted as invisible (infrared) radiation, even in the best incandescent lamps. Hot gases in flames may also emit sharp spectral lines characteristic of the atoms occurring in the flame. The yellow color which arises when kitchen salt is sprinkled in a flame is due to the characteristic yellow spectral line of sodium atoms.

In gas discharge tubes, atoms or molecules are excited by collisions with electrons in the ionized gas. The energy is provided by the generator which provides the voltage necessary to maintain the discharge current. An arc is a discharge in air or in a high-pressure vapor. Mercury and sodium discharges are used for street lighting. Fluorescent tubes for office and home lighting use a gas discharge with a substantial amount of ultraviolet components. This ultraviolet light excites electrons in fluorescent centers on the walls of the tube. The electrons drop immediately from the highly excited state to an intermediate state with a lower energy. From this state they finally drop down to the original ground energy level with the emission of visible light. Gas discharges at relatively low pressure may serve as spectroscopic sources to study the emission spectra of atoms, ions and molecules. From the relationship between the energy levels and the frequency of radiation, it follows that a material, when heated, can emit precisely those frequencies which it absorbs when it is in the lower energy level at low temperature.

All these light sources are incoherent in the sense that there is no phase relationship between the light waves emitted by the different atoms in the source. This is quite different from the property of the usual sources of electromagnetic radiation at lower frequencies. In the oscillator tubes of radio- or microwave transmitters, all electrons move and vibrate in step with each other. The analogy between light and low-frequency electromagnetic radiation raises the question, "Can coherent light sources be constructed?" Recently such coherent light sources have been developed. They are characterized by the emission of a highly directional, highly monochromatic light beam of high intensity. They are called LASERS because they are based on *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation. In the conventional sources, all light is emitted spontaneously. In lasers, the original spontaneously emitted light forces the other excited atoms to emit their radiation in step, or coherently. If stimulated emission thus dominates the spontaneous emission, a laser results. This requires a high concentration of excited atoms and a sufficient feedback mechanism of light by mirrors. In its simplest form a laser consists of a gas discharge in a tube of suitably chosen dimensions and gas pressure between a set of parallel mirrors. Because the atoms in the laser source all act constructively in step, these sources provide a more efficient means to transmit light energy.

The high light intensities available in focused laser beams have led to the development of the branch of nonlinear optics. The optical properties of materials are different at high intensities, because the electronic oscillators are driven so hard that anharmonic properties become evident. A typical effect is the harmonic generation of light in which red laser light is converted into ultraviolet light at exactly twice the frequency, when the high-intensity beam traverses a suitable crystal such as quartz. It should be possible to duplicate at light frequencies all nonlinear effects known from the field of radio communications, such as modulation, demodulation, frequency mixing, etc. It is no longer correct to say that the propagation of a light wave is independent of the presence of other light waves. At high intensities, there is a noticeable interaction between light waves of different frequencies.

The combination of the laws of quantum mechanics and electromagnetic theory gives a consistent description of the generation, propagation and detection of light. Since these same laws also describe many other properties of matter such as electronic structure, chemical binding, electricity and magnetism, etc., it may be said that the nature of light is well understood. In this context, it is not necessary and not even desirable to pose the question, "What is it, precisely, that vibrates in a light wave in vacuum?" The electromagnetic fields acquire meaning only through their relationships with detectors and sources. Human knowledge or understanding is here used in the operational sense that a relatively simple framework of physical concepts and mathematical relationships exists, which gives an accurate description of the wide variety of optical phenomena at present accessible to observation or verification in experimental situations. The following references will introduce the reader to the vast literature of optics and spectroscopy.

LIGHT SCATTERING

When a beam of light falls on a particle, part of this incident beam is diverted from its original path; that part which is diverted and not absorbed is *scattered*.

Light scattering is a familiar phenomenon. The colors of visible objects (other than light sources) are determined by the wavelengths which they scatter most effectively. Scattering by small particles was first studied experimentally by Tyndall (1869) in connection with the blue of the sky.

Classical physics is appropriate for the description of most light scattering phenomena. Thus, light scattering is explained in terms of the forces exerted by the electromagnetic field on the electronic charges which all matter contains. The oscillating electromagnetic field of the incident light exerts a periodic force on each electronic charge, causing it to execute harmonic motion at the frequency of the light wave. It is the fact that an oscillating charge radiates in all directions (except along the line of its motion) which accounts for the scattering. The intensity of the radiation scattered from a particle will be large in directions for which the radiation from the individual elements of the particle interferes constructively, and small in directions in which it interferes destructively.

For particles comparable in size to the light wavelength, the amount of energy scattered as well as the angular distribution of the intensity and polarization of the scattered light are influenced by the distribution of induced oscillating charge within each scatterer. Any correlation which may exist between the positions of the scatterers also affects the extent to which the radiation interferes constructively or destructively to make up the resultant scattered field. Thus, in principle, light scattering provides a tool for the investigation of surfaces as well as of the number, size, structure, and orientation of particles and their interactions.

The problem of relating the light scattering to these properties and vice versa has proved too difficult for exact solution in general, because it would be necessary to solve Maxwell's equations with the proper boundary conditions for each scatterer or scattering element. Many important cases have been solved, however, subject to certain approximations.[1,2,3] Widest success has been obtained for *single scattering*, i.e., for particles sufficiently dispersed that radiation scattered by any one particle can be considered to escape from the medium without being further scattered by other particles. Even for single scattering, however, exact solutions of Maxwell's equations have been obtained only for simple shapes such as spheres (Mie, 1908), spheroids, and cylinders. Thus, even for single scattering, it is often necessary to resort to approximation methods.

If the particles are less than about one-tenth of the light wavelength and if their index of refraction is near to that of their surroundings, only the induced electric dipole radiation is important. (The amplitude of the induced dipole moment is given by the polarizability of the scatterer times the amplitude of the electric vector of the light wave.) Lord Rayleigh (1871) explained Tyndall's principal results in terms of the intensity and polarization of the induced electric dipole radiation. This type of scattering has since become known as *Rayleigh scattering*.[1,2]

Rayleigh scattering is of particular importance. If the particles are dispersed at random (molecules of an ideal gas or widely dispersed macromolecules in an optically homogeneous solution), the individual particles may be regarded as independent sources. In this event, the total scattered intensity is merely the sum of the intensities scattered by the individual particles. The special case of isotropic particles and unpolarized light is both simple and illuminating. The Rayleigh formula is

$$\frac{\text{Intensity of scattered light}}{\text{Intensity of incident light}} = \frac{8\pi^4 N\alpha^2(1+\cos^2\theta)}{\lambda^4 r^2}$$

where N is the number of particles, α is their polarizability, θ is the angle of scattering, λ is the wavelength (in the surrounding medium), and r is the distance from the scattering system to the point of observation (with r much greater than any relevant dimension of the scattering system). Thus, Rayleigh scattering from independent particles is proportional to the number of particles. Moreover, if the dielectric constant of the surroundings is close to that of the scatterer, the polarizability is insensitive to the shape of the scatterer. Accordingly, the Rayleigh formula has been used to determine Avogadro's number and, when the total mass of scatterers is known, to determine molecular weights.

For electrically conducting scatterers (e.g., metals), the conduction electrons are relatively free so the incident electromagnetic wave induces relatively large amplitude oscillations of these electrons. For such particles, magnetic (as well as electric dipole) radiation may be important even for scatterers that are quite small relative to the light wavelength. Moreover, if the frequency of the incident light is close to the natural frequency of charge oscillation (*surface plasmon oscillation*), particularly large amplitude oscillations may be induced. At such frequencies, the polarizability may be enhanced by several orders of magnitude, making the particle an extraordinarily efficient and color-selective scatterer. The resonant frequency can be controlled, since it depends on the shape, the index of refraction, and the electrical conductivity of the scatterer as well as on the index of refraction of the surrounding medium. For example, gold and silver yield a wide range of striking colors, and their suspensions were used in the Middle Ages in stained and other colored glasses.

As we consider larger particles which begin to violate the criterion that their dimensions be very small compared with the wavelength, or the criterion that they are sufficiently dispersed that their positions are not correlated, the Rayleigh formula breaks down. This breakdown first appears at large scattering angles, (corresponding to large optical path differences) where the destructive interference is first significant, and quickly spreads to moderate and small angles. Nevertheless, for scattering angles near zero, the Rayleigh formula retains validity, since for zero scattering angle the radiation from all volume elements is essentially *in phase* regardless of particle positon or size (provided that the index of refraction of the scatter is close to that of its surroundings so that all relevant optical path differences are small). Thus, the Rayleigh formula, when properly applied, is useful over an extremely wide range of molecular weights (10^2–10^7).

For scattering from surfaces and dense media such as liquids in which there is local order over dimensions comparable to the light wavelength, individual scatterers cannot be treated as independent scatterers. Perhaps the most general formulation of the problem is in terms of the radial density function, which describes the correlation between the positions of scatterers, and thus determines the extent to which their radiation interferes constructively and destructively. For scattering by molecules of a solution, however, it is often preferable to relate the light scattering directly to thermodynamic properties of the medium. This may be accomplished through an ingenious approach due to Smoluchowski (1908) and Einstein (1910). It takes advantage of the fact that for molecules small compared with the wavelength, the scattered field may be regarded as made up of radiation from elements of volume small enough that each element may be considered an electric dipole source and yet large enough that the elements can be considered to be independent of each other. If the index of refraction of every element were identical, the solution would be homogeneous and no scattering would result. But the index of refraction of an element will fluctuate according to the number of molecules it contains. The total scattering is found to be proportional to the mean square fluctuation in index of refraction, which is related to the thermodynamic properties of the solution through free energy. For crystalline solids and other media in which correlation extends over distances comparable to the wavelength, it is necessary to use more specialized techniques.

In many cases, light scattering is related to the composition and structure of the medium in a way similar to x-ray scattering. The criterion which must be satisfied is that the electromagnetic field within the scatterers should be closely approximated by the unperturbed incident field, just as in the x-ray case. Light scattering under this approximation is widely known as *Rayleigh-Gans*, or *Rayleigh-Debye*, scattering. It is applicable if the phase shift for radiation passing through a particle is not too different from the phase shift which would occur for radiation passing through the same distance in the surrounding medium. When this approximation is valid, the angular distribution of the scattered light is related, as in x-ray scattering, to a *form factor* which describes the structure of the individual scatterers and to the previously mentioned radial density function which describes their spatial correlation.

In general, each of the above approximate methods rests on approximating the dipole moment that is induced in the scatterers. When inadequate, these approximations can be very significantly improved by variational techniques. Variational principles for identical scatterers were described by Levine and Schwinger (1948), and have been developed and applied also to statistical distributions of nonidentical scatters by many investigators.[4]

To this point, the frequency of the scattered light has been regarded as identical to that of the incident light. Actually, as predicted by Brillouin (1914), frequency displacement and line broadening occur due to thermal and other motion of the scatters (via the DOPPLER EFFECT), and also due to variations in the directions or magnitudes of their polarizability tensors (e.g., due to chemical reaction). Highly monochromatic laser light and techniques of light-beating (correlation) spectroscopy extend the use of light scattering to the study of these kinetic phenomena, e.g., to measurement of velocities and properties of particles that influence their motion, such as diffusion constants.[3]

The scattered light also has a RAMAN SPECTRUM of relatively weak lines (or bands) first discovered by Raman (1928), originating from the light analog of the Compton effect, and explained by quantum theory.

LIQUEFACTION OF GASES

The liquefaction of all readily available gases has become a routine operation in industrial technology. Prominent among the reasons for converting a gas to a liquid are the net saving in the cost of storing or of transporting a normally gaseous material in liquid form, the convenience and flexibility of providing very low temperature refrigeration, in the form of a low-boiling liquid, to mulitple sites of modest or intermittent requirements, and the efficiency attainable in the separation of the components of a gaseous mixture by the partial liquefaction of the mixture, or its total liquefaction followed by rectification.

The transoceanic shipment of liquefied natural gas, the commercial distribution of liquid helium to scientific laboratories, and the production of pure oxygen and pure nitrogen from air are representative examples of the first, second, and third reasons, respectively. The first and last examples currently operate on scales such that thousands of tons of liquid are produced daily.

To produce a cold liquid product from gaseous raw material at ambient temperature requires a heat-pumping operation. Thermodynamic analysis gives the (unattainable) irreducible minimum work W_{min}, which must be expended in the heat pump operating in an environment at temperature T_0, to convert a unit mass of warm gas to liquid to be

$$W_{\text{min}} = (H_{\text{liquid}} - H_{\text{gas}}) - T_0(S_{\text{liquid}} - S_{\text{gas}})$$

where H_{liquid} and H_{gas} are the enthalpies and S_{liquid} and S_{gas} are the entropies per unit mass of liquid product and gaseous raw material, respectively. These thermodynamically reversible works of liquefaction are listed for various of the "permanent" gases in Table 1, which assumes that the starting material is gas at one atmosphere pressure and 300 K. In large-scale practical operations, the actual work requirement will range from ~3 times the minimum for a gas such as methane to ~15 times the minimum for helium.

To achieve the minimum thermodynamic work requirement for cooling and liquefying a stream of gas, an infinite sequence of perfectly efficient refrigerators operating at successively lower temperatures ranging from ambient to the boiling point of the material would be required. Various approximations to this theoretical ideal have been developed.

Cascade Process If the critical temperature of the gas which is to be liquefied lies well *above* the boiling point of some second fluid, whose critical temperature in turn lies above the boiling point of yet another fluid, and so on to some fluid that is condensable at ambient temperatures, then one can replace the infinite sequence of refrigerators of the thermodynamic ideal with this discrete series, or cascade, of liquid cooling baths.

Such an arrangement is shown schematically in Fig. 1. The raw material is compressed to the pressure necessary to condense it at the temperature of the final refrigerant bath. The resulting liquid is expanded through a throttle valve, and the vapor that boils off in the throttling process is recycled to conserve the refrigeration it represents. The penalty in increased work over the thermodynamic minimum arises from the small number of steps in the sequence with the attendant irreversible exchange of heat between the process gas and the much colder baths; from the throttling losses for the product liquid and the various cooling fluids; and from the imperfect efficiency of any real compressor.

For small-scale systems, the operational complexity and the equipment cost of a cascade are prohibitive. However, for large-scale operations, the economic performance of a cascade compares very favorably with any other process for the simple liquefaction of any gas for which a cascade of refrigerants can be found.

For large-scale operations such as the liquefaction of natural gas, one can realize significant savings in equipment costs if, rather than buying a smaller, separate compressor for each individual fluid in the cascade, one mixes the fluids together and buys a single, large compressor for the mixed refrigerants. This saving in equipment cost can more than compensate for the slightly lower thermodynamic efficiency

TABLE 1. MINIMUM WORK OF LIQUEFACTION OF VARIOUS GASES.

Substance	Boiling Point (K)	Work Required (kW-hr/kg)
Methane	111.7	0.320
Oxygen	90.2	0.176
Nitrogen	77.3	0.212
Hydrogen	20.4	3.26
Helium	4.22	1.90

(and higher power costs) that characterize such a system compared to a discrete cascade.

Such systems are represented schematically in Fig. 2. Commercially, they are frequently used for the production of liquefied natural gas (LNG) and are referred to variously as MCR (multicomponent refrigerant) or ARC (autorefrigerated cascade) cycles. Cooling of the compressed mixture of refrigerants to ambient temperature results in the liquefaction of a liquid rich in the highest boiling component of the refrigerant mixture. That liquid is separated from the residual gaseous phase and injected into the first exchanger to cool the compressed product stream and the residual gaseous refrigerant stream. That cooling condenses yet more of the refrigerant stream; this liquid is in turn separated and injected into the main exchanger, etc., until the final fraction of the refrigerant stream is throttled directly and returned to the exchanger as coolant.

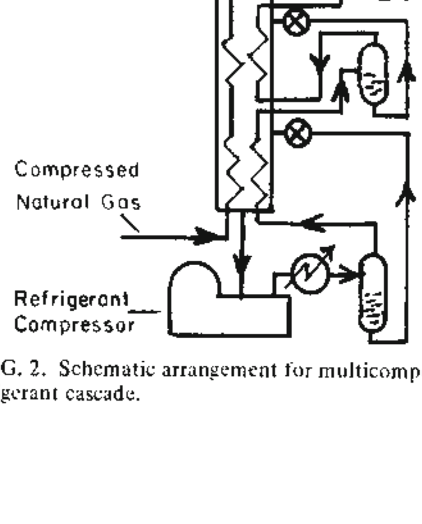

FIG. 2. Schematic arrangement for multicomponent refrigerant cascade.

Linde and Claude Processes A stream of cold gas, flowing countercurrent to the process stream in a heat exchanger that establishes perfect thermal equilibrium between the two streams at every point along their paths could substitute for the infinite sequence of refrigerators in the theoretical ideal system. The problem is just to produce the stream of cold gas (let alone to produce it with perfect efficiency) and to produce a refrigerator to extract the heat of vaporization from the product material at its boiling point.

Application of the first law of thermodynamics to the system shown in Fig. 3, consisting of a constant high-pressure source of fluid at P_1 that flows at constant rate through an insulated heat exchanger B, then through a throttling device C, and back through exchanger B, leaving the exchanger against some constant low pressure P_2 at the *same* temperature at which high-pressure fluid enters, gives

$$H_1 + Q = H_2.$$

H_1 and H_2 are the enthalpies per unit mass of fluid entering and leaving the system, respec-

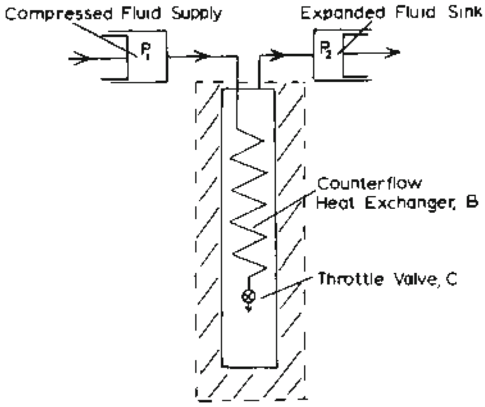

FIG. 3. Adiabatic throttling flow system.

tively, and Q is the amount of heat *absorbed* by a unit mass of fluid in passing through the system. The initial and final kinetic and gravitational potential energies are assumed equal. H_1 will be smaller than H_2 for most gases at absolute temperatures less than 8–10 times the normal boiling point and for initial pressures of several hundred to a few thousand pounds per square inch. At higher temperatures, H_1 will be larger than H_2 so that Q is negative—heat is *liberated* within the exchanger-throttle valve system. If the thermal insulation of the exchanger-throttle valve system is perfect, then for $H_1 < H_2$, the exchanger-throttle valve system and the circulating gas itself will be continually cooled until some of the circulating gas accumulates within the system as liquid, and a new energy balance

$$H_1 = fH_{\text{liquid}} + (1 - f)H_2$$

is attained. The fraction f of the entering gas is withdrawn from the system as liquid product with enthalpy H_{liquid}, and the fraction $(1 - f)$ returns through the exchanger as its refrigerant.

Carl von Linde, in 1885, was the first to couple the relatively feeble (40°C maximum for air expanded from 4000 psi to one atmosphere at room temperature) Joule-Thomson cooling, produced by throttling a high-pressure gas, and a regenerative heat exchanger to give the very simple system that, starting from room temperature, is capable of liquefying any gas except helium, hydrogen, or neon—albeit with poor efficiency. For helium, hydrogen, and neon, throttling at room temperature produces heating ($H_2 < H_1$). Sir James Dewar used a bath of liquid oxygen to precool compressed hydrogen to ~90 K where $H_2 > H_1$. The precooled hydrogen was then fed into a simple Linde liquefier, and Dewar first liquefied hydrogen in this way in 1898.

Kamerlingh Onnes used a bath of liquid hydrogen boiling under vacuum near its freezing point to precool compressed helium to ~14 K (where $H_2 > H_1$ for helium). The precooled helium was then fed into a simple Linde liquefier, and Onnes first liquefied helium in 1908.

For any real system, whose thermal insulation leaks q units of heat per unit mass of entering gas and whose exchanger permits gas to leave the system at $T_2' < T_1$, the energy balance becomes

$$H_1 + q = fH_{\text{liquid}} + (1 - f) \cdot [H_2 + C_p(T_2' - T_1)].$$

Poor insulation (large q) and an inefficient exchanger (large $|T_2' - T_1|$) can easily reduce f to zero.

As the temperature of the gas entering the exchanger of a Linde liquefier approaches its critical temperature, the thermodynamic efficiency of the system as a refrigerator rises sharply. A simple Linde liquefier, coupled to any of several types of efficient auxiliary precooling refrigerators, forms the final stage of almost every large-scale liquefier in common use. Linde, himself, quickly modified his simple system to what, in essence, is a pair of simple liquefiers operating in cascade. The first (precooling) unit operates between the common initial high pressure and some intermediate pressure (chosen for optimum overall efficiency) rather than between the high pressure and one atmosphere. He also added a conventional ammonia refrigerator for precooling to further enhance efficiency.

It is possible to produce a stream of cold gas with relatively good efficiency by allowing compressed gas to expand in a reciprocating expansion engine, or in an expansion turbine. If the expansion engine is preceded by an efficient regenerative heat exchanger, relatively modest ratios of inlet pressure to exhaust pressure at the expansion engine can produce gas near its dew point. The thermodynamic efficiency of such expanders commonly approaches or exceeds 80%. A fraction of this cold exhaust gas can be used to refrigerate the feed to a simple Linde liquefier. Georges Claude in 1905 combined a reciprocating expansion engine with a simple Linde liquefier, as shown schematically in Fig. 4, to produce an air liquefier of improved efficiency which became known as the *Claude cycle*.

Peter Kepitza, in 1934, combined a precooling bath of liquid nitrogen in sequence with a reciprocating expansion engine to precool compressed helium feed for a final Linde stage and produced a Claude cycle which liquefied helium without the use of any auxiliary liquid hydrogen. Collins developed a similar machine which was produced commercially in relatively large numbers. Modifications in various sizes were developed and produced commercially. The machines typically use a cascade of two expansion engines in a Claude-cycle liquefier capable, when combined with liquid nitrogen precool-

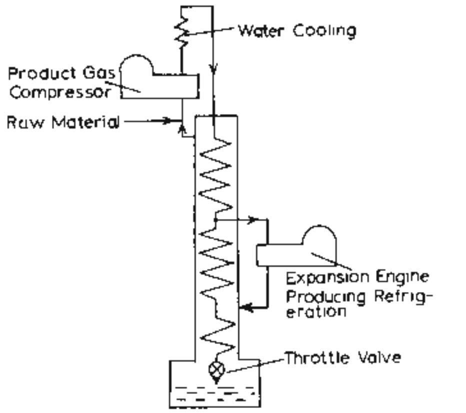

FIG. 4. Schematic arrangement for Claude cycle.

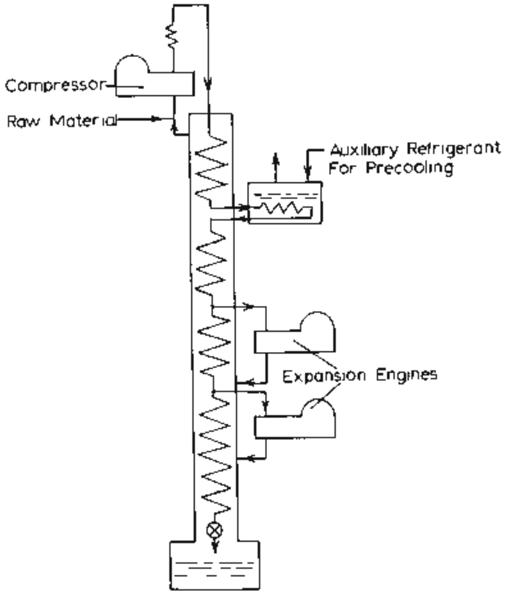

FIG. 5. Composite system for helium liquefaction.

ing, of producing up to 40 liters of liquid helium per hour. The schematic arrangement is shown in Fig. 5. The same schematic arrangement of a liquid precooling bath followed by expansion engines, all precooling the feed to a final Linde liquefier, describe in essence the large plants currently used for the large-scale liquefaction of hydrogen or helium.

LIQUID STATE

Liquid is the term used for a state of matter characterized by that of a pure substance above the temperature of melting and below the vaporization temperature, at any pressure between the triple point pressure and the critical pressure (see Fig. 1). The liquid state resembles the crystalline in the relatively low dependence of density on *P* and *T*, and resembles the gas state in the inability to support shear stresses (see reference to glasses below). Structurally the molecules are relatively close together but they lack long-range crystalline order. The mutual solubility of different liquids is also intermediate between the complete mutual solubility of most gases, and the relatively rare appreciable mutual solubility of pure crystalline compounds. Two liquids of similar molecules are usually soluble in all proportions, but very low solubility is sufficiently common to permit the demonstration of as many as seven separate liquid phases in equilibrium at one temperature and pressure (mercury, gallium, phosphorus, perfluoro-kerosene, water, aniline, and heptane at 50°C, 1 atm.

Stability Limits With the exception of helium and certain apparent exceptions discussed below, Fig. 1 gives a universal phase diagram for all pure compounds. The triple point of one *P* and one *T* is the single point at which all three phases, crystal, liquid, and gas, are in equilib-

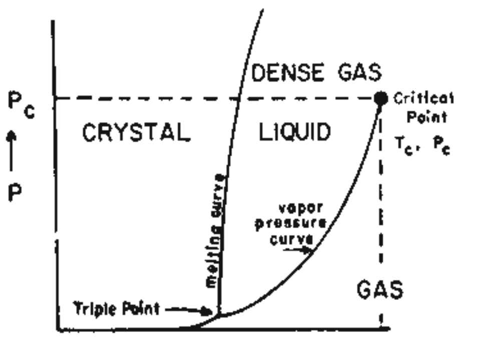

FIG. 1

rium. The triple point pressure is normally below atmospheric. Those substances, i.e., CO_2, $P_t = 3885$ mm, $T_t = -56.6°C$, for which it lies above, sublime without melting at atmospheric pressure.

From the triple point, the melting curve defines the equilibrium between crystal and liquid, usually rising with small but positive dT/dP, and presumably always with positive dT/dP at sufficiently high P values. The line is believed to extend infinitely without a critical point (it has been followed to $T \cong 16T_c$ for He, and calculations indicate that hard spheres would show a gas-crystal phase change). The gas-liquid equilibrium line, the vapor pressure curve, has dT/dP always positive and greater than the melting curve. The vapor pressure curve always ends at a critical point, $P = P_c$, $T = T_c$, above which the liquid and gas phase are no longer distinguishable. Since the liquid can be continuously converted into the gas phase without discontinuous change of properties by any path in the P-T diagram passing above the critical point, there is no definite boundary between liquid and gas.

The term *liquid* is commonly reserved for $T < T_c$, and "dense gas" is used for $T > T_c$. However, certain properties, such as the ability to dissolve solids, change rather abruptly at the critical density. In many respects, the dense gas resembles the low-temperature liquid of the same density more closely than it does the dilute gas.

The slope, dT/dP, of all phase equilibrium lines obeys the thermodynamic Clapeyron equation:

$$dT/dP = \Delta V/\Delta S = T\Delta V/\Delta H \qquad (1)$$

with ΔV, ΔS, and ΔH the differences, for the two phases, of volume, entropy, and heat content or enthalpy, respectively. The quantity ΔH is the heat absorbed in the phase change at constant P. Since always $S_{\text{cr.}} < S_{\text{liq.}} < S_{\text{gas}}$ and usually $V_{\text{cr.}} < V_{\text{liq.}} < V_{\text{gas}}$, one usually has $dT/dP > 0$; the relatively rare cases, including water, for which $V_{\text{liq.}} < V_{\text{cr.}}$ at low pressures leads to $dT/dP < 0$ for the melting curve near the triple point.

Figure 1 gives the P-T boundaries of the stable liquid phase. Clean liquids can readily be superheated or supercooled, and in vessels having walls to which the liquid adheres, they can be made to support negative pressures of several tens of atmospheres. Thus the properties of the metastable liquid can be investigated outside the limits shown in the diagram.

Two apparent exceptions to the universality of the phase diagram of Fig. 1 deserve mention. First, many of the more complicated molecules decompose at temperatures below melting or boiling, and the diagram is unobservable. Secondly, some liquids, notably glycerine and SiO_2 and many multicomponent solutions, supercool so readily that crystallization is difficult to observe. In these cases, there is a continuous transition on cooling to a glass, which has the elastic properties of an isotropic solid. The structure of the glass is qualitatively that of the high-temperature liquid, lacking long-range order. Since glass and liquid are not sharply differentiated, the term *liquid* is sometimes used to include glasses, although common parlance reserves liquid for the state in which flow is relatively rapid.

Quantum Liquids The one real exception to the phase diagram of Fig. 1 is that of helium, Fig. 2. Both isotopes, ^{4}He and ^{3}He, have no triple point, the liquid is stable to 0 K below about 20 atm for ^{4}He and below about 30 atm for ^{3}He. The liquids have zero entropy at 0 K in both cases. This is also the only case in which isotopic mixtures form two liquid phases at equilibrium, the isotopic solution separating below 1 K. The isotope ^{4}He has itself two phases, He I above the dotted λ-line of the diagram, and He II with remarkable properties of superfluidity, second sound, etc., below the λ-line. The phase transition along the λ-line is second order; that is, whereas S and V are continuous, heat capacity and compressibility change discontinuously across the λ-line.

Although no completely satisfactory single theory of liquid helium has yet been formulated, one can say that most of the remarkable properties are qualitatively understood and are due to the predominance of quantum effects, including the difference in the statistics of the even and odd isotopes. Thus helium is the one example in nature of a quantum liquid, all other liquids showing only minor deviations from classical behavior.

Structure Considerable confusion in the description of liquid structure exists, due primarily to difficulties of precise formulation of verbal concepts. The geometric arrangement of any small number (say 10 to 12) of close lying molecules resembles the arrangement in the crystal, but the order rapidly disappears as larger groups are considered. Long-range order is lacking. The fact that numerical theories

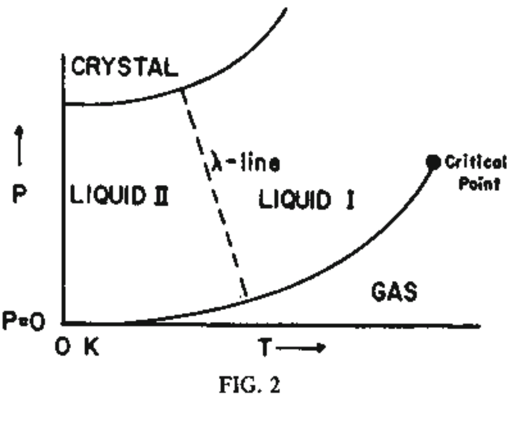

FIG. 2

based on a lattice or cell structure have some success is evidence only that most properties depend on the configuration of near neighbors alone. Insofar as the arrangement of nearest neighbors is describable in terms of that of the crystal, the structure of the normal liquid is probably characterized best by a somewhat closer spacing than the crystal of the same molecules, the reduced density arising from a considerable number of vacancies in the lattice; the coordination number or number of nearest neighbors is lower than in the crystal. The exception is water, in which the low coordination number, 4, of the crystal, is increased by interstitial molecules in the liquid, leading to a higher density of the liquid.

Structural descriptions of this nature usually lack the possibility of precise formulation. It is, however, possible to define for any disordered array of molecules in three-dimensional space an arrangement of contiguous cells, each containing one and only one molecule, the faces of the cells being the loci of the midpoints of neighboring molecules. The statistics of the fraction of cells with n faces and of the distances of the faces from the molecules would give the fraction of molecules having a given number of nearest neighbors and the distance distribution of these in a precisely defined manner. Neither present experimental information nor present theories lend themselves to analysis in such terms.

The only clearly defined manner of describing liquid structure in use at present involves the concept of a set of probability density functions, ρ_n, for ascending numbers, n, of molecules. The function ρ_n depends on the vector coordinates $\mathbf{r}_1, \mathbf{r}_2, \cdots, \mathbf{r}_n$ of n molecules, and

$$\rho_n(\mathbf{r}_1, \mathbf{r}_2, \cdots, \mathbf{r}_n) d\mathbf{r}_1, \cdots, d\mathbf{r}_n$$

is defined as being the probability that in the liquid of definite P and T, there will be at any instant of time, one molecule at each position, $\mathbf{r}_i$, within the volume element, $d\mathbf{r}_i$. For a fluid, unlike a perfect single crystal, $\rho_i(\mathbf{r})$ is a constant independent of $\mathbf{r}$ and equal to the number density: the number, ρ, of molecules per unit volume. The first significant member of the set is then the pair density function, $\rho_2(\mathbf{r}_1, \mathbf{r}_2)$, which depends only on the distance, $r = |\mathbf{r}_1 - \mathbf{r}_2|$, between the two molecules. At large distances $\rho_2(r \to \infty) = \rho^2$. This function can be found experimentally from the x-ray scattering intensities of the liquid (it is the three-dimensional Fourier transform of the scattering intensity at angle θ vs $(4\pi/\lambda)/\sin(\theta/2)$). A typical plot is shown in Fig. 3. The area under the ill-defined first peak integrated over $4\pi r^2 dr$ is the average number of nearest neighbors, and is of order 10 to 11 for normal liquids.

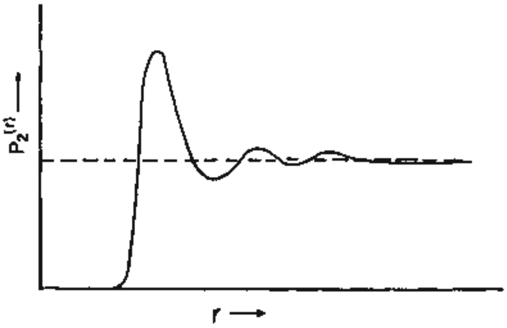

FIG. 3

The quantity of dimensions of energy,

$$W_n(\mathbf{r}_1, \cdots, \mathbf{r}_n) = -kT \ln [\rho^{-n} \rho_n(\mathbf{r}_1, \cdots, \mathbf{r}_n)]$$

can be shown to be the potential of average force of n molecules located at the positions $\mathbf{r}_1, \cdots, \mathbf{r}_n$. That is, if there are n molecules at these positions there will be some average force, $\overline{f_{xi}}$, along the x-coordinate of molecule i. This average is the sum of the direct force due to the other $n - 1$ plus the average of a fluctuating force due to the others, whose average position is affected by that of the n specified ones. This average force is

$$f_{xi} = -(\partial/\partial x_i) W_n(\mathbf{r}_1, \cdots, \mathbf{r}_n)$$

One frequently assumes that W_n is a sum of pair forces only,

$$W_n(\mathbf{r}_1, \cdots, \mathbf{r}_n) = \sum_{n \geqslant i > j \geqslant 1} \sum{}' W_2(\mathbf{r}_{ij})$$

although this assumption is known to be only approximate. With this assumption, the pair average force potential, $W_2(\mathbf{r}_{ij})$, can be computed as the solution of an integral equation, and the solutions agree quite well with the experimental curves.

The knowledge of the complete set of functions ρ_n plus that of the intermolecular forces would permit the computation of all equilibrium properties of the liquid, and indeed if the intermolecular forces are the sum of pair forces, only a knowledge of ρ_2 at all P, T values is necessary. An adequate, although numerically difficult, theory of the transport properties also exists, using the equilibrium functions, ρ_n. At present, only qualitative success is obtained in the completely a *priori* use of the equations.

Associated Liquids The description given above is adequate only for liquids composed of spherically symmetric molecules or molecules that are nearly so. These constitute the so-called normal liquids, which obey reasonably well the law of corresponding states, for which the entropy of vaporization at the boiling point has the Trouton's rule value of approximately 21 cal/deg. For molecules containing large dipole moments, or those forming mutual hydrogen bonds, the concept of the probability density functions must be extended to include angles or other internal degrees of freedom in the coordinates. Such inclusion is conceptually easy, but incredibly complicates the already difficult numerical evaluation of any equations. However, certain qualitative statements may be made.

Liquids composed of molecules with large dipole moments are frequently referred to as associated. Although in some instances relatively stable dimer or definite polymer units of relatively fixed orientation may exist, in many cases, notably water, it is extremely doubtful if an exact knowledge of the structure would reveal any distinguishable entities of associated molecules other than that of the whole liquid. In such cases, one would, however, expect that certain mutual angular orientations between neighboring molecules will be highly preferred, whereas in the dilute gas this will not be the case. The effect of this restriction on the internal coordinates will be to decrease the entropy of the liquid markedly compared to the gas. This effect is qualitatively the same as in association, and the properties of these liquids, particularly the high entropy of vaporization, will simulate those of a liquid composed of definite associated complexes.

LORENTZ TRANSFORMATIONS

An event specified at a point $r \equiv (x, y, z)$ in ordinary space at an instant of time t defines an event described by the space-time coordinates (x, y, z, t). Such an event observed in a particular reference frame S may also be described in another reference frame S', in motion with a velocity v with respect to S. A Lorentz transformation relates the space-time coordinates in frame S' describing the event in frame S to the space-time coordinates in S. This Lorentz transformation forms the basic mathematical foundation for Einstein's *special theory of relativity* (see RELATIVITY).

An interval between two events may be described by an invariant measure of length, a metric, that is the same in all reference frames:

$$\begin{aligned}(\Delta s)^2 &= (\Delta x_1)^2 + (\Delta x_2)^2 + (\Delta x_3)^2 + (\Delta x_4)^2 \\ &= (\Delta x_1')^2 + (\Delta x_2')^2 + (\Delta x_3')^2 + (\Delta x_4')^2\end{aligned} \tag{1}$$

where we have set $(x_1, x_2, x_3, x_4) \equiv (x, y, z, ict)$ and where c is the velocity of light. A space-time with the above metric is called a *Minkowski space*. In the Einstein picture there is no invariant separation of space and time. Observation of an event from two different reference frames moving with a relative velocity v along the z axis (for simplicity) would be related by the Lorentz transformation:

$$\begin{aligned}x' &= x \\ y' &= y \\ z' &= (1 - v^2/c^2)^{-1/2}\,(z - vt) \\ t' &= (1 - v^2/c^2)^{-1/2}\,(t - vz/c^2).\end{aligned} \tag{2}$$

One readily observes that these relations satisfy Eq. (1).

Every observer, related by a Lorentz transformation, observes the same physical process in all of space-time and conversely, any physical process must be Lorentz invariant. Such processes described by Newtonian mechanics, for example, are valid approximations when $v \ll c$ of a more general relativistic mechanics. Classical theories such as electromagnetism involving the velocity c are Lorentz invariant.

The Lorentz transformation of Eq. (2) is a subgroup of a general class of rotations in Minkowski space. We first consider ordinary rotations of the spatial coordinates leaving the x_4 coordinate unchanged. If we perform a rotation in the x_1-x_2 plane about the x_3 axis through an angle ω in a clockwise direction, a point described by (x_1, x_2, x_3, x_4) in the original coordinate system is described in the new (primed) coordinate system by

$$\begin{aligned}x_1' &= x_1 \cos\omega + x_2 \sin\omega \\ x_2' &= x_2 \cos\omega - x_1 \sin\omega \\ x_3' &= x_3 \\ x_4' &= x_4.\end{aligned} \tag{3}$$

These relations also satisfy Eq. (1). Such a transformation may be obtained by a unitary operator

$$\exp\left[-\omega\left(x_1 \frac{\partial}{\partial x_2} - x_2 \frac{\partial}{\partial x_1}\right)\right]. \tag{4}$$

Noting that $\exp M = 1 + (M/1!) + (M^2/2!) + (M^3/3!) + \ldots$, and that

$$\begin{aligned}M^{2n}x_1 &= (-1)^n \omega^{2n} x_1; \\ M^{2n}x_2 &= (-1)^n \omega^{2n} x_2; \\ M^{2n+1}x_1 &= (-1)^n \omega^{2n+1} x_2; \\ M^{2n+1}x_2 &= (-1)^{n+1} \omega^{2n+1} x_1\end{aligned}$$

one easily obtains the relations (2) that give the primed coordinates in frame S' in terms of the unprimed coordinates in S.

Similarly if we perform a "rotation" in the x_3-x_4 plane in Minkowski space through an imaginary angle $i\chi$ where $\tanh\chi = v/c$ such that the primed coordinate system moves along the x_3 axis with a velocity v, the primed coordinates may be obtained by use of the operator

$$\exp\left[-i\chi\left(x_3\frac{\partial}{\partial x_4}-x_4\frac{\partial}{\partial x_3}\right)\right].$$

The transformation obtained by this Lorentz transformation often called a Lorentz boost to distinguish it from the ordinary rotations yields

$$\begin{aligned} x_1' &= x_1 \\ x_2' &= x_2 \\ x_3' &= x_3 \cosh\chi + ix_4 \sinh\chi \\ x_4' &= x_4 \cosh\chi - ix_3 \sinh\chi. \end{aligned} \tag{7}$$

Noting that $\cosh\chi = (1 - v^2/c^2)^{-1/2}$ and $\sinh\chi = (v/c)\ (1 - v^2/c^2)^{-1/2}$ one sees that expressions (7) are identical to those of (1) when expressed in the corresponding parameters.

One can express generally the Lorentz rotations and boosts of the coordinate frame in matrix form:

$$x_\mu' = a_{\mu\nu}x_\nu \tag{8}$$

with the orthogonality condition on the matrices

$$a_{\mu\nu}a_{\lambda\nu} = \delta_{\mu\lambda}. \tag{9}$$

A summation is to be made over repeated indices. The Lorentz transformations (8) correspond to a six-parameter homogeneous group.

However, events occurring in a coordinate system involve a physical process associated with a physical object in that coordinate system. An equivalent description may be obtained by "rotating" the physical system rather than the coordinate system, but in the inverse direction. A physical quantity may be expressed by a function involving the coordinates and may or may not have other intrinsic degrees of freedom not directly involving the space-time coordinates. Examples are scalars, spinors, polar four-vectors, antisymmetric tensors, etc. These other intrinsic degrees of freedom are designated as spin and they occur in the quantum mechanical description of elementary particles. The Lorentz transformation properties of these *wave functions* must be examined. We consider two examples, the transformation properties of a scalar and a polar four-vector wave function.

Consider a wave function in frame S' described by (1) that is considered to differ infinitesimally from S by an angle $\delta\omega$ in the x_1-x_2 plane. We make a Taylor expansion about the unprimed coordinate system where $x_1' = x_1 + \delta\omega x_2$ and $x_2' = x_2 - \delta\omega x_1$. The coordinates are expressed in a shorthand notation, i.e., $\phi(x) \equiv \phi(x_1, x_2, x_3, x_4)$.

$$\phi(x') = \phi(x) + \delta x_1\frac{\partial\phi}{\partial x_1} + \delta x_2\frac{\partial\phi}{\partial x_2},$$

consequently

$$\phi(x) = \left[1 + \delta\omega\left(x_1\frac{\partial}{\partial x_2} - x_2\frac{\partial}{\partial x_1}\right)\right]\phi(x').$$

The part within the parentheses is related to the orbital angular momentum operator L_{12} such that

$$\phi(x) = \left(1 + \frac{i}{\hbar}\,\delta\omega L_{12}\right)\phi(x'). \tag{10}$$

We may generally express a finite Lorentz rotation or boost in a particular x_μ-x_ν plane through an angle ω by the operator

$$\phi(x) = \exp\left(\frac{i}{\hbar}\,\omega L_{\mu\nu}\right)\phi(x') \tag{11}$$

which is obtained by exponentiation of (10)

The requirements of special relativity, that physical processes be independent of the reference coordinate frame, leads to rather profound conservation laws that may be obtained from variational principles involving infinitesimal variation of the Lagrangian function describing the system. The conservation of orbital angular momentum is a direct consequence of invariance under Lorentz transformations involving scalar particles.

A more complicated example is that of the four-vector field such as the electromagnetic vector potential $A_\mu(x)$ consisting of three spacelike components A_1, A_2, A_3 and a timelike component $A_4 = icV(x)$. The components may be represented by a column matrix:

$$A(x) = \begin{bmatrix} A_1(x) \\ A_2(x) \\ A_3(x) \\ A_4(x) \end{bmatrix}. \tag{12}$$

Omitting details too lengthy to treat here, we must introduce an operator analogous to $L_{\mu\nu}$ that rearranges the components of $A_\mu(x)$ into a new *local* arrangement $A_\mu'(x')$ referred to the transformed coordinate system. It should be emphasized that $L_{\mu\nu}$ involves the coordinates while the spin operator introduced here involves the components of $A(x)$.

These spin operators are defined in this Cartesian representation as

$$S_{23} = \hbar\begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & -i & 0 \\ 0 & i & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix},$$

$$S_{31} = \hbar \begin{bmatrix} 0 & 0 & i & 0 \\ 0 & 0 & 0 & 0 \\ -i & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix},$$

$$S_{12} = \hbar \begin{bmatrix} 0 & -i & 0 & 0 \\ i & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix},$$

$$S_{14} = \hbar \begin{bmatrix} 0 & 0 & 0 & -i \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ i & 0 & 0 & 0 \end{bmatrix},$$

$$S_{24} = \hbar \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -i \\ 0 & 0 & 0 & 0 \\ 0 & i & 0 & 0 \end{bmatrix},$$

$$S_{34} = \hbar \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -i \\ 0 & 0 & i & 0 \end{bmatrix}.$$

The action of an operator similar to that of (11) involving these spin operators $S_{\mu\nu}$ may be obtained by expansion of the exponential

$$A'(x') = \exp\left(\frac{i}{\hbar}\,\omega S_{\mu\nu}\right) A(x).$$

Noting that, for example,

$$\left(\frac{i}{\hbar}\,\omega S_{12}\right)^{2n} = (-1)^n\,\omega^{2n} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

and

$$\left(\frac{i}{\hbar}\,\omega S_{12}\right)^{2n+1} = (-1)^n\,\omega^{2n+1} \begin{bmatrix} 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}.$$

After rearranging in trigonometric series and carrying out the matrix multiplication, one obtains expressions for the components of the four-vector field $A(x)$:

$$\begin{aligned} A_1'(x') &= A_1(x')\cos\omega + A_2(x')\sin\omega \\ A_2'(x') &= A_2(x')\cos\omega - A_1(x')\sin\omega \\ A_3'(x') &= A_3(x') \\ A_4'(x') &= A_4(x'). \end{aligned} \tag{14}$$

It is not obvious from the operation performed here that, not only are the components of the polar vector field rearranged by this operator, but also the dependence on the coordinates that are in the primed system. This feature would be made obvious in the transformation of the Lagrangian function involving these fields, which is beyond the scope of this article. This *local* dependence may be made global by inclusion of the operator L_{12} occurring in (11) that transforms the coordinates of the primed system to those of the unprimed system:

$$A'(x) = \exp\left[\frac{i}{\hbar}\,\omega(L_{12} + S_{12})\right] A(x) \tag{15}$$

so that we have

$$\begin{aligned} A_1'(x) &= A_1(x)\cos\omega + A_2(x)\sin\omega \\ A_2'(x) &= A_2(x)\cos\omega - A_1(x)\sin\omega \\ A_3'(x) &= A_3(x) \\ A_4'(x) &= A_4(x). \end{aligned} \tag{16}$$

The sum of $L_{\mu\nu}$ and $S_{\mu\nu}$ representing the orbital and spin angular momentum operators yield that for the total angular momentum $J_{\mu\nu}$.

The Lorentz rotation of a particle or field through an angle ω in the x_1-x_2 system is thus given by the operator

$$\exp\left(\frac{i}{\hbar}\,\omega J_{12}\right). \tag{17}$$

The corresponding Lorentz boost of a particle to velocity v along the X_3 direction is given by the operator.

$$\exp\left(\frac{i}{\hbar}\,\chi J_{34}\right) \tag{18}$$

where $\tanh\chi = v/c$. In this latter case the components of a four-vector field become

$$\begin{aligned} A_1'(x) &= A_1(x) \\ A_2'(x) &= A_2(x) \\ A_3'(x) &= A_3(x)\cosh\chi + iA_4(x)\sinh\chi \\ A_4'(x) &= A_4(x)\cosh\chi - iA_3(x)\sinh\chi \end{aligned} \tag{19}$$

where as before

$$\cosh \chi = (1 - v^2/c^2)^{-1/2} = E/mc^2$$

$$\sinh \chi = (v/c)\,(1 - v^2/c^2)^{-1/2} = p/me.$$

In these expressions, m is the rest mass of the particle, E is the total energy, and p is the momentum.

In any physical process involving particles or fields the invariance of the Lagrangian under infinitesimal homogeneous Lorentz transformations leads directly to the law of conservation of total angular momentum whenever the particle has an intrinsic spin. The orbital and spin angular momentum are not independently invariants in a dynamical process.

There are other Lorentz transformations allowable. The six-parameter homogeneous group (8) may be extended to the ten-parameter inhomogeneous group that includes the translations

$$x_\mu' = a_{\mu\nu} x_\nu + \epsilon_\mu. \tag{20}$$

The constant ϵ_μ represent a translation or shift of the coordinate x_μ. Such translations obey the invariant metric condition (1).

The corresponding Lorentz translation of a wave function is given by

$$\phi(x') = \exp\left(-\frac{i}{\hbar}\,\epsilon_\mu P_\mu\right)\phi(x) \tag{21}$$

where P_μ are the operators corresponding to the components of the four momenta $(p_1, p_2, p_3, (i/c)E)$.

$$P_\mu = \frac{\hbar}{i}\,\frac{\partial}{\partial x_\mu}.$$

Invariance of the Lagrangian function under infinitesimal Lorentz translations leads directly to the conservation of momentum and energy.

There are also the improper Lorentz transformations in which the space and/or the time coordinates are inverted. Space inversion corresponds to

$$x_i' = -x_i, \qquad i = 1, 2, 3 \tag{22}$$

while time inversion corresponds to

$$x_4' = -x_4. \tag{23}$$

Both of these improper Lorentz transformations obey the invariance condition (1). They are discussed in detail in the article PARITY.

LUMINESCENCE

Introduction Luminescence is the phenomenon of light emission in excess of thermal radiation. Excitation of the luminescent substance is prerequisite to the luminescent emission. Photoluminescence depends upon excitation by photons; cathodoluminescence, by cathode rays; electroluminescence, by an applied voltage; chemiluminescence, by utilization of the energy of a chemical reaction. Luminescent emission involves optical transitions between electronic states characteristic of the radiating substance. The phenomenon is essentially the emission spectroscopy of gases, liquids, and solids. The same basic processes may yield infrared or ultraviolet radiation in substances with suitable electronic energy states; therefore, such emission in excess of thermal radiation is also described as luminescence.

Luminescence can be distinguished from the Raman effect, Compton and Raleigh scattering and Čerenkov emission on the basis of the time delay between excitation and luminescent emission being long compared to the period of the radiation, λ/c, where λ is the wavelength and c is the velocity of light. The radiative lifetimes of the excited states vary from 10^{-10} to 10^{-1} sec depending on the identity of the luminescent substances whereas λ/c is approximately 10^{-14} sec for visible radiation. At ordinary densities of excitation, the spontaneous transition probability predominates so that the luminescent radiation is incoherent; under conditions of high densities of excitation in suitable luminescent substances, the induced transition probability may predominate, the emitted radiation is coherent, and laser action is attained.

The initial persistence of luminescent emission following the removal of excitation depends on the lifetime of the excited state. This emission decays exponentially and is often called fluorescence. In many substances, there is an additional component to the afterglow which decays more slowly and with more complex kinetics. This is called phosphorescence. For many inorganic crystals, the emission spectra for fluorescence and phosphorescence are the same; the difference in afterglow arises from electron traps from which thermal activation is prerequisite to emission. For organic molecules, the emission spectra for fluorescence and phosphorescence are often different: the former occurs from an excited singlet; the latter, from a triplet state.

Luminescence of Gases The simplest luminescent substances are monatomic gases. The electronic states are characteristic of the isolated atoms; therefore, the excitation and emission spectra depend only on the differences in energy of the stationary electronic states of the many-electron atom, and the spectral lines are broadened only by the lifetimes of the excited states or at higher pressures, by collisions. The transitions are to a good approximation one-electron transitions. Resonance fluorescence is photoluminescence in which the exciting radiation is the exact frequency or wavelength for the transition from the ground to the excited state and emission occurs with the same frequency. Resonance fluorescence is shown diagrammatically in Fig. 1 for low pressure alkali metal vapor. The well-known 2537Å line of mercury vapor is another example of resonance fluorescence. This emission can also be excited by electrons accelerated by 5 or more volts. The simplest case of sensitized fluorescence (photoluminescence in which absorption of the exciting radiation is by one substance and the excitation is transferred to another which emits radiation) occurs with mixtures of monatomic gases. For example, the characteristic fluorescence of thallium is observed when mixtures of Tl and Hg vapors are illuminated with the 2537Å radiation of Hg.

For diatomic and polyatomic gases, the energies of the electronic states are dependent on the interatomic distances of the molecule. This dependence is shown in Fig. 2 for the ground and excited states. For a diatomic molecule the coordinate R is the distance between the two atoms. For each electronic state, there is a series of vibrational levels which are also shown in Fig. 2. Optical transitions occur between individual vibrational levels of one electronic state and individual vibrational levels of another electronic state. These transitions occur in accordance with the Franck-Condon principle, i.e., with fixed nuclear coordinates, vertically as shown in transitions 1 and 2 of Fig. 2. In most cases the emission will involve a smaller transition energy and occur at longer wavelength than the photo-excitation. This is referred to as Stokes' emission. In some cases, for example at high temperatures when the higher vibrational levels of the ground electronic state are populated thermally, anti-Stokes' emission is also observed. Additional structure in the photoexcitation and emission spectra arises from rotational states of the molecule. Iodine is a typical diatomic luminescent molecule excited by green light with visible emission at slightly longer wavelengths. Benzene and aniline are typical polyatomic molecules which are luminescent as vapors.

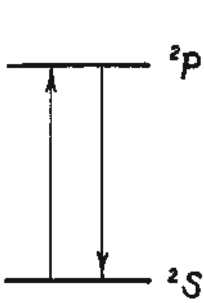

FIG. 1. Resonance fluorescence of atoms, e.g., Na.

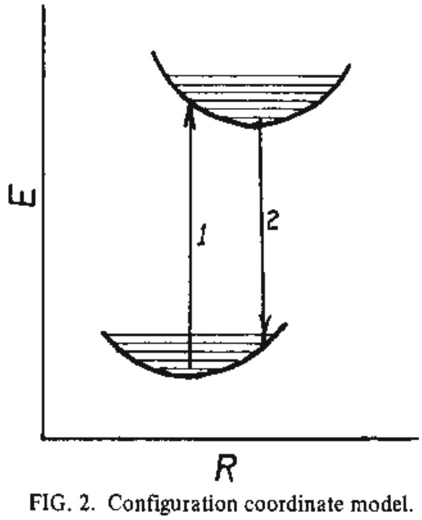

FIG. 2. Configuration coordinate model.

Luminescence of Organic Materials The electronic states of most organic luminescent materials in the liquid or solid phase, either as pure materials or as solutes in dilute concentration in inert solvents, are to a good approximation describable in terms of the electronic states of the free molecule in the gaseous phase. In other words, the intermolecular forces are weak compared to the intramolecular forces. The photoexcitation and luminescent emission spectra of these substances in condensed phases are similar to the spectra of the vapors. The intermolecular forces are, however, great enough to bring about broadening of absorption and emission lines and in some cases to bring about electronic energy transfer between molecules before intramolecular, vibrational relaxation with the accompanying Stokes' shift can occur. On the other hand, in a viscous or rigid medium collisional, nonradiative de-excitation is reduced.

Many of the organic luminescent materials are aromatic molecules related to dyes. The sodium salt of fluorescein in dilute aqueous solution is well known as an efficient fluorescent material. Other organic substances luminesce efficiently when dissolved in organic solvents. Terphenyl

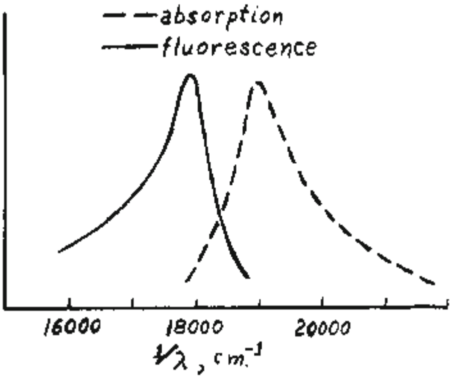

FIG. 3. Mirror symmetry of absorption and emission.

in xylene is a liquid β- and γ-ray scintillator with emission in the near ultraviolet. Some organic molecules luminesce most efficiently in a rigid medium. A solid solution of 1 per cent anthracene in napthalene is a scintillator with blue emission. For these solutions, energy is absorbed by the solvent molecules and transferred to the solute where the luminescent emission occurs. Crystals of some pure organic substances luminesce, particularly at low temperatures.

The fluorescent emission and the long-wavelength absorption of organic materials are often simply related as mirror images of each other. This is shown in Fig. 3 for rhodamine in ethanol and can be explained on the basis of the configuration coordinate model in Fig. 2. with the force constants for the two electronic states approximately equal. For organic molecules, the configuration coordinate R is interpreted as representing, schematically, all the intramolecular nuclear coordinates. In addition to the fluorescent emission, many organic substances exhibit phosphorescent emission. This arises from nonradiative relaxation from the excited singlet to the triplet state followed by radiative decay from the triplet to the ground singlet state, as illustrated in Fig. 4. Because of the spin selection rule governing radiative transitions, the triplet has a long lifetime and the oscillator strength for direct excitation to the triplet is negligible. In suitable systems, polarized excitation and emission arising from the anisotropy of the organic molecules can be observed.

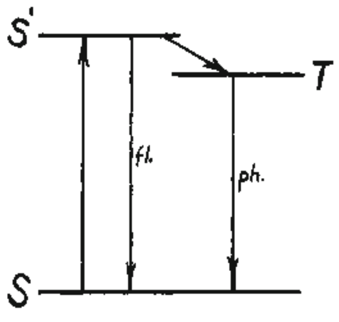

FIG. 4. Fluorescence and phosphorescence of organic molecules.

Chelates involving organic molecules as ligands bound to a metal atom or ion are a class of substances with members which luminesce. The fluorescence and phosphorescence of chlorophyll both *in vivo* and *in vitro* have been investigated for many years. On the other hand, rare earth chelates with organic ligands have been intensively investigated quite recently as lasers. The photoexcitation occurs in the broad absorption bands of the ligand; the energy is transferred to the localized 4*f* shell of the rare earth by a mechanism related to the transfer process occurring in the scintillators; luminescent line emission characteristic of the rare earth occurs as coherent radiation with high excitation intensities. A fluorinated Eu-acetonate dissolved in acetonitrile has been announced as a liquid laser operating near room temperature.

Luminescence of Inorganic Crystals Inorganic crystals which luminesce are often called phosphors. Their luminescence in most cases originates from impurities or imperfections. Exceptions include the luminescence of alkaline earth tungstates which is characteristic of the WO_4^{2-} group perturbed by the crystal field, the luminescence of some rare earth salts, and radiative recombination of conduction electrons with valence band holes in semiconductors. The impurities and imperfections responsible for luminescence in inorganic crystals are of diverse atomic and molecular types whose characteristics depend on the structure of the defect and on the electronic structure of the pure crystal. In some cases, the electronic states involved in the luminescence can be described in terms of energy levels of the impurity ion perturbed by the crystal field; in other cases, in terms of the crystal band structure perturbed by the impurity. The existence of conduction bands in inorganic crystals, particularly in semiconducting crystals, introduces additional mechanisms for the excitation of luminescence and for phosphorescence. For example, suitable impurities can be excited by alternate capture of injected conduction electrons and valence band holes, thus providing one mechanism for electroluminescence; on the other hand, an excited luminescent impurity may lose an electron to another defect via the conduction band, and the thermal activation necessary for return to the luminescent impurity is responsible for phosphorescence.

The alkali halides are simple ionic crystals which become luminescent when doped with suitable impurities. Thallium substituted in dilute concentration at cation sites in potassium chloride has the absorption and emission shown

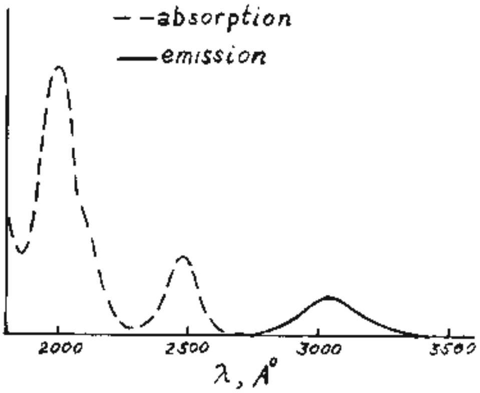

FIG. 5. Spectra of KCL:Tl.

in Fig. 5. The absorption bands involve the $^1S \rightarrow ^3P^0$, $^1P^0$ transitions of the free ion perturbed by crystal interactions; the principal emission band, $^3P^0 \rightarrow ^1S$, is similarly perturbed. The spectra can be understood qualitatively with the aid of Fig. 2, modified with a second excited state and with the configuration coordinate interpreted as symmetric displacement of the six nearest-neighbour Cl^- from the Tl^+. It is this interaction which is most dependent on the electronic state of the Tl^+ and is, therefore, largely responsible for the band widths and Stokes' shift.

Many inorganic crystals become luminescent when certain transition metal ions are dissolved in them. The luminescence involves intercombination transitions within the 3*d* shell; therefore, crystal field theory can be used to interpret the absorption and emission spectra. Divalent manganese is a common activator ion. Zn_2SiO_4, ZnS and $3Ca_3(PO_4)_2 \cdot CaF_2$ are important phosphors activated with Mn^{2+}. The last, activated also with Sb^{3+}, is the principal fluorescent lamp phosphor. The excitation at 2537Å from the Hg discharge occurs at the Sb^{3+}, whose energy level structure is similar to that of Tl^+; part of the energy is radiated in a blue band due to Sb^{3+} and part is transferred to the Mn^{2+} which is responsible for an orange emission band. It has been shown that the Sb^{3+} at a Ca^{2+} site is locally charge-compensated by an O^{2-} at a halide site and that the blue emission is in part an electron transfer transition. The ruby laser involves the luminescence of Cr^{3+} in Al_2O_3. Excitation occurs in a broad absorption band, and the system relaxes to another excited state from which emission occurs in a narrow band.

Rare earth ions, particularly trivalent, in solid solution in inorganic crystals and in glasses exhibit the emission characteristic of transitions in the 4*f* shell. For examples, samarium, europium, and terbium give visible emission; neodymium, infrared; and gadolinium, ultraviolet. Because of their narrow emission bands and stability, the rare earth activated phosphors are of interest as lasers and as phosphors for fluorescent lamps and for color television. Crystal field theory can be used to explain the optical absorption and luminescent emission of the 4*f* transitions of rare earth ions in crystals and glasses. Phosphors doubly activated with rare earths, e.g., YF_3 : Yb, Tm, have been found to be capable of large anti-Stokes' emission. This occurs by multiphoton infrared excitation and with visible emission.

The zinc sulfide phosphors, which are widely used as cathodoluminescent phosphors and well-known for their electroluminescence, are now recognized as large band gap, compound semiconductors. Two impurities or imperfections are essential to the luminescence of many of these phosphors: an activator which determines the emission spectrum and a coactivator which is essential for the emission but in most cases has no effect on the spectrum. Activator atoms such as Cu, Ag and Au substitute at Zn sites and perturb a series of electronic states upward from the valence band edge. In a neutral crystal containing only these activator impurities, the highest state is empty, i.e., it contains a positive hole and can accept an electron from the valence band; therefore, in semiconductor notation, the activator is an acceptor. In a similar way, coactivators such as Ga or In at Zn sites or Cl at S sites are donors in ZnS. The simultaneous introduction of both types of impurities results in electron transfer from donor to acceptor lowering the energy of the crystal and leaving both impurities charged. The coulomb attraction of the donor and acceptor leads to a departure from a random distribu-over lattice sites and to pairing. The electronic states and some of the transitions of acceptors, donors and donor-acceptor pairs are shown in Fig. 6. The spectrum of ZnS:Cu, Ga is shown in Fig. 7. The longer-wavelength emission band involves the transition from the lowest donor state to highest acceptor state (transition 3) in approximately fifth nearest-neighbor pairs; the shorter-wavelength emission corresponds more nearly to transition 1 of Fig. 6. Luminescent emission from donor-acceptor pairs has been more clearly seen with gallium phosphide crystals. In addition to luminescence due to donors,

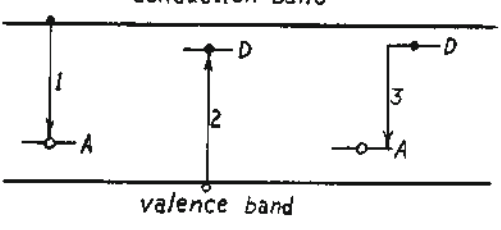

FIG. 6. Band model for acceptor, donor, and pair transitions.

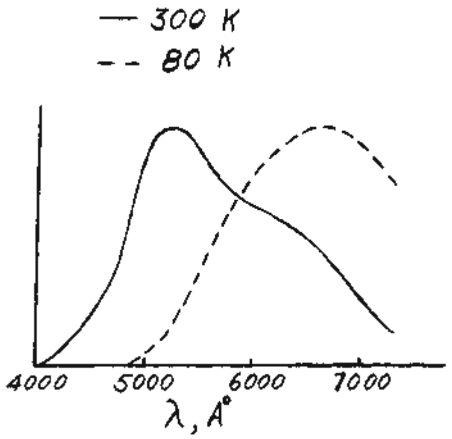

FIG. 7. Spectra of ZnS: Cu, Ga.

acceptors and their pairs, emission bands due to transition metals are well known for zinc sulfide as noted earlier. In zinc sulfide crystals, the donors which are unassociated with acceptors serve as electron traps and are responsible for long-persistent, temperature-dependent phosphorescence. Uncharged or isoelectronic dopants, such as N at phosphorous sites in GaP, have been shown to be efficient radiative recombination centers, particularly in indirect band gap semiconductors. The III-IV semiconductors with isoelectronic dopants or with donor-acceptor pairs are currently the principal electroluminescent light-emitting diodes.

Trends in Luminescence Research Both molecular and solid-state luminescence research have become increasingly sophisticated in experimental techniques and theoretical concepts; the materials investigated, more diverse and structured. Low temperatures, high electrical and magnetic fields, intense excitation and short times are among the conditions used to investigate luminescent phenomena. Luminescent excitation is most generally formulated theoretically as a collective excitation of a many-body problem encompassing the source of excitation and its probe, as well as the luminescent body itself. Inhomogeneously doped crystals, amorphous materials and man-made superlattices are now investigated as luminescent materials, as well as are homogeneous solutions, crystals and powders.

The configuration coordinate model shown in Fig. 2 for diatomic and polyatomic molecules is also applied to luminescent centers in the condensed phase. The configuration coordinate represents the local and/or normal atomic coordinates of the luminescent system. The model is based on the adiabatic approximation to the Born-Oppenheimer expansion for a system of many electrons and many nuclei, for which the electrons are assumed to move rapidly compared to the nuclei. However, luminescent excitation of these many-particle systems involves to some extent all the particles and thus the exact description of the excitation is a collective excitation.

Under some conditions of luminescent excitation (for example, very high excitation intensity), a more complete formulation is necessary, including the radiation field of the excitation, the detector of emission, and the source of any applied stresses to the luminescent body. Even at low intensities of excitation the coupling of the electromagnetic probe to transverse excitons must be included to describe excitonic luminescent transitions, that is, excitonic polaritons. Another example is the recent analyses of the effects of hydrostatic pressure on luminescent spectra in which a type of double adiabatic approximation is used, with the electrons, nuclei and pressure apparatus approximated respectively as fast, intermediate, and slow components of the total system.

The usual luminescent transitions depend on thermalization of the excited molecule or center among the vibrational levels illustrated in Fig. 2. Emission which occurs before thermalization is termed "hot" luminescence. It is well-known for molecular dopants such as O_2^- in alkali halides. This phenomenon is investigated more widely by nanosecond and picosecond time-resolved spectroscopy.

Hot electrons are responsible for the excitation of luminescence with high electrical fields, that is, high field electroluminescence. This phenomenon is investigated in thin film devices consisting of a phosphor sandwiched between insulators, all films prepared by evaporation or sputtering, and subjected to a.c. voltages. The mechanism is well-established for ZnS:Mn and ZnF_2:Mn as collision excitation of Mn^{2+} by hot electrons, and cross sections have been measured and calculated theoretically. These and rare earth doped components are used in thin film displays.

For systems exhibiting inhomogeneous spectral broadening, site selection spectroscopy is used to resolve components of the spectra. Ions or molecules at specific sites are selectively excited to fluorescence or phosphorescence with laser sources at low temperatures. Organic compounds in solutions, crystals, and amorphous materials are investigated by site selection spectroscopy. "Hole burning," that is, optical depletion of selective ground state molecules followed by optical probing of these molecules is another valuable tool for studying the origin of inhomogeneous broadening and also to investigate energy transfer.

MAGNETIC FIELD

Magnetic field is generated by the passage of electrical currents through conductors or by the circulation of microscopic charges within magnetic materials. The magnetic field exerts a mechanical stress on its sources.

Basic Equations To separate electromagnetic theory from the theory of the solid state, Maxwell's equations can be written in terms of the magnetic induction or flux-density **B** and the total current density **J**:

$$\nabla \cdot \mathbf{B} = 0 \qquad (1)$$

$$\nabla \times \mathbf{B} = 4\pi \mathbf{J} \qquad (2)$$

where, for purposes of the present article, the displacement current $(1/c^2)\partial \mathrm{E}/\partial t$ is neglected relative to $4\pi\mathbf{J}$ (see ELECTROMAGNETIC THEORY and MAGNETISM).

The solution of Eqs. (1) and (2) is

$$\mathbf{B}(\mathbf{r}) = \int d^3 r_1 \, \frac{\mathbf{J}(\mathbf{r}_1) \times (\mathbf{r} - \mathbf{r}_1)}{|\mathbf{r} - \mathbf{r}_1|^3} \qquad (3)$$

where the integral includes all current-carriers, and **B** vanishes at infinity.

From Eq. (3) it follows, for example, that an infinite straight conductor [Fig. 1(a)] carrying a total axial current I_c gives rise to an azimuthally directed external magnetic induction of strength $\mathbf{B} = 2I_c/r$, where r is the distance from the conductor axis. The same is true for an axial current in any axisymmetric conductor, e.g., the toroidal conductor of Fig. 1(b). An infinitely long circular cylindrical conductor [Fig. 2(a)] carrying an azimuthal current density I_c' per unit length contains an axially directed magnetic induction of strength $\mathbf{B} = 4\pi I_c'$. The same expression holds for a straight cylindrical conductor of arbitrary cross section [Fig. 2(b)], or for an infinite plane current sheet. A circular cylinder like that of Fig. 2(a), but of finite length L and radius R, has a central magnetic induction of strength $\mathbf{B} = 4\pi I_c' L(L^2 + 4R^2)^{-1/2}$.

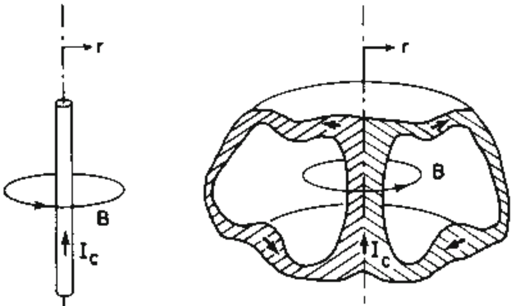

FIG. 1. Axisymmetric configurations with axially directed current I_C.

In terms of the vector potential **A**,

$$\mathbf{B} = \nabla \times \mathbf{A} \qquad (4)$$

and the gauge $\nabla \cdot \mathbf{A} = 0$, one has

$$\nabla^2 \mathbf{A} = -4\pi \mathbf{J} \qquad (5)$$

and

$$\mathbf{A}(\mathbf{r}) = \int d^3 r_1 \, \frac{\mathbf{J}(\mathbf{r}_1)}{|\mathbf{r} - \mathbf{r}_1|} \qquad (6)$$

for **A** vanishing at infinity.

Magnetic lines of force are defined by $\mathbf{dr} \propto \mathbf{B}$

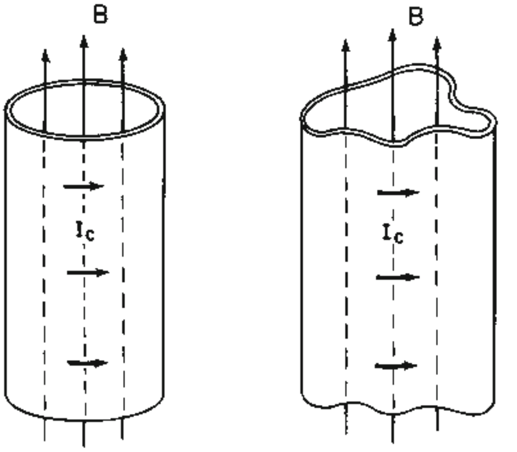

FIG. 2. Infinitely long cylindrical configurations with axially directed magnetic induction **B**.

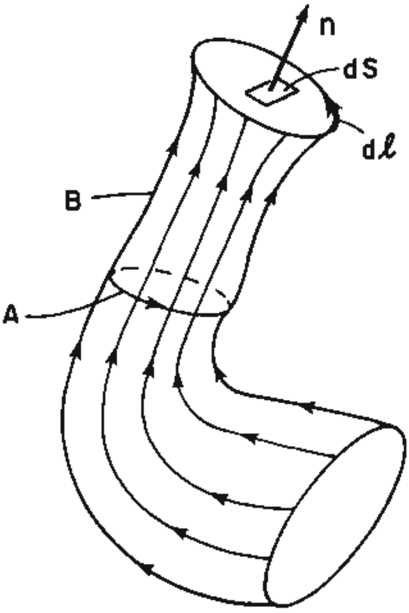

FIG. 3. Magnetic flux tube.

and are endless, by virtue of Eq. (1). The magnetic flux Φ through a surface S, bounded by a closed curve ℓ (Fig. 3), is given by

$$\Phi = \int dS\mathbf{B} \cdot \mathbf{n} = \oint d\ell \cdot \mathbf{A} \qquad (7)$$

where $\mathbf{n}$ is the normal to S. The flux tube defined by the field lines passing through ℓ contains constant flux, independent of S.

At a large distance from a localized current distribution at $\mathbf{r} = 0$, Eq. (6) gives the dipole potential

$$\mathbf{A} = \frac{\mathbf{m} \times \mathbf{r}}{r^3} \qquad (8)$$

where

$$\mathbf{m} = \frac{1}{2} \int d^3r_1\mathbf{r}_1 \times \mathbf{J}(\mathbf{r}_1) \qquad (9)$$

Equations in the Presence of Magnetic Materials A macroscopic current density $\mathbf{J}_\mathrm{M}$ can be defined by local averaging of the microscopic current density $\mathbf{J}_\mathrm{m}$ within magnetic materials

$$\mathbf{J}_\mathrm{M} = \langle \mathbf{J}_\mathrm{m} \rangle_\mathrm{av} \qquad (10)$$

More conveniently, a magnetization vector $\mathbf{M}$ can be introduced, where

$$\mathbf{J}_\mathrm{M} = \nabla \times \mathbf{M} \qquad (11)$$

In experiments, only $\mathbf{J}_\mathrm{M}$ can be measured directly (via measurements on $\mathbf{B}$), and $\mathbf{M}$ is then uniquely derivable from Eq. (11) only with the added condition that it is to be a local state variable of the magnetic material (i.e., it is constant in uniform samples and constant fields). This condition follows automatically from the interpretation of $\mathbf{M}$ as a magnetic-moment density per unit volume:

$$\mathbf{M} = N\mathbf{m}_0 \qquad (12)$$

The theoretical molecular magnetic moment $\mathbf{m}_0$ (with number density N) is derived from $\mathbf{J}_\mathrm{m}$ by evaluation of Eq. (9) over the molecular volume.

For macroscopic purposes, the total current density $\mathbf{J}$ of the preceding section is now specified by

$$\mathbf{J} = \mathbf{J}_\mathrm{c} + \mathbf{J}_\mathrm{M} \qquad (13)$$

The component $\mathbf{J}_\mathrm{c}$ flows in conductors of resistivity η in accordance with Ohm's law:

$$\eta\mathbf{J}_\mathrm{c} = \mathbf{E} \qquad (14)$$

The component $\mathbf{J}_\mathrm{M}$ is derived from $\mathbf{M}$.

In the analysis of configurations involving magnetic materials, the magnetic field $\mathbf{H}$ is a convenient vector

$$\mathbf{H} = \mathbf{B} - 4\pi\mathbf{M} \qquad (15)$$

Then Eqs. (1) and (2) take the form

$$\nabla \cdot \mathbf{H} = -4\pi\nabla \cdot \mathbf{M} \qquad (16)$$

$$\nabla \times \mathbf{H} = 4\pi\mathbf{J}_\mathrm{c} \qquad (17)$$

At the interface between two magnetic materials, Eqs. (1) and (17) imply continuity of the normal component of $\mathbf{B}$ and of the tangential component of $\mathbf{H}$.

Across a sheet-current of density I_c' per unit length, the tangential component transverse to $\mathbf{J}_\mathrm{c}$ of both $\mathbf{H}$ and $\mathbf{B}$ undergoes an increment $4\pi I_\mathrm{c}'$. The other components of $\mathbf{H}$ and $\mathbf{B}$ are unaffected.

The field patterns set up by a magnetized sphere are illustrated in Fig. 4. The magnetic induction (a) and magnetic field (b) are identical outside the sphere, but differ inside it, because of the magnetization (c). The same pattern of magnetic induction could be generated in the absence of magnetization by a surface current (d). The source of the magnetic field in Eq. (16), that is to say the quantity $\nabla \cdot \mathbf{M}$, is also referred to as the magnetic pole density. The north and south polar regions are indicated in (c).

For weakly magnetic materials, Eq. (15) can generally be written in terms of a scalar magnetic permeability μ

$$\mu\mathbf{H} = \mathbf{B} \qquad (18)$$

For ferromagnetic materials, one can still write

$$\mu\mathbf{H} = \mathbf{B} - 4\pi\mathbf{M}_0 \qquad (19)$$

where $\mathbf{M}_0$ is a permanent magnetization, but μ now depends on the time history as well as the

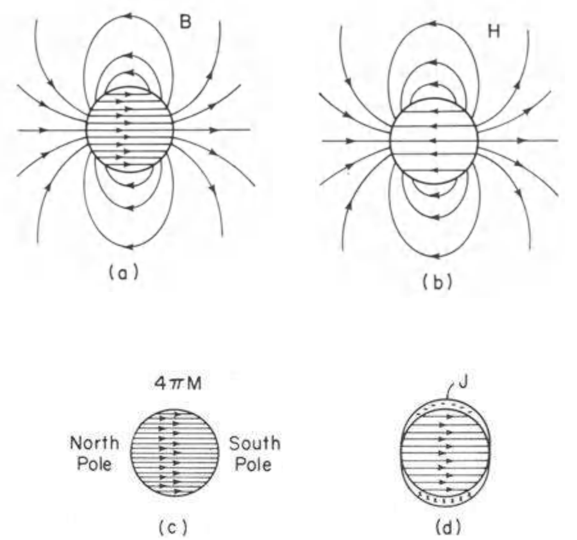

FIG. 4. Magnetic induction (a) and magnetic field (b) arising from sphere with magnetization pattern shown in (c) or with surface current pattern shown in (d).

magnitude of **H**. The typical relation between **B** and **H** for ferromagnetic materials is illustrated in Fig. 5.

When $\mathbf{J}_c$ is zero everywhere, one can define a scalar potential Ω, such that

$$\mathbf{H} = -\nabla\Omega \tag{20}$$

$$\nabla^2\Omega = 4\pi\nabla \cdot \mathbf{M} \tag{21}$$

If the boundary condition on Ω is simply that it vanish at infinity, the solution is

$$\Omega(\mathbf{r}) = -\int d^3r_1 \, \frac{\nabla_1 \cdot \mathbf{M}(\mathbf{r}_1)}{|\mathbf{r} - \mathbf{r}_1|} \tag{22}$$

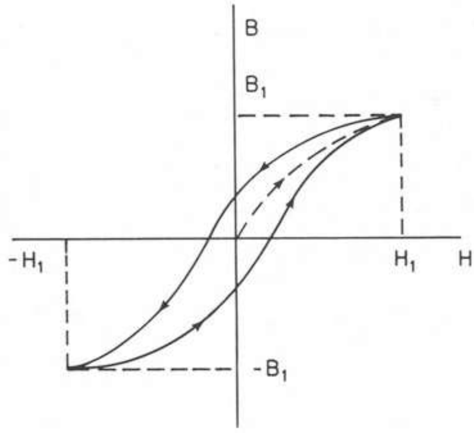

FIG. 5. As magnetic field **H** is initially raised to $\mathbf{H}_1$, magnetic induction **B** rises to $\mathbf{B}_1$. Cyclical pattern shown is typical of ferromagnetic materials: **B** saturates as **H** becomes large; **B** remains finite as **H** returns to null; **B** goes to $-\mathbf{B}_1$ as **H** goes to $-\mathbf{H}_1$. Double-valuedness of **B**(**H**) is known as hysteresis.

In the presence of current-carrying conductors Eqs. (20) and (21) still hold in the region where $\mathbf{J}_c = 0$, but Eq. (17) now implies a multivalued potential

$$\oint d\ell \cdot \mathbf{H} = \oint d\Omega = 4\pi I_c \tag{23}$$

where the integral is taken around a loop enclosing the total conductor current I_c. To keep the potential single-valued, so that the solution of Eq. (22) remains valid, one may adopt the "magnetic-shell" approach: $\mathbf{J}_c$ is replaced with an equivalent **M**, in analogy with Eq. (11).

Magnetic Force and Energy From Maxwell's stress tensor, we find the volume force

$$\mathbf{f} = -\nabla\left(\frac{B^2}{8\pi}\right) + \frac{1}{4\pi}(\mathbf{B} \cdot \nabla)\mathbf{B} \tag{24}$$
$$= \mathbf{J} \times \mathbf{B}$$

which agrees with the summation of the Lorentz forces on the moving charges composing **J**. The "magnetic pressure" against a current sheet bounding a region of finite **B** (as in the Meissner effect or ordinary skin effect) is thus $B^2/8\pi$, evaluated at the surface. The force and torque on a body localized in a nearly uniform field are

$$\mathbf{F} = (\mathbf{m} \cdot \nabla)\mathbf{B} \tag{26}$$

$$\mathbf{N} = \mathbf{m} \times \mathbf{B} \tag{27}$$

From the microscopic point of view underlying Eq. (2), the magnetic energy density is

$$w = \frac{B^2}{8\pi} \tag{28}$$

In the presence of magnetic materials, one is more interested in the electrical input energy required to go from $\mathbf{B}_0$ to **B**, and this is given by

$$\Delta w = \frac{1}{4\pi}\int_{\mathbf{B}_0}^{\mathbf{B}} \mathbf{H} \cdot \mathbf{dB} \tag{29}$$

For $\mathbf{H} = \mu\mathbf{B}$, with constant μ, this becomes

$$\Delta w = \frac{1}{8\pi\mu}(B^2 - B_0{}^2) \tag{30}$$

The derivation of Eqs. (28) and (29) depends on the complete set of Maxwell's equations.

Units and Magnitudes The equations used here are based on the emu system. If the currents are expressed in amperes, they must be divided by 10 to give magnetic inductions in gauss or fields in oersteds. A magnetic induction of 10 kilogauss (one weber per square meter) can exert a maximum stress $\mathbf{B}^2/8\pi$ of about 4 atm, and contains an energy density of 0.4 joules/cm^{-3}.

The strength of the earth's magnetic induction is about 0.2 gauss. For typical ferromagnetic materials, the maximum value of $4\pi\mathbf{M}$ is 20 kilogauss; at this point of saturation, the permeability μ approaches unity. At magnetic fields below one gauss, permeabilities of 1000 or more can be reached. The strength of materials limits the magnetic induction obtainable nondestructively with laboratory electromagnets to peak values well below a million gauss.

MAGNETIC RESONANCE

The magnetic resonance phenomenon is the resonant interaction between an oscillating magnetic field and an orthogonal static magnetic field mediated by the presence of objects possessing both angular momentum and a magnetic moment. The objects in question are normally microscopic in character (molecules, atoms, atomic nuclei or subatomic particles: protons, neutrons, electrons, muons, etc.), although historically the effect was first demonstrated with magnetized iron rods.

In atoms and molecules, a magnetic moment may arise from the orbital motions of electrons, in the same manner as an electric current flowing in a loop of wire generates a dipole-like magnetic field. According to quantum theory, angular momentum for such orbital or rotational motions is restricted to values which are integral multiples of $\hbar (\hbar = h/2\pi$, where $h = 6.626176 \times 10^{-34}$ J s is the Planck constant). Thus, we may calculate the magnitude of the magnetic moment μ due to the orbital motion of an electron in the smallest ($n = 1$) orbit of the classical Bohr atom using Ampere's law (μ = current × area) and the fact that the angular momentum $L = mvr = nh$. The result,

$$\mu_B = \frac{e\hbar}{2m} = 9.274078 \times 10^{-24} \text{ J T}^{-1},$$

where e/m is the magnitude of the electron charge to mass ratio, is known as the Bohr magneton, and is a convenient unit in which to denote atomic and molecular magnetic moments.

The spin, or intrinsic angular momentum, of an elementary particle or a nucleus may take on values which are integral multiples of $\hbar/2$. The nuclear equivalent of the Bohr magneton, based on a classical model of the proton as a rotating sphere of charge is the nuclear magneton

$$\mu_N = 5.050824 \times 10^{-27} \text{ J T}^{-1}.$$

The actual intrinsic magnetic moments for the free electron and proton are respectively $-1.001160\ \mu_B$ and $+2.792846\ \mu_N$. The g factor is a dimensionless measure of magnetic moment (in units of $-\mu_B/2$) which is traditionally used for electron-associated moments.

A particle possessing both angular momentum $\mathbf{J}$ and a proportional magnetic moment $\boldsymbol{\mu} = \gamma\mathbf{J} = \gamma\mathbf{I}\hbar$ will precess gyroscopically when placed in a magnetic field $\mathbf{B}_0$ in a manner similar to that of a spinning top precessing about the Earth's gravitational field. The proportionality constant γ is known as the *magnetogyric ratio*. The precession rate in radians sec^{-1}, the *Larmor frequency*, may be derived by a classical calculation to be

$$\omega_0 = \gamma B_0. \tag{1}$$

Coincidentally, an exact quantum calculation, using a Hamiltonian $\mathrm{H} = -\boldsymbol{\mu}\cdot\mathbf{B}_0$, yields an energy separation (Zeeman interaction) between adjacent energy levels of a particle with spin angular momentum quantum number I of $E_0 = \hbar\omega_0$. A total of $2I + 1$ states with energies $-\hbar\omega_0 I_z$ occur, I_z being the z component (magnetic) angular momentum quantum number and taking on the values $-I, -I + 1, \ldots, +I$.

This beautiful correspondence between the quantum and classical descriptions is made even stronger for isolated spins by the fact that a quantum dynamic calculation shows that the expectation values $\langle I_x \rangle$, $\langle I_y \rangle$, and $\langle I_z \rangle$ behave with time in precisely the same manner as the components of angular momentum of a wholly classical particle. Thus, we are entitled to formulate and visualize descriptions of magnetic resonance phenomena in terms of classically precessing vectors.

The vector description of magnetic resonance is due to Rabi. If a spin experiences simultaneously a static magnetic field and a field rotating in a plane perpendicular to the static field, resonance becomes possible. (In practice, linearly polarized transverse oscillatory fields are used; these may be decomposed into two counterrotating fields, one of which moves along with the precessing spin, the effect of the other being unimportant.) The detailed analysis of this situation is conveniently accomplished by a coordinate transformation to a frame of reference rotating synchronously with the rotating field (Fig. 1). By convention, the z-axis of the laboratory and rotating reference frames are collinear with the applied static

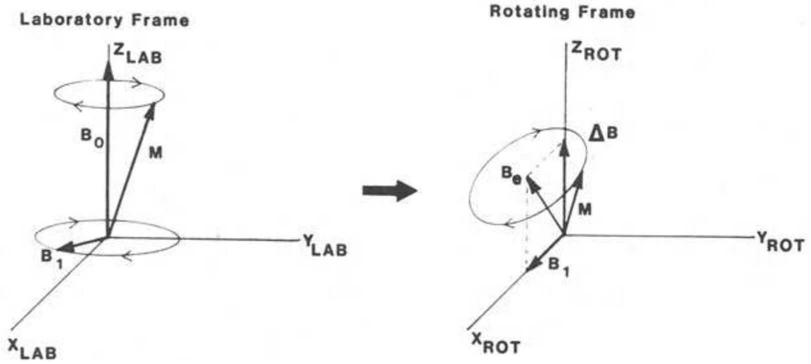

FIG. 1. Rotating coordinate transformation. The rotating reference frame rotates in synchronism with the applied $\mathbf{B}_1$ RF magnetic field. Within the rotating frame, the $\mathbf{B}_1$ field is static, the original $\mathbf{B}_0$ field is replaced by the resonance offset field $\Delta\mathbf{B}$, and the magnetization **M** precesses about the net field $\mathbf{B}_e$.

field $\mathbf{B}_0 = B_0\mathbf{k}_{\mathrm{LAB}}$. The rotating field amplitude is B_1, and the laboratory and rotating frame vectors are defined as

$$B_1\ (\cos\omega t\ \mathbf{i}_{\mathrm{LAB}} + \sin\omega t\ \mathbf{j}_{\mathrm{LAB}})$$

and

$$B_1\mathbf{k}_{\mathrm{ROT}}$$

respectively, ω being the angular rotation frequency.

Thus, in the absence of a B_1 field a spin with true Larmor frequency ω_0 appears in the rotating frame to precess at $\omega_0 - \omega \equiv \Delta\omega$. In order to preserve the form of the dynamical equations upon transformation into the rotating frame, we adopt the idea of the spin experiencing an effective field given by $\Delta B = (\omega_0 - \omega)/\gamma$, which acts along $\mathbf{k}_{\mathrm{ROT}}$.

Now the resonance effect becomes clear and simple to analyze. Upon application of a B_1 field, a net effective field $\mathbf{B}_e = B_1\mathbf{i}_{\mathrm{ROT}} + \Delta B\mathbf{k}_{\mathrm{ROT}}$ results which is no longer parallel to the z-axis. The spin now precesses at rate γB_e about the effective field direction (often denoted by an effective field angle $\theta = \tan^{-1}[B_1/\Delta B]$) and may suffer large excursions in direction. When the frequency of the applied B_1 field is far above or below ω_0 [Fig. 2(b)] the effective field direction is essentially the same as that of the laboratory field, and no significant effects on the spin are observed. The maximum effect occurs when the frequency of the applied B_1 field exactly matches ω_0 [$\Delta B \to 0$, the reso-

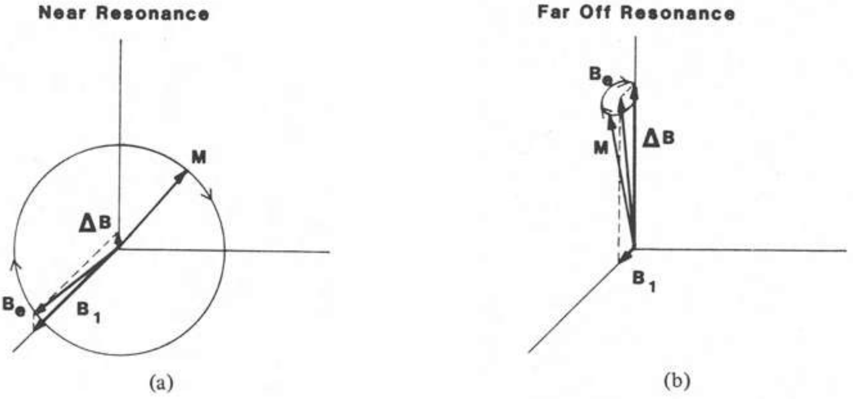

FIG. 2. Magnetic resonance—development of transverse magnetization. (a) On or near resonance ($|\Delta B| \lesssim B_1$) the magnetization **M** may be nutated from its thermal equilibrium position along z into the xy plane (90° pulse), inverted (180° pulse), and so forth. (b) When the applied RF is far from resonance ($|\Delta B| \gg B_1$) the magnetization is not significantly perturbed.

nance condition, Fig. 2(a)]. In this case it is possible to nutate the spin into the transverse direction and leave it there (a "90° pulse") or invert its orientation entirely (a "180° pulse," etc.).

The phenomenological description of the collective behavior of a system of weakly interacting spins was provided by a set of equations given by Bloch. Although they fail quantitatively in a number of specific instances (most notably for spin systems in solids or other strong-interaction situations), they offer an enormously useful and generally applicable conceptual framework:

$$\begin{aligned}\frac{dM_x}{dt} &= \gamma(\mathbf{M} \times \mathbf{B})_x - \frac{M_x}{T_2}\\ \frac{dM_y}{dt} &= \gamma(\mathbf{M} \times \mathbf{B})_y - \frac{M_y}{T_2} \qquad (2)\\ \frac{dM_z}{dt} &= \gamma(\mathbf{M} \times \mathbf{B})_z - \frac{(M_z - M_0)}{T_1}.\end{aligned}$$

Basically, the Bloch equations describe the time behavior of the components of the magnetization **M** (summation over the individual microscopic magnetic moments) in the rotating frame. M_0 is the magnitude of the magnetization in thermal equilibrium with the "lattice" (i.e., the remaining motational degrees of freedom of the material in which the spin system resides) given by the Curie law

$$M_0 = \frac{CB_0}{T}, \qquad (3)$$

C being the Curie constant and T the absolute temperature. In thermal equilibrium, the magnetization must be parallel to the static field (transverse components zero).

The cross-product terms in Eq. (2) represent the precessional or nutational behavior discussed above. The remaining terms are damping terms which describe the tendency of the system to return to thermal equilibrium. The time-dependent solution of the equations starting with an arbitrary **M** yields a z-component M_z which decays exponentially toward M_0 with a time constant T_1 (the longitudinal or "spin-lattice" relaxation time). The transverse components M_x and M_y decay exponentially to zero with time constant T_2 (transverse or "spin-spin" relaxation time). Longitudinal relaxation involves exchange of energy with the lattice, while transverse relaxation involves energy exchange between spins or dephasing of precessing components; hence the differentiation in relaxation times. It must always be true that $T_1 \geqslant T_2$. A low power $(B_1 \ll (\gamma^2 T_1 T_2)^{-1/2}$ steady-state solution gives a nonzero transverse magnetization parallel to B_e which may exhibit saturation (disappearance of the transverse component for sufficiently large values of B_1 near resonance).

The Bloch equations also suggest ways of experimentally observing magnetic resonance phenomena. The CW (continuous wave) technique is based on the steady-state solution. The static transverse component of **M** in the rotating frame corresponds in the laboratory frame to an oscillating transverse magnetization at the frequency of the applied field. It may be observed as a net power absorption by the sample or the appearance of a coupling between two orthogonal transverse radiofrequency (RF) coils containing the sample as field and applied RF are slowly brought into resonance according to Eq. (1) (either field or frequency may be swept). The transient response may be observed directly after a suitable (e.g., 90°) pulse has been applied. The resulting oscillatory decaying magnetization induces a voltage in a coil surrounding the sample (which may be the same coil used to apply the pulse). This signal is known as the *free induction decay* (FID), and contains components from all spins which were significantly affected by the pulse. The CW spectrum may be recovered by Fourier transformation of the FID (see FOURIER ANALYSIS).

The CW method is traditional for observation of nuclear magnetic resonance (NMR) and is still almost exclusively employed for electron spin resonance (ESR, or electron paramagnetic resonance, EPR). Over the past decade (1970s), pulsed, or Fourier transform, techniques have gradually supplanted CW in chemical NMR applications because of the higher potential sensitivity for a given measurement time (all of the spectral information is "captured" in one short time interval) and the convenience with which computer-based signal averaging may be adapted. (See Figs. 3-5.)

The great preponderance of magnetic resonance measurements are in NMR and ESR. Every chemical element has at least one observable isotope. Common examples are listed in Table 1. ESR measurements may be made on any substance with net unpaired electron spin density. Examples are organic free radicals, high-spin metal ions, conduction electrons in metals, some doped semiconductors, as well as systems with long-range collective interactions: ferromagnetic, antiferromagnetic, and ferrimagnetic materials. The spontaneous polarization of ferromagnetic systems allows the occurrence of NMR and ESR without an external B_0 field.

Several types of interactions affect NMR and ESR spectra. The presence of the B_0 field induces a circulation of electrons in materials which in turn gives rise to a small opposing field. This field-proportional shielding effect depends sensitively upon the chemical environment and orientation at the spin under observation. In NMR the effect is called the *chemical shift*, and is always reported with respect to a reference compound of the isotope in question;

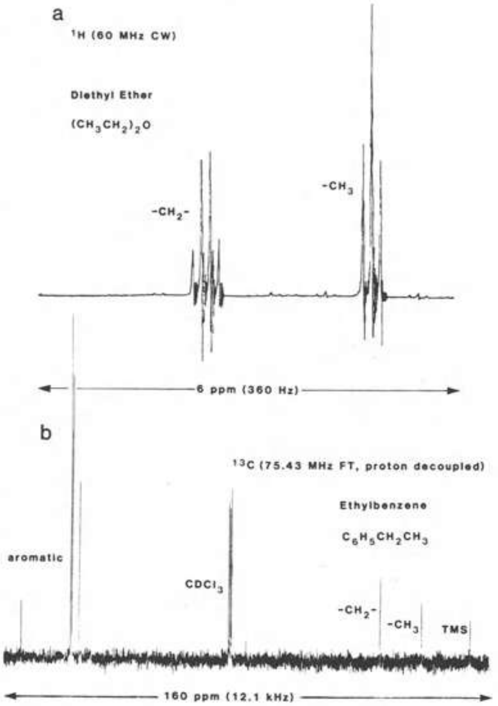

FIG. 3. Typical solution NMR spectra. (a) Proton 60 MHz (B_0 = 1.409 T) continuous wave spectrum of diethyl ether. Positions of spectral patterns are due to the chemical shift, line splittings within patterns are due to J couplings. Integral of each spectral pattern is proportional to the number of protons giving rise to that resonance. (b) ^{13}C 75.43 MHz (B_0 = 7.046 T) Fourier transform spectrum of ethylbenzene. Couplings to protons are removed by continuous irradiation of protons simultaneous with acqusition of carbon free induction decay. Carbon-carbon couplings do not appear because the low concentration of the isotope about 1% of ^{12}C) makes the occurrence of ^{13}C pairs rare. Solvent is deuterochloroform, $CDCl_3$. Chemical shift reference, tetramethylsilane (TMS), $(CH_3)_4Si$, has been added.

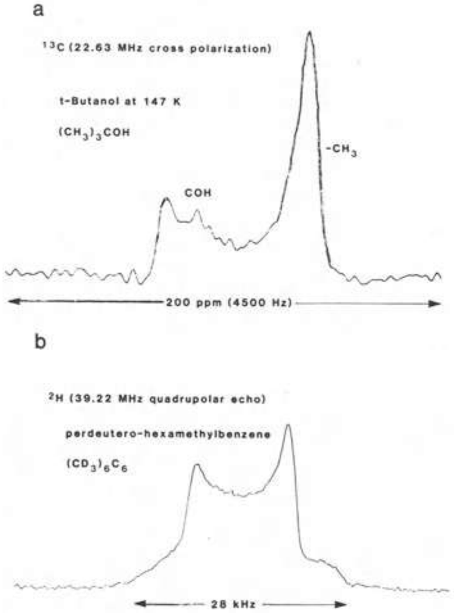

FIG. 4. Typical solid state Fourier transform NMR spectra. (a) ^{13}C spectrum of tertiary butanol, employing proton decoupling [see Fig. 3(b)]. The widths and shapes of the lines are due to the anisotropy of the chemical shift. (b) ^2H spectrum of deuterated hexamethylbenzene. The width and shape of this spectrum are due to the anisotropy of the quadrupole splitting interaction.

typical ranges of chemical shifts vary from 10 ppm (parts per million of field or frequency) for the three hydrogen isotopes to 250 ppm for carbon to several thousand ppm for the heavier elements or for shifts arising from conduction electrons in metals (these are called *Knight shifts*). This exquisite sensitivity to chemical effects has made NMR one of the most powerful and ubiquitous techniques of chemical analysis and research. Shieldings in ESR are reported as *g* values, which range from roughly 1.9 to 2.2. Shifts arising from bulk magnetic susceptibility are also observed.

Interactions also occur between all the magnetic dipoles in systems, such as between nuclei of the same isotope (homonuclear dipole-dipole), between different isotoptes (heteronuclear dipole-dipole), between nuclei and unpaired electrons, or between electrons. These interactions may occur directly through space, or may be "conducted" through chemical bonds as a slight bias in spin polarization (*indirect* or *J coupling* when speaking of NMR, *hyperfine coupling* when speaking of couplings to nuclei in ESR spectra).

Couplings between molecular rotation-induced moments and nuclei or electrons can also occur (spin-rotation coupling). These are usually most apparent in their effect on relaxation (see next paragraph). Nuclei with $I > \frac{1}{2}$ have nonspherical charge distributions, and therefore interact with electric field gradients in materials. Quadrupole couplings can range from zero to small perturbations on NMR spectra to values which completely dominate the nuclear Zeeman energy. In the latter case, the quadrupole interaction can serve as the source of nuclear polarization rather than the B_0 field, making possible "zero-field" NMR (normally called nuclear quadrupole resonance, NQR).

All of these interactions may be time dependent due to atomic or molecular motions, or due to natural or experimentally induced mo-

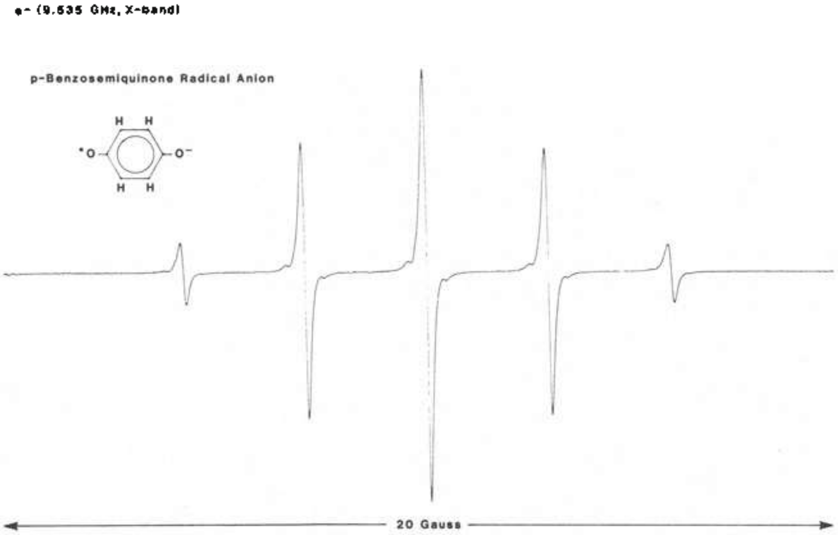

FIG. 5. Typical solution ESR spectrum. Most ESR spectra are obtained by a continuous wave method in the derivative mode. Spectrum of parabenzosemiquinone radical anion in alkaline ethanol. Line splitting (hyperfine coupling to the four protons) is 2.368 gauss, g-value is 2.005.

[a] Magnitude of magnetic moment vector $\mu = \gamma\hbar[I(I+1)]^{1/2}$. Positron and muon moments in units of their respective magnetons. Values for all nuclei except ^{1}H are those observed in specific chemical compounds, uncorrected for shielding.

[b] Electric quadrupole moments are often known with only poor accuracy, due to certain assumptions which must be made in their experimental determination, and due to conflicting results from different experimental techniques. The table values represent a range from several sources.

[c] Approximate detection voltage signal to noise ratio, assuming equal B_0 fields, line shapes, relaxation times, measurement bandwidths, and total measurement noise, relative to protons; proportional to $\omega_0{}^3 I(I+1)$.

[d] Product of natural isotopic abundance and relative receptivity per particle.

tions of some of the magnetic dipoles in the system. Depending on the type of interactions, such motions can be the source of relaxation (e.g., T_1 and T_2 in the Bloch equations) between specific types of spins or between spins and the lattice.

Aside from the chemical and physical research and measurement, other applications of magnetic resonance include measurement of magnetic fields (proton magnetometers) and the use of ferrites (high RF resistivity ferrimagnetic ceramics of general formula $MOFe_2O_3$, M a divalent cation) as magnetic field-controllable microwave switches, phase shifters, attenuators, filters, circulators and isolators.

Most recently, magnetic resonance has been employed for noninvasive clinical imaging of the human body (zeugmatography). Lauterbur first demonstrated that the NMR spectrum of a compound with a single spectral line (e.g., protons in intracellular water) is the projection of the distribution of the compound in the object if a linear B_0 field gradient, rather than a uniform B_0 field, is applied across the object. Multiple projections in several directions may be used to reconstruct an image using algorithms similar to those employed in x-ray or emission computed tomography.

The formal description of magnetic resonance given above has been applied (by Feynman, Vernon, and Hellwarth) to the generalized two-level quantum system, and has proved extremely useful in understanding coherence phenomena in microwave, infrared and optical spectroscopies.

MAGNETISM

Magnetization Magnetic fields are produced both by macroscopic electric currents and by magnetized bodies. The first observed manifestations of magnetism were the forces between naturally occurring permanent magnets, and between these and the earth's field. North- and south-seeking poles could be identified. Poles were observed to be localized near the ends of long rods magnetized by contact with natural magnets or by a current-carrying coil. From the observed attraction and repulsion of unlike and like poles with an inverse square law came the concept of pole strength and the definition of the unit pole, that which acts on another in vacuum with a force of one dyne at a distance of one centimeter. The unit magnetic field, the oersted, could then be defined as that in which a unit pole experiences a force of one dyne. The magnetic moment of a long, uniformly magnetized rod of length l with a pole strength of m unit poles at each end is defined as ml, the largest couple that the sample can experience in a field of one oersted. The magnetization, M, is defined as the magnetic moment per unit volume, ml/al, where a is the cross-sectional area, and is thus also equal to the pole strength per unit area, m/a.

Magnetic Induction The induction, or flux density, B, is numerically equal to the field H in free space and is described as one line of flux per square centimeter for a field of one oersted. Its direction is that of the force on a unit north pole. If magnetic material is present, the flux density is equal to $H + 4\pi M$, since 4π lines of force emanate from the unit pole at each end of a dipole equivalent to a specimen of unit magnetization. Magnetic poles are observed to occur in pairs. Lines of B are continuous, i.e., $\operatorname{div} B = 0$. If a material becomes strongly magnetized in a small field, the lines of flux can be considered to crowd into the material, leaving their original locations and reducing the field there. This is how magnetic shielding is accomplished. Changes of B within a coil induce voltages which can be measured and form the basis of galvanometer and fluxmeter measurement methods. For a coil of N turns of cross-sectional area a, in which the flux is changing at dB/dt gauss/sec, E in volts is given by

$$E = -10^{-8} Na \frac{dB}{dt}$$

Forces on magnetic bodies in field gradients are proportional to M.

Types of Magnetic Behavior In general a field H will produce a magnetization M in any material. If M is in the same direction as H, a sample will be attracted to regions of stronger field in a field gradient. It will be repelled if M is in the opposite sense. This experiment, as first performed by Faraday, is the basis for the broad classification of materials into paramagnetic, diamagnetic, and ferromagnetic. The susceptibility κ is defined as M/H. The force F_x on a small specimen of volume v in a field H_y and a field gradient dH_y/dx is

$$F_x = (\kappa_2 - \kappa_1)vH_y \frac{dH_y}{dx}$$

where κ_2 and κ_1 are the volume susceptibilities of the specimen and the surrounding medium, usually air.

For paramagnetic materials, κ is small and positive, usually between 1 and 1.001 at ordinary temperatures. These substances contain atoms or ions with at least one incomplete electron shell, giving them a non-zero atomic or ionic magnetic moment μ_a. Many salts of the iron-group and rare-earth metals are paramagnetic, as are the alkali metals, the platinum and palladium metals, carbon, oxygen, and various other elements. Antiferromagnetic substances also have small positive κ, as do ferromagnetics above their Curie temperatures. In the classical theory of paramagnetism, the orientations of the moments are considered to be initially thermally randomized in space. An applied field produces a net magnetic moment in its direction, as described by the classical Langevin function

$$\frac{M}{M_s} = \coth\left(\frac{\mu_a H}{kT}\right) - \frac{kT}{\mu_a H}$$

where k is the Boltzmann constant. M_s is the value of M attained for very large H/T. Under most conditions, only the initial portion of this curve is observed, with the corresponding constant κ. The conduction electrons at the top of the Fermi distribution in a metal can also give rise to a temperature-independent Pauli paramagnetism. The quantum-mechanical analogue of the Langevin function is called the Brillouin function (see PARAMAGNETISM).

For diamagnetic materials, κ is small and negative. Diamagnetism is a universal phenomenon but is often masked by paramagnetic or ferromagnetic effects. Net diamagnetic behavior is observed in a number of salts and metals, and in the rare gases, in which there is no net moment. The effect can be regarded as the operation of Lenz's law on an atomic scale (see DIAMAGNETISM).

Ferromagnetic materials show a value of M which may be of the order of 10^3 in small fields. Thus κ can be very large. It is common to describe their properties in terms of the permeability $\mu = B/H$. Since M saturates in ordinary fields, κ and μ are not constant. M is not necessarily in the same direction as H, so κ and μ are, in general, tensors. Furthermore, ferromagnetics generally exhibit hysteresis in the dependence of M on H, and the details are very structure-sensitive. Still another distinction is the rather abrupt disappearance of ferromagnetism at a characteristic temperature, the Curie temperature, T_c.

Atomic Magnetic Moments There are two possible sources for the moments of individual atoms. They are electron orbital motion and electron spin (see ELECTRON SPIN). In most ferromagnetic materials, most of the moment comes from spin rather than orbital motion, a fact that is revealed experimentally by gyromagnetic measurements (see FERROMAGNETISM) and by magnetic resonance experiments (see MAGNETIC RESONANCE). Orbital motions are quenched by the electric fields of the neighboring atoms in the crystal lattice. In the rare earth metals the unfilled shell is deep within the atom, orbital motion is not quenched, and the orbital contribution to the magnetic moment is observed. The unit of atomic moment is the Bohr magneton, μ_B, which is the moment associated with one electron spin, numerically equal to 0.9274×10^{-20} erg/oersted. The spin quantum number, S, is one-half the number of unpaired electrons. The moment per atom is $Sg\mu_B$ where g is the gyromagnetic ratio, close to 2 for most materials. The moment in Bohr magnetons of an isolated atom or ion of the first transition series is equal to the number of unpaired d electrons, considering the first five electron spins to have one orientation and the next five the opposite (Hund's rule). The Ni^{++} ion, with eight d electrons, has the expected moment of $2\mu_B$ in ferrites, in which the ionic spacing is great enough so that the d levels are not disturbed (see FERRITES). In metallic nickel, however, the d levels overlap considerably, and the moment corresponds to only 0.6 μ_B per atom. Similarly the Bohr magneton numbers for metallic iron and cobalt are 2.2 and 1.7 respectively.

Ferromagnetism Ferromagnetism can only occur in a material containing atoms with net moments. Also, quantum-mechanical electrostatic "exchange" forces must be present, holding neighboring atomic moments parallel below the Curie temperature. These are much greater than the Lorentz force due to the average magnetization and are, in fact, equivalent to an effective field on the order of 10^6 oersteds. Such an effective "molecular field" was postulated in 1907 by Weiss in extending the Langevin theory of paramagnetism to include ferromagnetic behavior. The Langevin function predicts a temperature dependence of magnetization, for small M, of

$$M = \frac{CH}{T}$$

where C is a constant. The susceptibility is then C/T, which is Curie's law. Weiss pointed out that if the field H were augmented by an additional field NM proportional to the magnetization, the temperature dependence became

$$M = \frac{CH}{T - T_c}$$

where $T_c = NC$. This is the Curie-Weiss law, approximately obeyed by ferromagnetic substances above their Curie points. Below T_c, the presence of the molecular field produces an alignment of the atomic moments corresponding to the spontaneous magnetization M_s even when no external field is present. However, ferromagnetic samples can have any net externally measured value of magnetization, including zero, which seems to contradict this result. Weiss therefore postulated the existence of domains separated by boundaries. In each domain the atomic moments are parallel, the domain magnetizations having different orientations. The net external magnetization is then the vector sum of the domain magnetizations and can be varied by a rearrangement of the domain structure, which may happen in very small applied fields. This prediction has been completely verified by experiment. The motion of domain boundaries as observed under the microscope has been directly correlated with external changes in magnetization. Domain boundaries in iron are on the order of 1000 Å thick. Within a boundary, neighboring magnetic moments are not quite parallel. The change in orientation of the magnetization from one domain to another is distributed through the thickness of the boundary.

Within a domain, the magnetization will in general preferentially lie along some particular crystallographic direction. The energy difference between magnetization in the easiest and hardest direction may exceed 10^8 erg/cm^3. This anisotropy is described in an appropriate trigonometric series with coefficients K_i. Usually only a few terms are necessary. Often a material is described by a single K; this implies a uniaxial anisotropy energy of the form $K \sin^2 \theta$. The K_i may pass through zero and change sign with changing composition or temperature. Although such details cannot in general be predicted, the magnetocrystalline anisotropy will have the same over-all symmetry as the crystal structure. Anisotropy is best investigated in single crystals, by analysis of magnetization curves in various directions or from the relationship between the measured torque and the direction of the applied field (see FERROMAGNETISM). Dimensional changes are also associated with the position of the magnetization vector relative to the lattice (see MAGNETOSTRICTION).

There are two mechanisms available for changing the externally measured magnetization of a ferromagnetic material: domain boundary motion, and domain magnetization rotation. Broadly speaking, in magnetically soft materials, boundary motion accounts for most of the changes in low applied fields, leaving the magnetization in each domain in the easy direction nearest the applied field. Then rotation against anisotropy produces the remaining change in higher fields. In very low fields, boundary motion is practically reversible, but when boundaries move considerable distances, they experience a net drag from impurities and irregularities in the material, causing hysteresis in the dependence of B on H. There will in general be a remanence B_r, the flux density remaining after saturation when the field is reduced to zero, and a coercive force H_c, the reverse field required to reduce the flux density to zero. A loss associated with the irreversibility of magnetization changes also occurs in rotating fields. This loss becomes zero in very large fields, except in a few special cases.

Even in very slowly changing fields, a wall characteristically moves in jumps, each giving a sudden change in B. This irregularity has been known for a long time as the Barkhausen effect, and its physical origin is the irregularity of wall motion through various inhomogeneities in the material. Usually a very large number of these small jumps takes place. In special circumstances, however, the material may remain at B_r, until, in a sufficiently large field, a single wall will be nucleated and sweep all the way across the specimen, leaving it at B_r in the other direction. Such a material has only two stable states, $+B_r$ and $-B_r$, a useful behavior in some applications.

Direct microscopic observation of domains, e.g., by the Faraday effect or the magnetic Kerr effect, is an important research tool. Understanding and control of domain structures has progressed to the point that under appropriate conditions large numbers of tiny cylindrical domains can be deliberately produced and controllably moved in certain single-crystal materials, enabling the development of memory devices utilizing this ability.

It is also necessary to consider the behavior in rapidly varying fields, discussed below.

Antiferromagnetism Exchange forces can operate to hold neighboring moments antiparallel, rather than parallel. Materials whose magnetic moments are arranged in this way show no external permanent moment and are called antiferromagnetic. The sign of the exchange force may depend, among other things, on the atomic spacing. Metallic manganese, for example, is antiferromagnetic, while many alloys of manganese, in which the average Mn-Mn distance is greater, are ferromagnetic. In some antiferromagnetic compounds, the exchange interaction appears to be of a next-nearest-neighbor type, taking place through an intervening atom such as oxygen. This type of interaction is termed superexchange. Antiferromagnetic materials, having no net external moment, show small positive susceptibilities that reach a maximum at the temperature above which the exchange forces can no longer hold the moments aligned against thermal agitation. This temperature, T_N, the Néel temperature, corresponds to the Curie temperature of a ferromagnet. Magnetocrystalline anisotropy exists for antiferromagnets just as for ferromagnets (see ANTIFERROMAGNETISM).

Ferrimagnetism With more than one type of magnetic ion present, in certain compounds, antiferromagnetic coupling may lead to a net external moment corresponding to a Bohr magneton number equal to the difference in ionic moments. Other more complicated cases occur. Ferrites, insulating oxides with the spinel structure, are important examples of this class of material, called ferrimagnetics (see FERRIMAGNETISM).

Exchange Anisotropy A ferromagnetic phase may be in exchange coupling with an antiferromagnetic phase, as in a cobalt particle covered with CoO. This leads to new phenomena, including non-vanishing high-field rotational hysteresis. Such a material cooled in a field through the Néel temperature, if $T_c > T_N$, may exhibit a hysteresis loop that is permanently displaced from the origin. This is equivalent to a unidirectional (not uniaxial) anisotropy and will appear in a torque curve as a $\sin \theta$ term. Ferromagnetic and antiferromagnetic regions in a single-phase alloy may also lead to these effects.

Other Configurations Atomic moments need not necessarily be either parallel or antiparallel. In a few materials they may be arranged in a triangular or spiral configuration. In some circumstances, an antiferromagnetic material may shift to a configuration having a large ferromagnetic moment in the appropriate combination of fields and temperatures (metamagnetism).

Rare Earths The rare earth elements have magnetic moments originating from unpaired electrons in the $4f$ shell. These electrons are close to the nucleus and are shielded by the $5s$ and $5p$ electrons. Thus direct exchange does not occur in the rare earths. However, several of them exhibit ferromagnetism at low temperatures, originating in indirect exchange via the three $5d$–$6s$ conduction electrons. The atomic moments can be large in the heavy rare earths, in which the spin and orbital moments add. In fact, Dy and Ho have a moment per unit volume, at low temperatures, half again as large as that of iron. The rare earths often exhibit complex magnetic ordering structures.

The rare earths form many solid solutions among themselves, in which the variation of moment and Curie temperature have been investigated. They also form many intermetallic compounds with other elements. Often a rare earth and another element will form several discrete binary compounds, sometimes showing extraordinary magnetic properties. A number of compounds, including RCo_5, have extremely high magnetocrystalline anisotropy. $TbFe_2$ and $DyFe_2$ exhibit the highest magnetostrictive strains known, on the order of 1%, thousands of times higher than values typical of other materials.

Amorphous Materials It is possible by rapid quenching from the molten state to prepare metallic samples whose atomic structure is amorphous. The atoms are not arranged in a crystal lattice but are randomly packed as in a glass. The saturation magnetizations and Curie temperatures of these materials, although generally somewhat less than those of their crystalline counterparts, are substantial. The demonstration of ferromagnetism in a glassy metallic structure is of great fundamental interest. Furthermore, in such a structure there is no macroscopic magnetic anisotropy. As a result, magnetization changes can take place readily in small fields. Thus these materials can show high permeabilities and narrow hysteresis loops, giving them potential usefulness in various devices.

Permanent Magnets A useful permanent magnet material should have as large a hysteresis loop as possible. In the early magnet steels, wall motion was made difficult by a heterogeneous alloy structure. A different approach is based on the theory that sufficiently small particles should find it energetically unfavorable to contain domain boundaries. The critical size is proportional to $K^{1/2}/M_s$. Reversal must then proceed by the difficult process of rotation against shape, strain-magnetostriction, or crystal anisotropy. Fine-particle (~1000Å) iron and iron-cobalt materials utilizing shape anisotropy have been developed. The Alnico permanent magnet alloys have very fine precipitate structures and are probably also best regarded as fine-particle materials. A magnetic oxide, $BaO \cdot 6Fe_2O_3$, utilizes magnetocrystalline anisotropy in fine-particle (~1 μm) form. A new class of permanent magnet materials based on Co_5-(rare earth)$_2$ intermetallic compounds shows by far the highest permanent magnet properties of any material. These originate in the extremely high magnetocrystalline anisotropy of these materials.

Thin Films Since a surface atom's surroundings are different from those in the interior, the magnetization and Curie temperature of thin films should yield important information about the range of ferromagnetic interactions. Experimental difficulties, primarily with purity, have beclouded the subject to some extent, but it now appears that any surface layer on nickel having substantially different magnetic properties from the bulk cannot be more than a few Angstroms thick.

There have been many investigations of flux reversal in films, usually vapor-deposited on glass, which have been motivated by computer technology needs. Such films show a uniaxial anisotropy associated with fields present during deposition or sometimes with geometric effects such as the angle of incidence of the vapor beam.

Dynamic Behavior of Ferromagnetic Materials Changes in flux in a conductor induce emf's resulting in current flows whose fields tend to oppose the change in flux. For various time rates and geometries these can be calculated, leading to expressions for phase relationships and skin depth in conductors (see ELECTROMAGNETIC THEORY). These expressions have often been applied to magnetic materials at power frequencies by simply replacing H by B. This is in general not a good approximation and leads to erroneous results. It is more nearly correct to recognize that highly localized eddy currents around moving domain boundaries are the entire source of loss under these conditions. For a given dB/dt, the loss calculated in this way is much greater, decreasing to the classical value as the density of domain boundaries increases.

In bulk metals, domain wall velocities are usually determined by the damping associated with local eddy currents. In ferrites and thin films, other types of damping may predominate. These and many other aspects of the dynamic behavior of magnetic materials of all types have been investigated through resonance methods (see MAGNETIC RESONANCE).

Superparamagnetism For particles whose volume v is on the order of 10^{-18} cm^3 or less, the direction of the entire particle moment M_Sv may fluctuate thermally. An assembly of such particles will exhibit the Langevin function magnetization curve of a paramagnetic with the extremely large moment M_Sv; thus it may be easily saturated with ordinary fields and temperatures. Such magnetization curves can be used to study particle sizes and size distributions.

Magnetic Bubbles A remarkable application of the principles of domain structure has been realized in the fabrication of computer memory components utilizing tiny cylindrical magnetic domains. In thin monocrystalline plates of a material such as a garnet or in thin amorphous films of certain alloys, having an appropriate combination of magnetization and anisotropy, it is possible to establish stable cylindrical magnetic domains passing completely through the material. These domains, universally referred to as *bubbles*, can be generated, erased, moved, and sensed by overlays of conducting strips and Permalloy guide patterns. Each bubble is a "bit" of information. The dimensions of these bubbles and the associated patterns are on the order of a few microns. The storage density and access times of these memories appear to fit them to an important range of applications. (See FERRIMAGNETISM.)

MAGNETO-FLUID-MECHANICS

Magneto-fluid-mechanics is the subject that deals with the mechanics of electrically conducting fluids (such as ionized gases and liquid metals) in the presence of electric and magnetic fields. Magneto-hydrodynamics is another name used extensively, but it suffers from the less general meaning of the words "hydro" and "dynamics." Other names used are: magneto-hydro-mechanics, magneto-gas-dynamics, magneto-plasma-dynamics, hydromagnetics, etc.

The fundamental assumptions underlying magneto-fluid-mechanics are those of continuous media. In this respect, magneto-fluid-mechanics is related to plasma physics (see PLASMAS) in the same way that ordinary fluid mechanics is related to the kinetic theory of gases. More specifically, such phenomenological coefficients as viscosity, thermal and electrical conductivities, mass diffusivities, dielectric constant, etc., are assumed to be known functions of the thermodynamic state, as derived from microscopic considerations or experiments.

From electromagnetic theory, we know that the "Maxwell stresses" give rise to a body force made up of the following components: electrostatic (applied on a free electric space charge); ponderomotive (the macroscopic summation of the elementary Lorentz forces applied on charged particles); electrostrictive (present when the dielectric constant is a function of mass density); a force due to an inhomogeneous electric field and its magnetic counterpart; and the magnetostrictive force. For any fluid the last two forces are negligibly small at normal temperatures, whereas the ones associated with the behavior of the dielectric constant, although normally small, are of the same order of magnitude as the buoyant forces under certain conditions. On the assumption that we deal with electrically neutral but ionized fluids, the only substantial force that remains is the ponderomotive force. Indeed, what is today called magneto-fluid-mechanics deals almost exclusively with this force.

Fundamental Equations The equations that govern magneto-fluid-mechanics are the following:

(1) Equation of conservation of mass, which is the same as in ordinary fluid mechanics.

(2) Equation of conservation of momentum, which is altered by the forces enumerated above. In particular, the ponderomotive force per unit volume is given by $\mathbf{J} \times \mathbf{B}$ where $\mathbf{J}$ is the vector current density and $\mathbf{B}$ the magnetic induction, both measured in the laboratory.

(3) Equation of energy conservation; the same as in ordinary fluid mechanics with the addition of the Joulean dissipation $\mathbf{E}' \cdot \mathbf{J}'$. The primes indicate that the electric field and current density are measured in a frame of reference moving with the fluid. In the nonrelativistic case and for zero space charge, we have $\mathbf{E}' = \mathbf{E} + \mathbf{q} \times \mathbf{B}$ and $\mathbf{J}' = \mathbf{J}$. The barycentric stream velocity is indicated by $\mathbf{q}$.

(4) Equation describing the thermodynamic state.

(5) Conservation of electric charge.

(6) Ampère's law.

(7) Faraday's law.

(8) Statement that the magnetic poles exist in pairs only.

(9) Ohm's phenomenological law.

(10) Constitutive equations linking the electric field with the displacement vector and the magnetic intensity field with the magnetic induction. Equations (1) to (3) are the conservation equations. Equations (5) to (8) are Maxwell's equations. For a large number of problems, the phenomenological coefficients of electrical and thermal conductivity, viscosity and the like are assumed to remain unaffected by the magnetic field. This implies that the collision frequencies among the particles are much higher than the cyclotron frequency associated with the property a charged particle has to rotate around a magnetic line under the influence of the Lorentz force. This means that the transfer of electric charge, mass, momentum, and energy is not realized in a preferential direction.

Physically, the magneto-fluid-mechanic system of the above equations is coupled in the following sense: A velocity field $\mathbf{q}$ cutting magnetic lines of flux $\mathbf{B}$ gives rise to an induced current whose magnitude is given by $\mathbf{J} = \sigma(\mathbf{q} \times \mathbf{B})$. At the same time the fluid feels an induced body force equal to $\mathbf{J} \times \mathbf{B}$. On the other hand, the electric currents induced by the motion create, according to Ampère's law, a magnetic field which distorts the original applied magnetic field. The basic mechanism of this distortion is the one created by the irreversibility introduced by the finite electrical conductivity, the same way that the distortion of the inviscid streamlines in ordinary fluid mechanics takes place by the action of viscosity.

Nondimensional Parameters and Some Important Theorems In order to study the nature of the solutions as they emerge from different problems, we shall form a number of nondimensional parameters that can be extracted from the different equations. The order of magnitude of the inertia force per unit volume is given by $\rho V^2/L$ where ρ is the mass density, V the velocity, and L a characteristic length; the order of magnitude of the ponderomotive force $\mathbf{J} \times \mathbf{B}$, after using Ohm's law, is equal to $\sigma B^2 V$. Also, the order of magnitude of the viscous force is: $\mu V/L^2$. The ratio of the typical inertia force over the viscous force is called the Reynolds number (Re) and, from the above, is found to be: $Re = \rho VL/\mu$. The ratio of the ponderomotive force over the inertia force is given by $\zeta = \sigma B^2 L/\rho V$. The ratio of the ponderomotive force over the viscous force is equal to $(Re) \cdot \zeta$ and is defined in the literature as the square of the "Hartmann number," denoted by M. We have $M = BL\sqrt{\sigma}/\sqrt{\mu}$.

The distortion of the magnetic field due to the hydrodynamic field can be studied best with the help of the following two equations:

$$\frac{d\mathbf{\Omega}}{dt} = (\mathbf{\Omega} \cdot \nabla)\mathbf{q} + \frac{\mu}{\rho} \nabla^2 \mathbf{\Omega}$$

$$\frac{d\mathbf{H}}{dt} = (\mathbf{H} \cdot \nabla)\mathbf{q} + \frac{1}{\sigma\mu_e} \nabla^2 \mathbf{H}$$

In the above μ_e is the magnetic permeability and $\mathbf{H}$ the magnetic field intensity. The first equation describes the diffusion of vorticity $\mathbf{\Omega} = \nabla \times \mathbf{q}$, whereas the second can be obtained by a combination of Ampère's and Ohm's laws after elimination of the electric field by using Faraday's law. In the ordinary fluid mechanic case, the streamlines obtained after solving the inviscid problem are distorted in regions of high vorticity through the mechanism of viscosity (last term in first equation). Similarly the magnetic field calculated in the case of ideal, nondissipative flow with $\sigma = \infty$ is distorted by the finite electrical conductivity (last term in second equation). The nondimensional number describing the influence of viscosity is the Reynolds number, and in perfect analogy as indicated by the above two equations, the magnetic field distortion is described by the number, $(Re)_m = \mu_e \sigma VL$ and is called the magnetic Reynolds number. When $(Re)_m$ is zero, the magnetic lines remain undisturbed, whereas in the limit $(Re)_m \to \infty$, the magnetic lines are frozen into the fluid in exactly the same way that vorticity is frozen according to Helmholtz's theorem. Mathematical similarities apart, the freezing of the magnetic lines with the motion is evident in the case of $\sigma \to \infty$ from the following physical considerations: An observer moving with the barycentric (stream) velocity in a medium of infinite electrical conductivity can measure only a zero electric field and hence he does not cut magnetic lines, which means that the magnetic lines must move along with his speed. From this argument it also follows that the total change in the magnetic flux through a given surface moving with the stream must be zero for an infinitely conducting medium. Finally, the remark should be made that except for stellar and interspace applications where the velocities and (especially) characteristic lengths are high, $(Re)_m$ is a small number. On the other hand, the assumption $(Re)_m = 0$ is a rather drastic one since it permits the uncoupling of Maxwell's equations from the conservation equations. In thermonuclear plasma physics, much of which is analyzed by MHD models, the approximation of frozen field lines is very useful, especially in dealing with phenomena which occur over brief time intervals, such as in MHD instabilities.

For the calculation of the ponderomotive force we can use Ampère's law ($\nabla \times \mathbf{H} = \mathbf{J}$) to find that $\mathbf{J} \times \mathbf{B} = (\nabla \times \mathbf{H}) \times \mathbf{B}$. Through regular vector operations, we can show that $(\nabla \times \mathbf{H}) \times \mathbf{B} = -\text{grad}\ (B^2/2\mu_e) + \text{div}\ (\mathbf{BB}/\mu_e)$. One can identify the last term as representing a tension equal to $B^2/2\mu_e$ acting along the lines of force, whereas the first one corresponds to an equivalent hydrostatic pressure equal to $B^2/2\mu_e$. This term is frequently called "magnetic pressure" and in different problems is found to behave precisely as the static pressure does. Furthermore, one can show that if the magnetic lines are lengthened, the magnetic field intensity is increased.

Consider now the propagation of small disturbances in the form of acoustic waves for which the speed of sound for an ideal gas is proportional to $\sqrt{p/\rho}$. Now one can show through a linearization of the equations of conservation, assuming the presence of the magnetic pressure alone, that a small disturbance (for a gas of infinite electrical conductivity) will be propagated, in perfect analogy, with a speed equal to $\sqrt{B^2/\rho\mu_e}$. This is the so-called Alvén speed, and these waves are called magneto-fluid mechanic waves. Of interest also are combinations of several mechanisms of propagation which might include sound and gravitational waves.

Because of the property of the magnetic lines to increase their tension when lengthened, along with the additional ones of distortion and propagation of disturbances, their properties are presented in loose terms as resembling very much those of rubber bands.

Applications There are both astrophysical and terrestrial applications of magneto-fluid-mechanics. One of the earliest ones was perhaps suggested by Faraday, who thought to harness the river Thames with electrodes on its banks that would collect the induced electric current resulting from the flow of the river as it cuts the earth's magnetic field perpendicularly. Because of the small electrical conductivity of water, the small magnetic field of the earth and the small velocities, the interaction is too weak to be useful. However, in the laboratory, with a mutually perpendicular magnetic field, flow, and induced current density fields, a large interaction is possible when hot ionized gases are used in conjunction with strong magnetic fields. This area of research is called magneto-hydrodynamic power generation, and its popularity emerges from the fact that mechanical energy can be converted to electrical without thermally stressed rotating parts. As a consequence, higher temperatures can be imparted to the working medium with better thermal efficiencies. This scheme, under development now, seems to be limited by losses due to heat transferred from the hot gas to the outside, corrosion of the electrodes, and Hall current losses. (When the gyrofrequency of the ionized particles is high compared to their collisional frequency, the particles drift in a direction parallel to the flow, and as a result, the current to be collected by the electrodes in the direction perpendicular to the flow, diminishes. The Hall effect can be turned to some advantage if it is designed to be substantial and if the current in the direction of flow is the one to be collected.)

One of the earliest astrophysical applications of magneto-fluid-mechanics lies in the area of solar physics and in particular the sunspots. Sunspots were seen and studied for the first time with the help of a telescope by Galileo about 1610. Three hundred years later, Hale discovered, through the Zeeman effect, that the magnetic field in the sunspots is very high (of the order of several thousand gauss). It was, however, only in the middle 1930s and in particular after the last world war that an explanation was sought in which the magnetic field was involved. At the writing of this article, there is no complete sunspot theory. However, the majority of workers in this area agree on the following rough picture. Because of mechanical equilibrium considerations, the pressure is the same at a given distance from the center of the sun in the sunspot proper or in the photosphere which is free of a magnetic field. This means that the magnetic pressure plus the static pressure in the sunspot region must balance the static pressure in the photosphere, a fact that implies that the static pressure in the sunspot region is smaller. If we picture the sunspot magnetic lines to be radial, the pressure gradient in this direction is independent of the magnetic field and balances exactly the gravitational force per unit volume ρg. Hence ρ is constant inside and outside the sunspot. Since the static pressure is proportional to density and temperature, the above arguments force us to accept a lower temperature inside the spot with a resulting darkening. The only question that rises is whether the order of magnitude of the magnetic pressure is enough for the effect to be significant. This seems to be so. If we assume a magnetic field of 1500 gauss (typical in a sunspot), the magnetic pressure is about 0.1 of an atmosphere which is the typical pressure in the photosphere.

An explanation for the bipolar nature of sunspots and the difference in the sign of their polarity has been offered. The differential rotation of the sun is invoked. The torroidal magnetic lines of the sun's field lying on its surface are twisted, since for very high electrical conductivity, they are frozen with the motion. As a result, the magnetic intensity is amplified and so is the magnetic pressure. Simple considerations based on the observed kinematics of the differential rotation establish the location in latitude with time where the intensities will be high enough to give rise to sunspot activity. The result compares favorably with observations. In fact, it can be shown that the sunspot activity migrates, time-wise, from the higher latitudes towards the equator as observations show. Because the twisted field is symmetric with respect to the equatorial plane, this model describes correctly the symmetry of the activity in the north and south hemispheres along with the fact that the polarity between two symmetric sunspot pairs is opposite in sign.

Efforts have been made to discover the mechanism for the generation and maintenance of cosmic magnetic fields, such as fields in stars, the earth, and galaxies. The most promising direction seems to lie in the so called "dynamo theories." Here, some general magnetic field is assumed (not necessarily strong), which upon interaction with the motion of a conducting medium (convective, or motion due to Coriolis forces), induces currents which reinforce the original magnetic field. As the magnetic field is reinforced, the ponderomotive force suppresses the motion until some kind of a steady state for both the motion and the magnetic field is reached.

Magneto-fluid-mechanics also studies problems related to magnetic confinement of plasmas and their stability to small disturbances. Consider for instance the so-called "pinch effect." Here, a strong current is passed through a cylindrical column made up of a plasma. The axial current filaments create an azimuthal magnetic field (the magnetic lines are then rings with the cylinder axis as the locus of their centers,) and as a result, a ponderomotive force is induced which compresses the plasma radially*. Through this confinement, it is hoped that temperatures of the order of 10^6 to 10^7 K will be created so that thermonuclear FUSION can take place. Such configurations are normally subject to instabilities. Consider, for instance, the case in which a small distortion in the form of a "kink" is formed in a cylindrical plasma column, such that the rings in the concave side are pressed together, whereas the rings in the convex side are separated. As a result, the magnetic flux density (and hence the magnetic pressure) will be higher on the concave side resulting in a force tending to increase the concavity. We say that this configuration is unstable, since the force induced by the imposed disturbance acts in a destabilizing direction. Note that in this configuration, the center of curvature of the undistorted plasma boundary cross section falls inside the plasma. One can now create another example in which the curvature of the confining undistorted boundary of the plasma is opposite (the center of curvature falls in the vacuum) and show that the configuration will be stable. We can then state that a sufficient condition for stability is met when the magnetic lines are everywhere convex towards the plasma. If the magnetic lines induced by the currents going through the plasma are in an unstable configuration, externally imposed magnetic fields can be used in order to "stiffen" the configuration.

The "aurora borealis" can be explained in terms of the interaction of the solar wind (due to the continuous expansion of the solar corona with a velocity of about 500 km/sec) with the geomagnetic field. The inertia associated with this "wind" will penetrate the magnetic lines of the earth, only up to the point where the induced magnetic pressure is smaller than these inertial forces. The earth's magnetic field falls off with the inverse third power from the center of the earth. Knowing the mass density and the velocity of the solar wind, we can locate the remotest magnetic line from the earth that is strong enough to stop the penetration of the solar corpuscles. When this happens, these particles will glide along this magnetic line and eventually will come to the foot of this line at the surface of the earth. An elementary computation shows that the latitude of this line is the one where the "aurora borealis" is observed. (see AURORA AND AIRGLOW).

Convective motions can be effectively subdued by the presence of a magnetic field. Consider, for instance, the convection in a thin horizontal layer due to heating from below. Convective cells will be formed when the buoyant force is enough to counterbalance the viscous force of the motion. (These were formerly called Bénard cells because it was believed that Bénard had observed them. However, the name *convective cells* is preferred.) At the same time, balance of energy dictates that the heat convected upwards be equal to the heat conducted from the hot source at the bottom. The ratio of these two energies is called the "Rayleigh number," and for a given geometry, it must be higher than a critical value for the convective cells to appear. However, when a magnetic field is present, the ponderomotive force in general inhibits the motion and at the same time changes the geometry of the cell. The extent of this inhibition is

*Pinch-effect devices are also useful in metallurgy where molten metals can be confined away from solid boundaries in order to remain pure.

given by the Hartmann number (defined earlier) so that the critical Rayleigh number is higher for higher Hartmann numbers. Available laboratory experimental results reconfirm the findings of this theory. On a cosmic scale, it has been hypothesized that the roll-like granulation in the sunspot penumbra is the result of the magneto-fluid-mechanic inhibition of the motion inside regular photospheric convective cells.

Magnetic fields are also known to inhibit the onset of turbulence. For instance, consider the flow of mercury in a channel. Experiments have shown that the flow can be laminar well above the critical Reynolds number of 2000 or so, if a coil is wrapped around the pipe thus creating an axial magnetic field. The small disturbances perpendicular to the direction of the main stream will be damped out through the action of the induced retarding ponderomotive force.

Many other cosmic scale phenomena seem to be explainable through magneto-fluid-mechanics. To list but a few, there are the solar flares and filaments, the spiral structure of some galaxies, the heating of the solar corona, explosion of magnetic stars and many others. Although order-of-magnitude analyses have been suggested to explain some of these phenomena, there are no complete self-consistent theories. Such theories seem to demand a simultaneous satisfaction of all the conservation and electromagnetic equations—a formidable, if ever possible, task. On the terrestial scale, many applications have been undertaken, and some of them are dependent upon technological development rather than fundamental physical understanding. To give a few more examples, in addition to those already mentioned, we list magneto-fluid-mechanic liquid metal pumps and flow meters, propulsion devices based on the acceleration of a neutral plasma through which a current and a normal magnetic field from the outside are supplied (an area called "plasma propulsion"), or a device in which positive ions (such as the ones easily produced by alkali metals) are accelerated with an electric field (ionic propulsion). Other examples are devices to reduce the heat transfer in reentry objects by using the decelerating action of a magnetic field carried by the vehicle or to use the ponderomotive force as a control force when needed for the navigation of space crafts.

MAGNETOMETRY

Magnetometry is the art of determining accurately magnetic fields and the magnetic properties of matter. Both applications are of interest to pure science as well as to technology. The principles employed for measurements are based on the magnetostatic interaction between fields and moments, on voltages induced by flux changes, on the deflection of charge carriers in fields and on the precession of nuclear and electronic spins in a field.

Matter exposed to a magnetic field of strength **H** (as produced by a current-carrying solenoid) is magnetized. This phenomenon is described by the vector of magnetization $\mathbf{M} = N\langle \mathbf{m} \rangle$, where N is the number of atoms per unit volume having a mean dipole moment $\langle \mathbf{m} \rangle$. The magnetic induction (flux density) is then given by $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$. One describes the magnetic response of a material by its susceptibility χ or its permeability μ_r using $\mathbf{M} = \chi\mathbf{H}$ and $\mathbf{B} = \mu_0\mu_r\mathbf{H}$. It follows that $\mu_r = 1 + \chi$. In magnetic materials the susceptibility χ is a function of temperature. Most often it will depend also on the magnitude and direction (relative to crystalline axes) of **H**. Equations are given in SI units, which form a rational system. In all systems of units μ_r and χ are dimensionless numbers. μ_r is the same in SI and emu, but χ is smaller by $1/(4\pi)$ in emu. Note also that χ is related to the number of atomic dipoles per m^3 in SI and per cm^3 in emu.

Magnetometry is a still expanding field, mainly because of the many practical aspects of magnetism. New magnetometer designs appear constantly, but especially for absolute measurements the classical systems are still in use with only minor modifications.

Originally magnetometry developed from the interest in geomagnetism, with its importance for navigation. Nowadays exact measurements of variations in the earth's field are important for questions like the dynamics of the inner core of our planet and of the surface of the sun (via changes in the magnetosphere by sun spot activities).

The *classical method*, devised by Gauss, determines the horizontal intensity of the earth field H_- absolutely, with a relative accuracy better than 10^{-5}. Two measurements must be performed. First the torsional frequency of a small standard magnet having the magnetization M and being suspended by a torsion fiber is recorded. It is proportional to MH_-. Then a small magnetic needle is suspended by the same fiber and its deflection under the action of the standard magnet placed at a well defined position is measured. From this M/H_- can be determined. In modern systems the standard magnets are replaced by precision coils activated by exactly measured currents (*sine galvanometer*).

With the *earth inductor*, devised by Weber, one obtains the inclination of the earth field. The induced voltage in a rotating coil is sensitively measured. If the rotation axis is parallel to the field direction the induced voltage vanishes. Angles of a tenth of a minute of arc can be resolved. Portable systems are available as survey instruments, particularly for prospecting of iron ores and related uses.

Highly accurate field measurement (to 10^{-8}) are needed for the design of particle beam optical systems such as high energy accelerators or particle spectrometers. Similarly, such devices require a high temporal constancy of the field which can only be achieved by high gain feedback loops.

Rotating coil gaussmeters are modern descendants of the earth inductor. A small coil is wound on a nonmagnetic core and driven by a high speed electromotor. Such systems allow absolute measurements, but the probe averages over the volume covered by the coil. The mechanics of the electrical contacts can also give rise to problems.

A convenient, simple, rather pointlike field probe (which has to be calibrated) is the *Hall-effect gaussmeter*. A constant current is sent through a small conductor or semiconductor ($2 \times 2 \times 0.1$ mm^3). The field component perpendicular to the current flow will deflect the charge carriers via the Lorentz force and a voltage perpendicular to field and current is generated. It is proportional to the induction of the field. Most sensitive are semiconductor probes like InSb. Typically a Hall voltage of 5 mV is generated per T at 10 mA current. Such devices are now common laboratory equipment. They can be used over a fairly wide temperature range.

An even simpler and cheaper method for coarsely measuring or controlling fields in the laboratory is the measurement of the *magnetoresistance* of a semimetal wire or film or of the *forward diode bias* of commercial semiconductor diodes at liquid helium temperatures. They have moderate sensitivity and an overall nonlinear response.

A highly precise field measuring device is the *NMR magnetometer*. One determines the precession frequency of the nuclear magnetic moment of protons (or ^{7}Li) with a standard nuclear magnetic resonance circuit. The extreme sharpness of the resonance line (e.g., of protons in water) allows detection of variations in induction of 10^{-8} in 1 T. Measurements of broadening of the resonance line give information on the presence of small field gradients. An example is the field distortion caused by the presence of weak para- or diamagnetic impurities near the probe. The system may thus also be used for measurements of susceptibility. The sensor probe can be as small as 10^{-3} ml. NMR magnetometers lend themselves for telemetric readout and for incorporation into a field stabilizing circuit.

In so-called *volume averaging NMR magnetometers* the protons (e.g., of water or alcohol) are flowing through a tube in a strong B-field where their spins are longitudinally polarized. The fluid then flows through a region with unknown B', where the spins are turned. The remaining longitudinal spin polarization is monitored by standard NMR. The method can be used between 0.1 μT and 1 T with a typical relative accuracy of 10^{-7} around 1 mT.

A very sensitive device for measuring extremely weak fields is the *Zeeman magnetometer*. One of its applications is probing interplanetary fields in space. In the presence of a field the $^2S_{1/2}$ ground state of an alkali atom (e.g., Cs vapor) splits into a doublet. The population of the upper state is increased over the thermal equilibrium by optical pumping with circularly polarized light. The transition to the Zeeman ground state is forbidden. It can be stimulated by application of an rf field. This will bring the population ratio back to thermal equilibrium. The absorption of the pumping light in the vapor is dependent on the population ratio of the two Zeeman levels. By tracing the absorption maximum as a function of rf frequency one obtains the energy separation of the Zeeman levels and hence the acting field since the atomic moment of the alkali is precisely known. Sometimes a feedback circuit is used to keep the system at exact resonance. Its sharpness allows measurements down to 0.1 nT.

It should be mentioned that most information on stellar or interstellar fields comes from the observation of the Zeeman splitting of spectral lines of certain elements present in stars or interstellar matter. However, the width of spontaneously emitted optical lines is orders of magnitudes wider and thus the sensitivity is down.

Next we mention the magnetometer most widely employed in technical application, the *flux gate* (or *Förstersonde*). It consists of two soft magnetic cores in parallel orientation. They are driven to saturation by ac currents of fixed frequency applied to a primary coil wound around each core; the two windings are of opposite direction. Thus in a secondary sensing coil wound around both cores nominally no signal will be present. A superimposed, ambient dc field will produce a signal with twice the ac frequency in the sensing coil. The amplitude of this second harmonic is proportional to the dc field strength, its phase is related to the field direction. Modern systems use an additional field coil excited by the sensing coil signal in a feedback circuit. It compensates the ambient field and brings the sensing circuit back to zero.

Uses range from airborne survey of mineral deposits to minesweeping, submarine detection, treasure hunting (in archeology), and security checks. In these applications often the difference signal between two flux gates separated by a certain distance is monitored. Three devices mounted mutually perpendicular to each other are used to determine the vector components of a field. Magnetometers of this type were flown to the moon during the Apollo mission. The sensitivity of flux gates can be better than 10^{-5} A/m.

The most widespread use of magnetometry is the study of magnetic properties of matter. In pure science the quest is for the basic principles of magnetism and thus the electronic structure of matter. In the foreground of technological applications stands the design of new permanent magnets, of magnetic cores of transformers and inductances and recently mainly for magnetic storage and recording devices. These technological applications favor magnetically ordered materials. For example, new technologies appear on the horizon through the use of amorphous magnets. These types of measurements are less concerned with the magnitude and spatial distribution of fields but rather with the magnetic parameters of materials such as the susceptibility or the magnetization. A widely used instrument for such applications is the *vibrating sample* or *Foner magnetometer*. The specimen is vibrated perpendicular to a uniform magnetic field. Two signal coils wound in opposite direction and connected in series are placed around the sample with their axes parallel to the direction of motion. The dipole field of the specimen induces an ac signal in the coils. It is compared after amplification with the signal excited in a second pair of coils by a ferromagnetic reference sample (located usually near the vibrator) which is moved together with the unknown specimen. Both samples are mounted on a nonmagnetic shaft set into oscillations of ~80 Hz by a loudspeaker system. The magnetic field may either be generated by an electromagnet or superconducting coils. Careful design of pickup coils and phase-lock noise reduction allow the detection of changes in magnetization down to 10^{-6} A/m at fields of 10^6 A/m. The principle of the *vibrating coil magnetometer* is very similar. The sample stays fixed in a homogeneous magnetic field and the signal coils oscillate perpendicular to the field along the axis of the dipole moments of the sample. Demands on the homogeneity of the field are extremely high.

The other workhorse for studies of magnetic properties of matter is the *magnetic* (or *Faraday*) *balance*. Superimposed on the magnetizing uniform field is an inhomogeneous field. The dipole moments induced in a magnetic material experience a force parallel to the direction of the gradient of the external field. The sample is usually suspended on a thin fiber from one side of the arm of a microbalance mounted some distance above the field-producing magnets. In modern designs a feedback system is used which keeps the equilibrium by electromagnetic or electrostatic forces acting on the other side of the balance arm. The measurement is absolute. Sensitivity is about 10^{-6}–10^{-7} A/m in good systems. Fields are produced either by an electromagnet with inclined pole caps or by a system of superconducting coils.

Both the vibrating sample magnetometer and the magnetic balance allow the variation of sample temperature rather straightforwardly. Sample and vibrating rod (or suspending fiber) are mounted inside a small dewar system or oven. Complete systems are available commercially in highly advanced designs.

Another system which makes use of the force exerted on a magnetic material in a nonuniform field is the *pendulum magnetometer*. The sample is fixed at the upper end of a pendulum rod which is suspended in the middle. A counterweight is mounted on its lower end. For small amplitudes the force on the magnetic dipole acts as a restoring force and will thus change the frequency of oscillation. Measurements of pendulum frequency are made with and without field. The same basic principle is used in the *vibrating reed magnetometer*. The sample is attached to one end of the nonmagnetic, metallic reed (e.g., Au), while the other end is rigidly fixed. The reed is forced into oscillations by an inhomogeneous ac field superimposed on the uniform magnetizing dc field. The mechanical vibrations are converted by a piezoelectric transducer to an ac voltage which is proportional to the magnetization of the sample. Using look-in techniques one can resolve moments down to 10^{-13} A m^2.

The *classical astatic magnetometer* is still used to determine the magnetization of rod-shaped samples. Two small, identical magnets are mounted horizontally and antiparallel to each other at the ends of a long, nonmagnetic rod suspended vertically by a weak torsion fiber. This is the measuring system which is unaffected by the earth field. Two opposing coils are placed in the plane of rotation of one of the magnets. The aligned axes of the coils stand perpendicular to the axis of the magnet. Their fields cancel exactly at the position of the magnet. The rod shaped sample is inserted into one of the coils. The balance of fields is disturbed by its magnetization and the resulting torsional deflection can be read out optically. Moments down to 10^{-9} A m^2 can be determined absolutely.

Critical parameters for commercial magnets are the *coercive force* and the *remanence*. They are determined by recording the hysteresis loop (i.e., the B vs H curve for rising and decreasing field intensity) in a simple *inductance magnetometer*. The sample is inserted into a gap of the core of a toroidal solenoid. The current through the solenoid gives H. One obtains B by electronically integrating the voltage induced in a concentric pickup coil. Automatic systems of this type are common in materials testing laboratories. The sensitivity can be improved by first balancing the signals from two toroids with empty gaps. After inserting the sample into one gap the difference in outputs is measured.

For comparisons of the high field susceptibilities of ferromagnets the *orbiting sample magnetometer* is an advanced modern system. Several specimens are mounted on a disk which rotates with constant angular frequency of some 10 Hz. The uniform magnetizing field is directed along the axis of rotation. The samples pass successively by a sensing coil. Its output is stored in phase with the rotation. Digital signal averagers can be used to reduce noise.

In single-crystal samples there are directions along which the material is more easily magnetized. In general they coincide with the principal crystal symmetry directions. The free energy of a crystal thus contains a term dependent on the direction of magnetization relative to the crystallographic axes. It is called the *magnetocrystalline anisotropy* (energy) and is usually expressed in a set of parameters referred to as *anisotropy constants*. They yield basic information on the anisotropy of magnetic interaction of the atomic magnetic moments which in turn is often caused by the anisotropic electron distribution of the orbital ground state.

Magnetic anisotropy can be detected by all static methods for the measurement of magnetization if provision is made that the axis of the magnetizing field can be turned with respect to crystal orientation. Also used are ac bridges and ferro-, ferri-, or antiferromagnetic resonance. The most commonly employed system is, however, the *torque magnetometer*. The sample is suspended by a torsion wire between the poles of an electromagnet which can be moved around the sample. The magnetizing field tends to align the sample magnetization along an easy axis, and a torque is thus exerted on the sample, which is read out by optical or capacitive methods or by the variation in resistance of a set of strain gauge wires. A set of data is taken by varying the original orientation of the specimen relative to the external field.

In the *ripple field magnetometer* the magnetization of the sample is modulated by an ac (~100 Hz) "ripple" field superimposed parallel to the dc magnetizing field. A sensing coil oriented at 90 degrees to the field measures the perpendicular magnetization, which is proportional to the angular derivative of the anisotropy energy density with respect to a reference crystalline axis.

On a similar principle operate *rotating sample magnetometers*. The specimen (often a sphere) rotates slowly (0.02-0.1 Hz) within a dc field applied perpendicular to its axis of rotation. The variation in flux with rotation is sensed by search coils oriented parallel and perpendicular to the dc field. The anisotropy constants are derived from the two measured flux components.

Information similar to the magnetic anisotropy can be obtained by measuring the magnetostrictive changes in dimensions of single-crystal samples as a function of magnitude and direction of the applied field. X-ray techniques are usually too insensitive for this purpose, and strain gauges have found the widest use. Capacitive read out has also been reported.

A predecessor of this system is the *spinner magnetometer*. It rapidly rotates a ferromagnetic sample without external field. It is available as a survey instrument for anisotropy studies of rock samples.

Finally we discuss briefly a very modern system used for special magnetic measurements, the *superconducting quantum interference device* (SQUID) which is rapidly gaining importance. Basically a fluxmeter, it does not, however, measure the flux itself but rather, with extreme accuracy, minute variations in flux. In fact, sensitivity has reached about 10^{-5} of a single flux quantum ($\phi_0 = h/2e = 2.07 \times 10^{-15}$ Wb).

Applications of the SQUID in physics range from ac measurements of very small magnetic moments (e.g., magnetization in extremely weak fields) to a search for the elusive magnetic monopole. Measurements of volume susceptibilities down to 10^{-10} for 1 μg samples have been reported. The SQUID has also become the central tool for magnetomedical and -biological research. Examples are magnetocardiography and the study of fields generated by the action of the human brain.

The SQUID is based on two macroscopic quantum effects in superconductors. The first is *flux quantization:* The flux trapped inside a superconducting loop must be an integral multiple of ϕ_0. The second is the *dc Josephson effect:* A superconducting ring is interrupted at one point by a weak link. Examples are a thin ($\lesssim 1$ mm) oxide layer or a point contact. The thickness of the insulating layer is such that electrons can tunnel through it. In a superconductor a current of Cooper pairs is flowing which requires no voltage across the barrier. Only when a critical current (which can be kept as low as some 10^{-5} A) is exceeded, a voltage proportional to the tunnel current appears at this so-called Josephson junction. The critical current drops rapidly when a field is applied perpendicular to the flow of Cooper pairs. After this field has increased so much that an additional flux quantum can be brought into the ring, the critical current jumps back to a higher value. These periodic discontinuities occur because the ring momentarily ceases to be superconducting, so that one quantum of flux can enter. In a wire loop, placed inside the ring, a voltage pulse is induced each time a flux jump occurs. By counting these pulses the total change of field through the ring can be calculated. For ~1 mm diameter a change in flux density of ~1 nT causes a jump.

A practical SQUID arrangement is the two-hole system: Inside an Nb cylinder a bore shaped like a dumbbell is drilled. The weak link is an Nb screw placed across the bar of the dumbbell. If the flux in one hole increases, an equal decrease of flux in the other hole must follow. The current through the Josephson junction depends on the flux difference between the holes. One uses an external search coil placed in the field the variations of which are to be measured. It is connected in series to a wire loop inside the first hole. This whole circuit works as a flux transformer. The second hole is inductively coupled to an *LC* circuit tuned at some 10 MHz. The appearance of a voltage drop across the junction due to flux brought into the first hole can be regarded as a change in inductance of the superconducting ring which mistunes the oscillator. The voltage across the circuit as a function of field acting on the search coil is saw tooth like with a period corresponding to trapping one flux quantum inside the two-hole ring. The sensing coil can be placed at a convenient distance from the SQUID. By giving it the appropriate shape one may also detect variations in the spatial derivatives of fields with extreme sensitivity. Furthermore, the SQUID has a fast response. Rates of $10^7\ \phi_0/s$ have been recorded.

MAGNETOSPHERIC RADIATION BELTS

The sun emits continuously a fully ionized gas, the *solar wind*, which flows radially outward throughout the solar system. The solar wind plasma is primarily made up of protons and electrons, and its properties although variable, have average values at earth orbit of bulk velocity $V \approx 350$ km/sec, number density $N \approx 5\ \text{cm}^{-3}$, and temperature $T \approx 15$ eV. Because of its high conductivity, the solar wind carries with it an embedded magnetic field, which on average is parallel to the ecliptic plane and traces an Archimedean spiral back to the sun in this plane due to solar rotation. At the orbit of earth the interplanetary magnetic field is highly variable in direction and magnitude, having an average value of ~5 nT (10^{-5} gauss).

The interaction of the supersonic solar wind with the intrinsic dipole magnetic field of the earth forms a region, the *magnetosphere* (Fig. 1), whose boundary, the *magnetopause*, separates interplanetary and geophysical plasma and magnetic field environments.[1] Upstream of the magnetopause is a *bow shock* formed in the solar wind–magnetosphere interaction process. At the bow shock the solar wind becomes thermalized and subsonic and continues its flow around the magnetosphere as *magnetosheath plasma*, ultimately rejoining the undisturbed solar wind. The bow shock is of interest because of its collisionless character, and much work is presently being done to understand the nature and the development of the electric and magnetic field configurations required to establish a shock front in a collisionless medium.[2]

A rough estimate of the position of the dayside magnetopause is obtained by balancing the solar wind pressure against the geomagnetic field with the resistive pressure of the geomagnetic field itself:

$$\tfrac{1}{2}\rho V^2 = B^2/8\pi,$$

where ρ = solar wind mass density, V = solar wind velocity, and $B = 0.34/R^3$ gauss is the earth's field at the magnetic equator, with R = geocentric distance in units of earth radii. Use of the average solar wind values given above

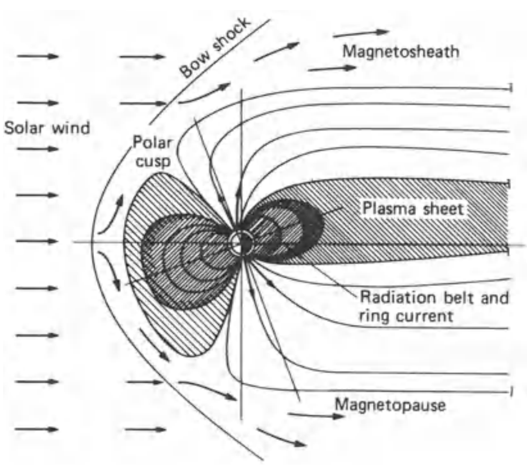

FIG. 1. An outline of the earth's magnetosphere. The lines represent magnetic field lines.

gives a dayside magnetopause distance of ~10.2 earth radii, as compared to an average observed distance of ~10.8 earth radii. More exact fluid and kinetic theory models give good agreement with the observed average latitudinal and longitudinal shape of the dayside magnetosphere.

In the antisolar direction, observations show that the earth's magnetic field is stretched out in an elongated *geomagnetic tail* (analogous to a cometary tail) to distances of several hundred earth radii. The geomagnetic tail field lines emanate from high geomagnetic latitudes from the vicinity of the auroral ovals to the geomagnetic pole. Topologically the geomagnetic tail consists of roughly oppositely directed field lines separated by a "neutral" sheet of nearly zero magnetic field. Surrounding the neutral sheet is a plasma of "hot" particles, the plasma sheet, having a temperature of 1-10 keV, a density of 0.01-1 particle/cm^3 and bulk flow velocity of a few tens to a few hundreds of km/sec. A definitive physical explanation of the extended geomagnetic tail has yet to be obtained.

Figure 1 is a schematic of the overall magnetospheric configuration. There are seasonal variations due to the ~12° tilt of the earth's magnetic dipole axis relative to its spin axis. More important, variations in solar wind parameters cause large perturbations to the picture shown in Fig. 1. These perturbations are observed to have scale variations much larger than the $V^{-1/3}$ and $\rho^{-1/6}$ dependences predicted by the simple pressure balance discussed earlier. Therefore, physical mechanisms other than simple pressure balance are required to explain observed magnetospheric variations. For example, geomagnetic field lines are known to interconnect with interplanetary magnetic field lines (magnetic field component normal to the magnetopause), causing a two-way transfer of particles and energy between the interplanetary medium and the solar wind. Neutral points (lines) are formed on the magnetopause and, by magnetic flux conservation, in the geomagnetic tail in the neutral sheet region. It is not known if sites of field line interconnection are responsible for large scale particle acceleration, but they are probably effective in altering the shape and size of the magnetosphere.

Electrostatic, induced, and polarization electric fields play a fundamental role in determining charged particle entry to and subsequent motion and acceleration within the magnetosphere. Much present work in magnetospheric physics is aimed at identifying these fields and deconvolving the subsequent currents responsible for sustaining the magnetospheric configuration and causing its variations.

The in situ phase of magnetospheric research began dramatically with the discovery by Van Allen and his colleagues[3] of a permanent, intense, trapped energetic particle population (the Van Allen radiation belts) residing in the geomagnetic field—a discovery made with data from the first United States satellite, Explorer I. Following this initial discovery, data obtained from the trapping regions showed the geomagnetic field to be at least at altitudes $\lesssim$ several earth radii, a very efficient and vast magnetic mirror machine.[4]

The most useful approach for describing the motion of charged particles in the earth's magnetic field has been the guiding center approximation and subsequent development of adiabatic invariant concepts.[5,6] In the guiding center approximation, the instantaneous position **r** of a particle moving in a magnetic field is broken down into its circular motion of radius **ρ**, and the motion of the guiding center **R**:

$$\mathbf{r} = \mathbf{R} + \boldsymbol{\rho}.$$

A general expression for the motion of the guiding center can be obtained by substituting the above into the equation of motion

$$m\,\frac{d^2\mathbf{r}}{dt^2} = m\mathbf{g} + \frac{e}{c}\,\frac{d\mathbf{r}}{dt} \times \mathbf{B} + \mathbf{E}e$$

where m = particle mass, e = electronic charge, c = velocity of light, $\mathbf{g}$ = acceleration of gravity, $\mathbf{B}$ = magnetic field, and $\mathbf{E}$ = electric field. This yields the nonrelativistic guiding center equation

$$\frac{d^2\mathbf{R}}{dt^2} = \mathbf{g} + \frac{e}{m}\left\{\mathbf{E} + \frac{1}{c}\,\frac{d\mathbf{R}}{dt} \times \mathbf{B}\right\} - \frac{\mu}{m}\,\nabla\mathbf{B} + O\left(\frac{\rho}{\alpha}\right)$$

where μ = particle's magnetic moment due to gyration, ρ = cyclotron radius, α = scale length over which the magnetic field changes appreciably, and $O(\rho/\alpha)$ = terms of order ρ/α. In this approximation the particle's motion in the earth's field is broken down into three components: gyration about a field line, bounce back and forth along the field line between mirror points, and a slow longitudinal drift around the earth. While these motions are not strictly separate from one another, the vast difference in the time scales associated with them makes such a separation possible and leads directly to the consideration of adiabatic invariants. These motions are illustrated in Fig. 2.

The adiabatic invariants may be considered constants of the particle's motion provided that magnetic field variations are small compared with the time and spatial scales associated with the particle's motion. The first of the adiabatic invariants is the magnetic moment generated by the particle as it gyrates around the field line,

$$\mu = mv_\perp^2/2B = mv^2 \sin^2 \alpha/2B = W_\perp/B$$

where α = angle between the field line and the velocity vector.

This leads directly to the mirror equation and definition of the particle's mirror point:

$$\mu = \frac{W \sin^2 \alpha}{B} = \text{constant.}$$

In a static field, W (the particle energy) is constant and

$$\sin^2 \alpha_1/B_1 = \sin^2 \alpha_2/B_2 = \text{constant.}$$

Using the earth's equatorial magnetic field as a reference, the mirror point B value on a given line of force is determined by the particle's pitch angle at the equator:

$$B_M = B_{eq}/\sin^2 \alpha_{eq}.$$

In a dipolelike field configuration, such as the earth's, having a minimum B value at the equator, particles will simply bounce back and forth between conjugate mirror points located in the northern and southern hemispheres (cf., Fig. 2).

FIG. 2. Illustration of the motion of a charged particle trapped in the earth's magnetic field.

The second adiabatic invariant, obtained from the action integral and associated with the particle's bounce back and forth along a field line, is given by

$$J = 2 \int_M^{M^*} P_\parallel \, ds$$

where $P_\parallel = mv_\parallel$ is the particle momentum along the field line and the integral is taken along the field line between the two conjugate mirror points M and M^*.

Forces due to the gradient of the earth's magnetic field and field line curvature cause a longitudinal drift across field lines with electrons drifting eastward and protons drifting westward. In an ideal dipole field this effect produces a drift surface which is simply the figure of azimuthal revolution of a line of force. Associated with this drift motion is the third adiabatic invariant, the flux invariant

$$\Phi_M = B \, dS.$$

Φ_M, the magnetic flux linked in the drift orbit of the particle, is the weakest of the three invariants (μ, J, Φ_M) since it has associated with it the largest spatial and temporal scales. Therefore the conditions for adiabatic invariance are most easily violated for Φ_M.

In Table 1 we show for reference characteristic times associated with charged particle motion in the magnetosphere.

Radiation belt particles represent significant energy storage in the magnetosphere (2×10^{22}–2×10^{23} ergs). Their gradient and curvature drifts establish a current encircling the earth, the ring current, which is responsible for worldwide depressions of the earth's surface magnetic field. During times of enhanced radiation belt intensities, particle energy densities significantly greater than the ambient magnetic field energy density are observed and can cause surface field variations up to several hundred nT. The bulk energy density of the ring current particles is contained within the energy range ~1–200 keV with a mean energy of ~85 keV. This high β plasma ($\frac{1}{2}\rho v^2 > B^2/8\pi$) decays primarily through charge exchange and ion-cyclotron wave generation.

Protons, helium, and oxygen together form the ring current but their relative contributions are unknown. Thus the ultimate source of radiation belt particles, the solar wind or the ionosphere, is still uncertain. It is expected that strong energy and spatial dependencies will be evident in the source mixture for the bulk of the radiation belt particles. The very high energy ($\gtrsim$ several tens of MeV) protons observed at low altitudes ($\lesssim$ 1.8 earth radii)

TABLE 1. CHARACTERISTIC TIMES ASSOCIATED WITH PARTICLES TRAPPED IN THE EARTH'S MAGNETIC FIELD.

Particle	Energy (keV)	Gyroperiod ($\propto R^3$) (sec)	Bounce Period ($\propto R$) (sec)	Drift Period ($\propto 1/R$) (hr)
Electron	10	9.4×10^{-6}	0.64	36.7
	100	13×10^{-6}	0.23	4.1
	1000	80×10^{-6}	0.13	0.54
Proton	10	17×10^{-3}	27	36.7
	100	17×10^{-3}	8.6	3.4
	1000	17×10^{-3}	2.7	0.35

Values correspond to $\alpha_e = \pi/2$ and $R = 2R_e$.

are supplied by neutrons, generated in the atmosphere by cosmic rays, which leave the earth's atmosphere and decay in the geomagnetic field.

Radiation belt particles are accelerated to their final energies via **E** × **B** convection across field lines and betatron and Fermi acceleration processes due to slow diffusion across magnetic field lines under conservation of the first two adiabatic invariants. The relative importance of these mechanisms has not yet been established. Radiation belt particles having a solar wind source obtain an initial heating in the geomagnetic tail where gradient and curvature drive across electric field equipotentials can increase particle energies by amounts up to several tens of keV. If the particles are from the ionosphere they are accelerated to energies of ~1–10 keV by electric fields parallel to magnetic field lines emanating from the auroral zones. In either case a radiation belt source, most likely the plasma sheet, can be formed at

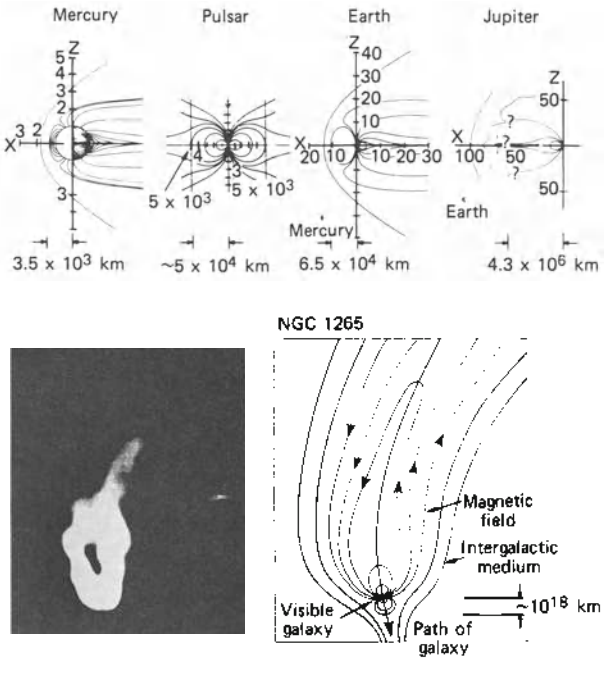

FIG. 3. Magnetospherelike systems are probably common throughout the universe, with a large range in scale sizes. For example, the subsolar magnetopause distance for Mercury is 3.5×10^3 km; for the radio galaxy NGC 1265, the analogous distance is roughly 10^{18} km.

altitudes $\gtrsim 6.5$ earth radii which then can be accelerated as discussed above to form the trapped particle population.

The second large energy storage region in the magnetosphere is the extended geomagnetic tail (3×10^{22}-3×10^{23} ergs). The plasma sheet particles and the stretched geomagnetic field lines contribute roughly equal parts to this energy storage. The relationship between the plasma sheet, the aurora, and the radiation belts is an intimate one but not yet fully understood. As discussed above, the earthward portion of the plasma sheet is a likely source for the radiation belts, but the relative contributions of the solar wind and ionosphere are unknown. It is also likely that diffuse auroral forms are due to plasma sheet electrons scattered into the loss cone by electrostatic waves. On the other hand, discrete auroral forms are most probably caused by electric fields parallel to auroral magnetic field lines. It is not known whether these fields are due to very narrow electrostatic field geometries called *double layers* or the observed shear flows in the high altitude plasma ($\nabla \cdot \mathbf{E} < 0$) coupled with ionospheric current continuity restrictions. There appears to be no requirement for anomolous resistivity mechanisms in auroral processes.

Associated with the parallel electric fields responsible for discrete auroral forms is an intense electromagnetic radiation in the 100-1000 kilohertz band, *auroral kilometric radiation*. The intensity of this radiation, normalized to a planetary radius distance scale, is comparable to Jupiter's emissions. In fact, integration over respective radiating solid angles may make the earth a radio source of the same order as Jupiter in total power output.

If we consider the earth's magnetosphere in a general sense as a rotating magnetized plasma, we find that such objects are plentiful throughout our solar system and perhaps the universe. This is not surprising, since most of the universe is filled with plasma and the basic interactions between plasmas, electric fields, and magnetic fields being uncovered in the earth's magnetosphere are present in the development of cosmic regions from small interstellar clouds to entire galaxies.

Interplanetary spacecraft have identified magnetospheres around Mercury, Saturn, and Jupiter.[7] Astronomers have detected similar structures around rotating neutron stars (pulsars) and radio wave-emitting galaxies. Figure 3 illustrates the scale sizes observed for these various magnetospherelike systems.

In all these cases it is evident that nature has been able to accelerate charged particles to very high energies. In the earth's magnetosphere there are at least four established methods of accelerating particles. The most general of these is magnetic field gradient and curvature drift across electric field equipotential surfaces. More specific mechanisms are betatron acceleration, Fermi acceleration, and acceleration by electric fields parallel to magnetic field lines. It remains to be shown that field line interconnection can directly transfer energy from the magnetic field to charged particles (field line merging, reconnection) or if plasma turbulence effects are inportant as acceleration processes.

Magnetospheric systems, while similar, often have their own unique characteristics. For example, Jupiter and Saturn have moons in the heart of the charged particle populations which are effective absorbers creating distinctive features in their radiation belts. At Jupiter, the volcanic moon Io is a copius source of sulfur and oxygen, both of which have been detected at all energies throughout the Jovian magnetosphere. Jupiter's high spin rate (period = 9 hours 55 minutes 29.7 seconds) can produce effects to accelerate particles in addition to those found in the earth's magnetosphere. For example, low energy plasma corotating with Jupiter's magnetic field will exceed the Alfven speed and become supersonic well within the Jovian magnetosphere (30-40 Jovian radii). Even tiny Mercury, with neither atmosphere nor ionosphere, possesses a magnetosphere capable of accelerating large numbers of particles to high energies.

Work remains to be done to understand how the laws of physics operate in interacting magnetized plasma systems which display the range of boundary conditions seen throughout the solar system and in the universe.

MAGNETOSTRICTION

When a polycrystalline nickel sample is placed in a magnetic field, it contracts along the field direction by about 30 parts per million and elongates in the transverse direction by about half that amount. There is also a small volume change. Such changes in dimension of magnetic materials with variation of magnetic field strength or direction, are termed *magnetostriction*. They are measured by strain gages, optical dilatometers, capacitance variation, and x-ray analysis.

Below the Curie temperature, magnetostriction in weak fields is caused by domain rotation, becoming appreciable at fields near the knee of the *B-H* curve.

In saturating fields there is still a small linear dependence of magnetostriction on magnetic field strength, and above the magnetic ordering temperature magnetostriction is, except in rare instances, quadratic in magnetic field strength. Field strength dependent distortions in the saturated and paramagnetic regions, designated *forced magnetostriction*, are due to the paraprocess, the induction of a moment by the field.

The saturation magnetostriction of single crystals depends upon the direction of the (sublattice) magnetization, α, and the direction of measurement, β, with respect to the crystal axes. In a cubic crystal (with collinear sublattices), to lowest order,

$$\frac{\delta l}{l} = \lambda_0 + \tfrac{3}{2}\lambda_{100}\,[\alpha_1{}^2\beta_1{}^2 + \alpha_2{}^2\beta_2{}^2 + \alpha_3{}^2\beta_3{}^2 - \tfrac{1}{3}] + 3\lambda_{111}\,[\alpha_1\alpha_2\beta_1\beta_2 + \alpha_2\alpha_3\beta_2\beta_3 + \alpha_3\alpha_1\beta_3\beta_1] \quad (1)$$

Clark[1] gives higher order expressions for cubic and hexagonal symmetry.

For cubic crystals the fractional change in length along the field (and the magnetization) direction induced by a saturating magnetic field is, in principle, found by averaging Eq. (1) over directions. This gives the saturation magnetostriction

$$\lambda_s = \frac{2\lambda_{100} + 3\lambda_{111}}{5}. \quad (2)$$

The assumption underlying the averaging that yields Eq. (2) is that before the field is applied the material is unmagnetized and all polycrystal orientations are equally likely. This is in fact rarely the case; there is often both some remanent magnetization and some preferential orientation of crystallites. Measurements of $\lambda_\parallel - \lambda_\perp$, the difference in distortions parallel and perpendicular to the field direction, are more reproducible and significant, in that they are independent of the distortion in a fiducial "unmagnetized" state.

Magnetostriction coefficients vary greatly, depending upon the material, temperature, and magnetization state. For pure iron at room temperature, the saturation magnetostriction constants are $\lambda_{100} \sim 20 \times 10^{-6}$; $\lambda_{111} \sim -20 \times 10^{-6}$, while for alloys near 80Ni-20Fe (weight per cent) these constants are almost zero. The cobalt ion causes a large magnetostriction; for cobalt ferrite $\lambda_{100} \sim -500 \times 10^{-6}$ while for nickel ferrite $\lambda_{100} \sim -30 \times 10^{-6}$. The largest known magnetostriction is that of dysprosium metal.[2] As a magnetic field is rotated in the basal plane of this hexagonal crystal, there is a basal plane distortion of almost one per cent, at liquid nitrogen temperatures and below. At room temperature, $TbFe_2$ shows a magnetostriction 5 times larger than does any other material[3]; ($\lambda \sim 2 \times 10^{-3}$).

The source of magnetostriction is the dependence of magnetic energy on strain. Because the elastic energy is quadratic in strain while the magnetoelastic energy is linear in strain, the minimum free energy occurs at nonzero strain. For example, in a cubic crystal the equilibrium shear strain ϵ_{xy} is given by

$$\epsilon_{xy} = \frac{B_2(T,H)}{c_{44}}\,\alpha_x\alpha_y \quad (3)$$

Here c_{44} is the elastic constant, the α's are magnetization direction cosines, and $B_2(T,H)$ is a magnetoelastic coefficient representing the variation of magnetic energy (magnetic anisotropy, dipolar, anisotropic exchange) with strain.

Quantum mechanical calculations of the magnetoelastic coefficients are in a somewhat more satisfactory state in the case of nonconductors than for metals. Extensive calculations by Tsuya of the *B* coefficients of the spinels are reviewed by Kanamori.[4]

The temperature dependence (and "forced" field dependence) of the magnetostriction coefficients is due to statistical averaging as the individual spins fluctuate around the average magnetization direction α. For some materials this temperature dependence can be expressed entirely in terms of a known function of the (sublattice) magnetization. For ferrimagnets[5]

$$\lambda_i(T, H) = \sum_n \lambda_i^n(0) f_i[m_n(T, H)] \qquad (4)$$

That is, the magnetostriction coefficient $\lambda_i(T, H)$ is the sum over sublattices of temperature independent sublattice magnetostriction coefficients $[\lambda_{1\,1\,1}^{\,n}\ (0) = B_2^{\,n}(0)/c_{44}]$ times a function f_i of the sublattice magnetization $M_n(T, H)/M_n(0)$. At sufficiently low temperatures this function reduces to

$$f[m_n(T, H)] = \left[\frac{M_n(T, H)}{M_n(0)}\right]^3; \; T \ll T_c \qquad (5)$$

for both λ_{100} and λ_{111}.

MANY-BODY PROBLEM

Scope and Definition A large part of the experimental data of physics is concerned with natural objects which may be looked upon as being made up from smaller bodies. For example, we may think of the solar system as an object composed of the planets and the sun; ordinary matter, in solid, liquid or gaseous form, as composed of molecules and atoms; atoms and molecules themselves as made up from nuclei and electrons, the nuclei as composed from neutrons and protons, and so on. We shall call the composite object the system, and its constituents, the particles; and note that it seems most reasonable to suppose that the properties of the system can be explained on the basis of the law of interaction between the particles and the laws of dynamics. The latter may be classical or quantum mechanical according to the demands of the situation. At each level of refinement we refrain from asking about the internal structure of the particles. This is to achieve a natural simplicity of description; but still, at each such level, we have a rich variety of natural phenomena to explain.

The many-body theory is not concerned with any fundamental or complete explanation of nature. Its chief aim is to formulate schemes according to which calculations of certain physical quantities can be performed theoretically and the results can be compared with experimental measurements. It is inherent in its methods that the number of particles is considered as being large, and no attempt is made to find all the details of motions of the particles —a characteristic which distinguishes it from the so-called one-, two- or three-body problems.

The main approaches to the theory of quantum-mechanical many-body systems, such as nuclei, solids, and fluids, were worked out in a period of approximately ten years starting in the early 1950s. This led to a great deal of activity and attracted much attention. As a result, the term many-body problem has come to mean, almost exclusively, the theory of such systems at or near the absolute zero of temperature. The latter qualification serves to distinquish the many-body problem as such from the closely related field of STATISTICAL MECHANICS. (By convention many-body scattering theory is a separate subject). The new developments were based on the observation that when the number of particles is so large that it may be considered effectively infinite, then the system becomes very similar to that of interacting fields—except for the nature of interactions considered—and the general formal methods of quantum field theory and quantum electrodynamics may be used with advantage.

There is only one general theorem in many-body theory; it is known as Poincare's theorem. Roughly speaking, it states that any given initial state of a finite many-body system will be repeated provided one waits long enough. The quantum mechanical form of this theorem states that all observables in a finite system are almost periodic functions of time. This theorem has not had much practical use but has played an important role in discussions concerning the foundations of statistical mechanics.

The so-called many-body theory is mainly a collection of special approximate methods developed for particular problems. The chief common features of some of the methods, especially the ones connected with modern developments, will now be described.

Reduction to an Equivalent System of Non-interacting Particles The very fact that we can recognize some constituent particles leads us to believe that in the lowest approximation we may neglect their interactions. This approximation is already quite successful in derivation of perfect gas laws and electron theory of metals. A slightly different form of this assumption occurs in the case of atoms, which are treated as systems of non-interacting electrons moving in the field of force of the nucleus. For planetary systems a similar approximation is used.

The normal mode analysis of a lattice provides an example where a transformation of coordinates is used to achieve such a reduction. Instead of considering the coordinates of individual particles which interact with each other through harmonic forces, one considers certain linear combinations of displacements, the modes. In terms of the new variables there are no interactions and the solution is immediately obtained. This is an example of a *transformation* which introduces a *collective* description of the system.

Another type of situation occurs in nuclear theory, where it is found that a shell-model of the nucleus, built in analogy with the atomic shell-model, is very successful. The non-interacting particles of this model are called neutrons and protons, but interaction between them which must be used in this model is vastly different from that observed in two-body scattering experiments. As a first approximation one can completely ignore the mutual interaction and assume that the particles move in a common one-body potential. This circumstance suggests that what are called neutrons and protons in this model are not the same as the free ones but are only some *quasi-particles* which are appropriate to the model and happen to have many properties in common with actual particles. An analogous situation occurs in some solids where electrons as observed by means of cyclotron resonance experiments possess an effective mass different from the mass of free electrons. In fact, one may even say that many-body theories always deal with quasi-particles. That is true of most existing theories, but from such a point of view one loses sight of one of the basic motivations of many-body theory.

Effective Field Method This is one of the methods of taking into account the mutual interactions of the particles. One starts with a given motion of particles, e.g., from an approximation of the type described in the last paragraph, and calculates the field of force experienced by one of the particles under the influence of all the others. As a further refinement the field may be made *self-consistent*, that being the situation when the motion produced under the influence of the field is the same as that which generated it. But for the approximations made in the course of calculation, such as omission of the effects of correlations among the particles, a fully self-consistent theory would be a complete theory.

Examples are: Hartree-Fock theory, Fermi-Thomas approximations, Brueckner theory of nuclei, Wigner-Seitz cell model in solid state theory, and several others.

Density Functional Method This method is based upon a theorem of Hohenberg and Kohn, which states that if the ground state of a many-particle system is degenerate then the corresponding wave-function is a unique functional of the particle density. The theorem implies the existence of a universal functional of the external potential and particle density which is a minimum for the true particle density. Others have generalized the theorem to nonzero temperatures, nonlocal external potentials, relativistic systems, and spin-dependent systems. In the latter case a space and spin-dependent density is used. The universal functional of the theory is inferred from the basic many-body quantum mechanical description of the system. Given the functional, the ground-state energy and particle density are obtained from a variational principle involving the particle density alone. Appropriate approximations reproduce Thomas-Fermi theory and its known generalizations, but the density functional approach can go much further. Extensive applications to atomic, molecular and solid state problems have been made. (Unfortunately no comprehensive review of these works exists; we give references to the first basic papers.)

Collective Motion Theory In some phenomena, such as propagation of sound and plasma oscillations, it is clear that many particles are performing coordinated movements. To study such cases, one introduces some collective variables in addition to the usual ones, and the Hamiltonian is re-expressed in terms of these mixed variables. *Subsidiary conditions* have to be imposed upon this extended system of variables to preserve the original number of degrees of freedom. The collective variables should be such that there is no appreciable interaction between these and other degrees of freedom. When quantum mechanics is applicable, the collective motions are also excited in quanta which for all practical purposes may be treated as new (quasi) particles. The stability of collective motions is then expressed in terms of the lifetime of quasiparticles. Solid-state physics is particularly rich in exhibiting collective motions. Quasiparticles associated with some of them are: the phonons (sound, lattice vibration); the polarons (electron and its polarization field in dielectric); and the excitons (electron-hole excitations in insulators). Collective motions in nuclei can also be interpreted in a similar manner. Superconductivity and superfluidity are also examples of collective motion. The quasiparticles responsible for superconductivity are electron pairs with equal and opposite momenta and spin.

Use of Techniques of Field Theory With these techniques it is possible to obtain formal expressions which represent the effect of interparticle interactions to any order in perturbation theory.

By carrying out rearrangements and partial summations of terms in perturbation series it is possible to see that, as far as the motion inside the system is concerned, the relationship between the coordinates and momenta and the potential and kinetic energies is changed in such a way that it has to be described in terms of an effective mass and an effective interaction, which differ from the original quantities in a known way. In certain cases these effects can be calculated and are finite.

Brueckner's theory of nuclear matter is an example of this type. The effective mass is found to depend on the momentum of the particle inside the system, and the effective interaction, the so-called t- or K-matrix, is given by an integral equation involving the original interaction. A self-consistent calculation of the properties of the system (nuclei or atoms) can be based on this understanding.

Similar techniques can be used for studying collective motions. An example is the treatment of electron gas by Gell-Mann and Brueckner.

Perhaps the greatest advance has been made in the theory of superconductivity, where variational and canonical transformation methods have been used.

A combination of all these methods is needed to study the difficult problem of relationship between various excitations, i.e., the interaction between various quasiparticles of a many-body system. One of the most useful tools in these calculations is the representation of matrix elements by means of diagrams, first introduced by Feynman. Many of these methods were first developed in connection with the theory of interacting fields and they are usually employed in many-body problems for the limiting case of an infinite number of particles, but these restrictions are not essential; in fact, they are quite general methods for treating arbitrary quantum mechanical systems.

MASER

The term "maser," coined by Townes and coworkers who pioneered this field, stands for m(icrowave) a(mplification by) s(timulated) e(mission of) r(adiation). "Microwave" has proved restrictive; stimulated emission amplifiers have operated in the UHF (~300 MHz), and at infrared, visible, and ultraviolet frequencies (see LASER). The principal advantage of the maser amplifier is its small intrinsic internal noise: the equivalent *noise input temperature* is but a few degrees Kelvin. The theoretical minimum noise input temperature is hf_s/k, where h is Planck's constant, k is Boltzmann's constant, and f_s is the signal frequency. This is 0.48 K at $f_s = 10$ Ghz (Giga Hertz) or 10×10^9 Hz. Maser oscillators can generate exceedingly monochromatic radiation, e.g., the ammonia maser has a short-term frequency stability of ~5 parts in 10^{12}, and the atomic hydrogen maser has a short-term stability of better than 1 part in 10^{13}.

Because "quasi-optical" techniques are being employed increasingly in the millimeter and submillimeter regions, the distinction between LASER and maser in these regions is becoming eroded. Historically, maser oscillators used resonant systems of dimensions comparable to a cubic wavelength, (λ^3); laser oscillators used resonators with dimensions exceeding λ^3 by many orders of magnitude.

Stimulated Emission of Radiation Because its energy is quantized, a molecule (here a generic term) can exchange energy with the electromagnetic radiation field only in discrete amounts (quanta). The emission or absorption of a quantum (photon) is associated with a transition between molecular energy states. For two states, $|m\rangle, |n\rangle$ of energies W_m, W_n, ($W_m > W_n$), the frequency f_{mn} of the radiation accompanying the (permitted) transition between them satisfies the Bohr condition

$$hf_{mn} = W_m - W_n. \qquad (1)$$

A molecule in state $|n>$, exposed to radiation of frequency f_{mn} and energy density u, has a probability per unit time $u \times B_{nm}$ (B_{nm} is a constant) of absorbing a photon hf_{mn} and reaching state $|m>$. There is also a probability $u \times B_{mn}$ that a molecule in the upper state $|m>$ will *emit* a photon hf_{mn} and return to the lower state $|n>$. The upper state molecule is *stimulated* to emit radiation of frequency f_{mn} by the radiation field at this frequency. Stimulated emission, like absorption, is a process which is *phase coherent* with the incident radiation. Thermodynamical arguments by Einstein (1917) showed that

$$B_{nm} = B_{mn}. \qquad (2)$$

A molecule in the upper energy state $|m>$ may also revert to the lower state $|n>$ by *spontaneously* emitting radiation of frequency f_{mn}. This spontaneous emission is a random process, which is phase incoherent with any incident radiation, and is therefore a source of noise in a maser.

The spontaneous emission probability A_{mn} is given by

$$A_{mn} = B_{mn} \times hf_{mn} \times \rho_f \qquad (3)$$

where ρ_f is the number of wave modes per unit volume per unit frequency range open to radiation of frequency f_{mn}. Table 1 shows values of ρ_f under various conditions; c is the velocity of light, v_g is the group velocity of radiation.

In the microwave region (say, 1 to 100 GHz), $A_{mn} \ll B_{mn}$; spontaneous emission is therefore negligible except as a source of noise. However, maser spontaneous emission noise is usually exceeded by noise arising from losses in ancillary microwave circuit elements.

Molecular transitions are excited by either the electric or magnetic component of the radiation field, depending upon whether the change in molecular energy is primarily electric or magnetic in character. Each radiative transition has associated with it an effective oscillating electric or magnetic moment, usually dipolar. The probability B_{mn} given above depends directly on this dipole moment and inversely on the frequency spread (line width) δ of the transition.

TABLE 1

Environment	ρ_f

Single mode resonant cavity, volume V, width of half-power response Δf	$2/(\Delta f \cdot \pi V)$
Waveguide, cross section A	$1/Av_g$

Conditions for Amplification Suppose radiation of frequency f_{mn} is incident on an assembly of molecules with an allowed transition at this frequency [Eq. (1)]. Let the number of molecules in the upper state $|m>$ be N_m, and in the lower state $|n>$ be N_n. If the incident radiation energy density is u, the power absorbed by the molecules will be

$$P_A = N_n u B_{mn} hf_{mn} \qquad (4)$$

and the power emitted will be (see equation 2)

$$P_E = N_m u B_{mn} hf_{mn}. \qquad (5)$$

Since at microwave frequencies spontaneous emission is negligible, the condition for amplification is

$$P_E > P_A; \text{i.e.}, N_m > N_n. \qquad (6)$$

There must be an excess of molecules in the *upper* energy state of the transition associated with the signal frequency.

For thermal equilibrium at temperature T, Boltzmann statistics give

$$(N_m/N_n) = \exp{(-(W_m - W_n)/kT]}$$
$$= \exp{(-hf_{mn}/kT)} \simeq 1 - (hf_{mn}/kT) \quad (7)$$

at microwave frequencies, where $hf \ll kT$. Clearly a molecular system in thermal equilibrium is thus always absorptive. Equation (7) allows the definition of an "effective temperature" T_m for an emissive system; Eq. (6) and (7) show that T_m will be a "negative" temperature, and that $|T_m| \to 0$ for $(N_m/N_n) \to \infty$. Obtaining an emissive condition, obtaining a "negative temperature," and obtaining "population inversion" are thus synonymous. The excitation of a molecular assembly to an emissive condition is perhaps the crux of the maser problem. The schemes used depend on the conditions and on the molecular system. Discontinuous methods (pulse inversion, adiabatic fast passage) can be used, but the account here is confined to the principles of continuous methods. In a gas, actual separation of the upper-state molecules may be possible. For example, the upper-state molecules for the 23.87 GHz ammonia maser transition tend to increase their energy in a static electric field, while the lower-state molecules tend to decrease their energy (Quadratic Stark effect). In an inhomogeneous electric field, the wanted upper-state molecules will therefore drift to the low-field regions. An electrode system (with geometrical axial symmetry) which gives a low-field region along the symmetry axis will therefore confine the upper-state molecules in a beam along this axis while rejecting the lower-state ones.

In the atomic hydrogen maser, a state-selector *magnet* is used, with alternating north and south poles, again in an axial arrangement. The electron and nuclear spins can either be "parallel" ($F = 1$) or "antiparallel" ($F = 0$). The energy of the atoms with $F = 0$ decreases with the magnetic field as they go off axis, while that of the atoms with $F = 1$ increases. Hence the atoms with $F = 1$, those in the higher energy state, are focused by the magnet system along its axis, while the lower-state atoms are lost to the beam. The upper-state atoms enter a teflon-coated quartz bulb inside a microwave cavity resonant at the transition frequency. The teflon coating minimizes the chance of an atom emitting its energy because of a collision with the wall of the bulb.

Most masers operate on the multilevel excitation scheme, requiring an input of energy ("pumping") at some frequency other than the transition frequency; forms of energy other than electromagnetic may also be used. The principles of the scheme will be illustrated by reference to a molecule having 3 levels with energies $W_1 < W_2 < W_3$, such that all transitions between levels are allowed. (The transitions other than the signal transition need not radiate electromagnetically). In thermal equilibrium the number densities $(n_i)_e$ of the particles in the different states (i) will satisfy

$$(n_1)_e > (n_2)_e > (n_3)_e.$$

The frequencies f_{32}, f_{21}, f_{31} are defined from

$$f_{mn} = (W_m - W_n)/h.$$

Suppose now by some means, that the transition $1 \rightarrow 3$ is *saturated*, i.e., $n_1 \simeq n_3$. (This might be achieved by a sufficiently strong electromagnetic field at frequency f_{31}—known as the "pump" frequency). Under these conditions, it may happen either that $n_2 > n_1$, or that $n_3 > n_2$. In the first case, amplification will be possible at f_{21}; in the second case, at f_{32}, provided that the appropriate transition is electromagnetically radiative.

There are many variants of the simple scheme just described. The frequency f_{31} may lie in the optical region (OPTICAL PUMPING); the excitation may be by collision processes in a gas discharge; or more than three levels may be involved, and pump frequencies lower than the signal frequency can sometimes be used.

Maser Materials Maser action has been achieved in gases (e.g., ammonia, formaldehyde, hydrogen, rubidium vapor) and liquids (e.g., protons in water) but the most important maser materials are the solid-state ones, since these have a high concentration of active centers in a small space. Present emphasis is on the use of certain paramagnetic ions diluted in a host crystal lattice. Three-level excitation, or some variant, is usually employed.

PARAMAGNETISM is associated with ELECTRON SPIN. The directional quantization of angular momentum leads to the quantization of the energy of the ionic magnetic moments in a steady magnetic field. In general, the ground-state multiplet of these ions is split by the crystal field of the host lattice (Stark effect), and the levels are completely separated by steady magnetic field (Zeeman effect). When the steady magnetic field is applied at an angle to the major symmetry axis of the crystal field, and the resultant Zeeman splitting is comparable with the initial Stark splitting of the levels, the usually forbidden "leap-frog" transitions necessary for 3- or multiple-level excitation become allowed. In crystal fields of low symmetry, "leap-frog" transitions may be allowed at very low or even zero magnetic fields. Clearly, ions having three or more energy levels are wanted, and any processes competing with radiative processes—e.g., the interaction of the "spins" with the lattice—are usually required to be small. Spin-lattice interaction can usually be reduced by cooling the lattice to a low absolute temperature; and indeed most solid-state paramagnetic masers operate at liquid nitrogen (77 K) or liquid helium (4.2 K) temperatures. Some ions and host lattices with which maser action has been achieved are listed in Table 2.

A "spin-spin" interaction process, known as *cross-relaxation* must also be taken into account, since it may either aid or inhibit maser action. Cross relaxation is dependent on spin concentration, but not on temperature. Consequently, maser action may be achieved at comparatively high temperature (77 K) but not at low temperature (4.2 K) where the considerably longer spin-lattice relaxation time might be expected to give better maser action. Rearrangement of the level populations occurs because of single or multiple quantum transitions between the levels, in which energy is "almost" conserved on the microscopic scale, any differential being exchanged with the energy of the macroscopic spin system (total magnetic moment).

Amplifier Systems Maser amplifiers may be of either traveling-wave or resonant circuit (cavity) form. Their performances are expressed in terms of a molecular Q-factor, Q_m, defined over unit length for the traveling-wave maser and over the resonator volume for a cavity maser. At the signal frequency f_s,

$$Q_m = -2\pi f_s \times \frac{\text{Energy stored in the structure}}{\text{Power emitted by the molecules}} \tag{8}$$

since the Q's similarly defined for losses are positive.

TABLE 2

Ion	Effective Spin	Host Lattice
Cr^{3+}	$\frac{3}{2}$	Al_2O_3, alumina (ruby)
Cr^{3+}	$\frac{3}{2}$	TiO_2 rutile
Cr^{3+}	$\frac{3}{2}$	$Be_3Al_2(Si_6O_{18})$ emerald
Fe^{3+}	$\frac{5}{2}$	Al_2O_3, alumina
Fe^{3+}	$\frac{5}{2}$	TiO_2 rutile
Fe^{3+}	$\frac{5}{2}$	Al_2SiO_5 andalusite

For a magnetic dipole transition,

$$|Q_m| \propto \delta(N^* p_m^2 \eta)^{-1} \tag{9}$$

where δ is the frequency width of the transition at half-intensity, N^* is the *excess* upper level population, p_m is the effective dipole moment for the transition, and η is the ratio of the magnetic energy coupled to the molecules to that stored in the microwave circuit.

Traveling-wave Maser The active maser material is placed in a waveguide carrying a pure traveling wave. The gain coefficient α_m is defined such that the power gain G for a length l of amplifier is given by

$$G = \exp(2\alpha_m l). \tag{10}$$

It can be shown that

$$\alpha_m = (2\pi f_s)/(|Q_m| v_g^{-1}) \tag{11}$$

where v_g is the group velocity of radiation in the guide. Because p_m is typically of the order of a Bohr magneton, and the active centers are diluted, it is necessary to use *slow-wave structures* ($v_g \simeq c/100$) in order to keep l to a reasonable value (a few centimeters). Suitable values of v_g are readily achieved by the resonant slowing obtained in periodic structures. Systems such as the Karp structure, comb structure, and meander line are favored, since these support waves with the magnetic field circularly polarized in a plane containing the direction of propagation and perpendicular to the plane of the periodic elements. A comb-structure traveling-wave maser is illustrated schematically in Fig. 1. The sense of circular polarization is reversed on crossing this plane and is opposite in any reflected wave to that in the forward wave. The nonreciprocal gyromagnetic properties of para- and ferrimagnetic materials may then be employed to obtain forward gain and reverse attenuation with these slow waveguides.

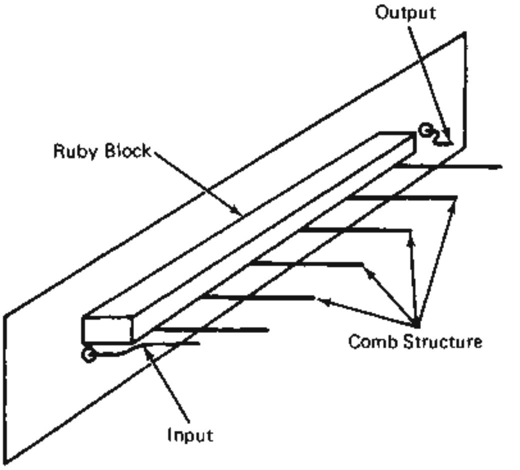

FIG. 1. A magnetic field is applied parallel to the "teeth" of the comb.

The noise input temperature T_{in} of a traveling wave maser is given approximately by

$$T_{in} \simeq |T_m| + T_1(|Q_m|/Q_e) \tag{12}$$

where T_m is the effective negative temperature of the maser material, Q_m is the molecular Q (negative), Q_e is the similarly defined ohmic loss factor, and T_1 is the actual temperature of the waveguide (and contents). In this approximation, $|Q_m| \ll Q_e$. The bandwidth b_m of the amplifier is approximately equal to, but less than, δ.

The *Resonant circuit Maser* may be of either transmission (two-port) or reflection (one-port) type: only the reflection type is considered here, since it is superior in performance to the transmission type. A reflection cavity maser and necessary ancillary equipment are illustrated schematically in Fig. 2. Assuming that the unloaded resonant circuit (cavity) losses are negligible, the coupling to the external circuits will give rise to a Q-factor Q_e, say. The power gain G of the reflection cavity maser is then given by

$$G = (Q_e + |Q_m|)^2 (Q_e - |Q_m|)^{-2} \tag{13}$$

The bandwidth b_c depends on the gain in such a way that

$$G^{1/2} b_c \simeq 2|Q_m|/f_s (\text{for } G > 10, \text{say})$$

The noise input temperature is given by Eq. (12) above, where now

$$Q_e^{-1} = Q_e^{-1} - |Q_m|^{-1}$$

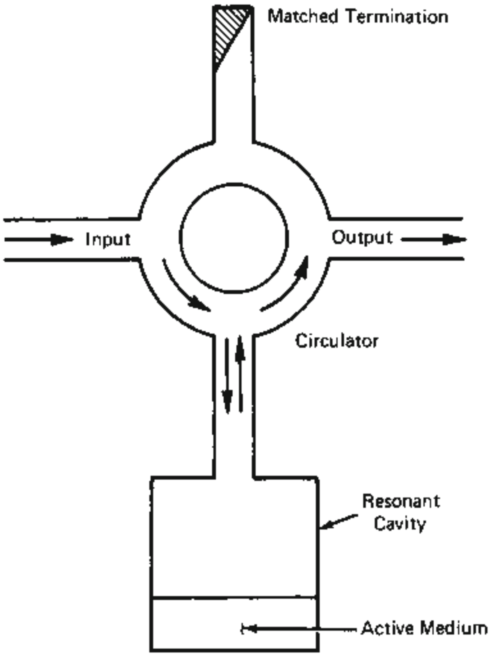

FIG. 2.

It is necessary to have some nonreciprocal device to separate the reflected amplified output from the input signal; the ferrite circulator is most commonly used. The bandwidth and gain stability of the cavity maser are inferior to that of the traveling-wave maser, but the cavity maser is more easily constructed. If three-level excitation is used, it is clear that any maser system must support both "pump" and signal frequencies.

Maser Oscillators Equation (13) indicates that if $|Q_m|$ is small enough, G becomes infinite; i.e., oscillation occurs when the stimulated emission is large enough to overcome all losses. The width of the signal emitted by a maser oscillator is very much less than δ, so that for narrow δ an extremely pure oscillation signal results, and a molecular transition which is relatively insensitive to external influences will thus give oscillations of high stability in frequency. The ammonia maser and the atomic hydrogen masers are two examples.

Two hydrogen maser oscillators have been compared against each other, and the relative frequency over several hours was stable to 1 part in 10^{14}. This stability has allowed the determination of the level separation of atomic hydrogen and its isotopes with greatly increased precision (e.g., 0.1 Hz in 1,420,405,751.768 Hz), and has thus allowed a further test of theoretical quantum electrodynamics, and given a more precise value for the fine structure constant. Hydrogen masers have also been flown in missiles and aircraft for the detection of small relativistic effects of the motion.

The Electron-Cyclotron Maser Relativistic free electrons gyrating in a static magnetic field undergo free-free transitions. If there is an energy-dependent level width, or an energy-dependent level spacing for the quantized free electron states, and a population inversion is also present, stimulated emission and hence amplification can occur.

The classical picture of cyclotron maser action can be obtained by considering the phases of electrons gyrating about the magnetic field. Each charge will radiate as an electric dipole; a multipolar contribution also occurs when relativistic effects are properly taken into account. Consider a system of monoenergetic electrons, initially distributed randomly in phase. If a phase bunching mechanism exists, coherent emission will take place. Because of the relativistic mass change, this bunching does in fact occur. Electrons absorbing radiation become more massive, and go back in phase; electrons emitting radiation become less "massive" and advance in phase. The ultimate phase distribution favors emission over absorption, thus increasing the intensity of the incoming electromagnetic wave.

From the quantum-mechanical viewpoint, a free electron in a uniform static magnetic field B is an anharmonic oscillator with quantized energy levels (neglecting spin)

$$W_n = mc^2[1 + 2(n + \tfrac{1}{2})h\Omega_0/2\pi mc^2]^{1/2} - mc^2 + p^2/2m$$

where Ω_0 is the rest electron gyrofrequency eB/m, and p is the unquantized momentum along the direction of B. Transitions between states $|n+1\rangle$ and $|n\rangle$ occur at angular frequency $\omega_n = (1 - nh\Omega_0/2\pi mc^2)\Omega_0$ for $nh\Omega_0/2\pi \ll mc^2$; note that ω_n decreases as n increases. If a system has a greater population in the state $|n+1\rangle$ than in $|n\rangle$, photons of angular frequency ω_n will induce more (downward) transitions $|n+1\rangle \to |n\rangle$ than (upward) transitions $|n\rangle \to |n+1\rangle$, because of the unequal level spacing; hence stimulated emission exceeds absorption. If the width of the level $|n+1\rangle$ exceeds that of $|n\rangle$, a similar effect can occur. This situation can be obtained by causing the radiating atoms to suffer elastic phase-interrupting collisions (e.g., with neutral atoms) if the energy-dependent collision cross section is sufficiently strong.

In a typical device, the *gyrotron*, a solenoid creates an axially symmetric magnetic field about a gently tapering waveguide system, whose different sections act as interaction space (open or "quasi-optical" cavity) and output (and if necessary, input) apertures. The electrons are produced at a cathode with a large emitting surface, and accelerated towards a collector. The magnetic field increases in intensity from the cathode to the interaction space, which has an almost uniform magnetic field. In the nonuniform field region, the electron orbital velocity $v_\perp$ grows from the initial cathode orbital velocity according to $v_\perp{}^2/B =$ constant: the orbital energy is drawn from that of the longitudinal motion, and from the accelerating electrostatic field. The electrons deliver up the RF energy in the interaction space, then pass through a section of decreasing magnetic field to an extended surface collector. Such devices are capable of powers of many kilowatts in the millimeter and submillimeter wavelength regions.

Applications Maser amplifiers are now in use wherever the requirement for a very low noise amplifier outweighs the technological problems of cooling to low temperatures. They have been used in passive and active radioastronomical work, in satellite communications ("Project Echo") and as preamplifiers for microwave spectrometry. The "deep-space tracking" stations around the world use ruby maser preamplifiers for the reception of signals from planetary probes. The ammonia and the atomic hydrogen masers are being studied as frequency standards and have been used in a new accurate test of special relativity. Sources and amplifiers in the submillimeter, micron, and optical wavelength regions are being studied and developed (see LASER). Maser theory has been used to explain numerous atomic and molecular emission lines observed in radio astronomy ('celestial masers').

MASS AND INERTIA

Mass is, along with length and time, one of the three fundamental undefinables of Newtonian dynamics (the explanation of matter in motion). These three undefinables combine to form the important operational quantity called *force*. One in turn may consider force as a measure of the interaction of mass with its environment.

Force is defined in such a way that it is dependent on either one of two intrinsic properties of matter, called *gravitation* and *inertia*. First, all matter exerts an attractive force on all other matter (active gravitational mass) and is in turn attracted by all other matter (passive gravitional mass). Secondly, all matter resists any change in its motion (inertial mass).

The gravitational role of mass is quantified by Newton's universal law of gravitation,

$$\mathbf{F} = -\frac{Gm_1 m_2}{r^2}\,\hat{\mathbf{u}}_r \tag{1}$$

wherein the force **F** of attraction (designated by the negative sign) between masses m_1 and m_2 is inversely proportional to the square of the distance r between their centers of mass, and directly proportional to the magnitudes of m_1 and m_2. **F** is called a *central force* because it acts in a straight line (the direction of which is given by a unit vector $\hat{\mathbf{u}}_r$) which originates at the center of mass m_1 and terminates at the center of mass m_2.

This force is independent of the physical dimensions of m_1 and m_2. Its strength, compared with forces of other kinds such as that of electricity, is determined by the size of the gravitational constant G. In view of the high degree of accuracy over centuries of application inhering in Eq. (1), which does not require any specification as to which of the two masses is the active and which is the passive gravitational mass, no quantitative difference is expected between these two states of gravitational mass. Further, Newton's third law of action and reaction, to be considered below, implies their equality.

The inertial property of mass is described by Newton's three laws of motion. According to the first law, a body will continue in its state of rest or in a state of uniform motion (unchanging speed along a straight line) unless acted upon by a net external force. This means, for example, that the earth, instead of orbiting about the sun, would move in a straight line and thus escape from the solar system. The "escape" is prevented by the force of gravitational attraction between the sun and the earth. It also means that motion of mass can exist without force. It is through Newton's second and third laws however, that an operational definition of inertial mass is achieved, one based on the concept of force which can be a push or a pull (such as that inherent in the force called *weight*). The second law states that the net force **F** is equal to the change (or derivative) of momentum with time, momentum being the product of mass m and its velocity **v**:

$$\mathbf{F} = \frac{d(m\mathbf{v})}{dt}. \tag{2a}$$

Taking the derivative of the momentum with respect to time leads to a two-term expression for the force **F**:

$$\mathbf{F} = m_i\mathbf{a} + \frac{dm}{dt}\,\mathbf{v}. \tag{2b}$$

For most conventional situations the inertial mass is constant, so that the second term $(dm/dt)\mathbf{v}$ is equal to zero, thereby leaving $\mathbf{F} = m_i\mathbf{a}$. The acceleration $\mathbf{a}$, which is the derivative of velocity $\mathbf{v}$ with respect to time $(d\mathbf{v}/dt)$, represents a time-dependent increase or decrease in velocity of the mass or a change in its direction of motion such as that encountered in rotation. Velocity is speed in a specific direction, and is an example of a vector, namely it has magnitude (i.e., speed) and a specific direction. In the case of the unit vector $\hat{\mathbf{u}}_r$, the magnitude is one. Operationally, Eq. (2b) states that when the force $\mathbf{F}$ is fixed, mass and acceleration are inversely proportional to each other. The interdependence of the concepts of force and mass reflected by $\mathbf{F} = m_i\mathbf{a}$ emphasizes the lack of a unique definition of what inertial mass is. The latter, however, may not prove ultimately to be a drawback, for the following reason. At least three of the hierarchy of four forces, i.e., gravitation, weak, electromagnetism, and strong, contain empirical constants, such as the permittivity of free space ϵ_0, the gravitational constant G, or the Fermi coupling constant G_F. A delineation of the origin of these constants would provide a deeper insight into the nature of the interaction of mass with its environment, as well as a potentially richer understanding of the nature of mass itself.

For example, Einstein in banishing the concept of absolute velocity by focusing attention on the role of the relativity of the velocity term in Eq. (2b), enlarged the Newtonian operational view of the concept of inertial mass. In his theory of special relativity, the amount of mass associated with an object was shown to be a function of its relative velocity,

$$m = \gamma m_0, \tag{3a}$$

a dependence quantified by the Lorentz transformation γ,

$$\gamma = \frac{1}{\sqrt{1 - (v^2/c^2)}}. \tag{3b}$$

Here c, the speed of light in a vacuum, is considered independent of any motion of its source. The total mass of an object m was now considered to be the sum of a constant, intrinsic rest mass m_0 and an increment of variable mass depending upon its velocity relative to some reference frame. This latter effect negates defining mass as a measure of the quantity of matter in a body. Significantly, mass could now be shown to be equivalent to energy via the relationship $E = mc^2$. It is worth noting that this energy expression for mass does not reflect the fact that it is considerably easier for stable mass to be converted into radiant energy than the reverse. Significantly, the special relativistic Newtonian operational definition of mass has been found to be highly compatible with the concept of electromagnetic fields as well as with the quantum of action. This success has culminated in the extraordinarily precise discipline of quantum electrodynamics.

It should not be concluded, however, that the concept of force is a unique prerequisite in Newtonian mechanics for the definition of inertial mass. Mach proposed an experiment for determining the relative inertial mass free of any consideration of force including that of weight. Two masses M and m on a frictionless surface are held together against a compressed spring between them. When released, they fly apart under the influence of the equal and opposite forces exerted by the spring. The second law states that the product of the mass and the magnitude of the acceleration for each object should be identical, or

$$mA = Ma. \tag{4a}$$

If we replace M by one standard unit of mass, the kilogram, i.e., $M = 1$, then

$$m = \frac{a}{A}. \tag{4b}$$

Mass m is therefore operationally defined as a ratio of two accelerations, i.e., that of the standard a and that of the object A; the ratio of the two accelerations is constant for a particular body and thereby quantifies an intrinsic property of matter. Its validity requires that Newton's third law hold, namely that for any force of action there must exist an equal and opposite force of reaction.

From the time of Galileo, there has existed reason to believe that the two intrinsic properties of mass might have a common origin. Since the mass of a falling object on earth is simultaneously inerting m_i and gravitating m_G, one can equate Eqs. (1) and (2b), where, on earth, M_e is the mass of the earth and r is the distance from the center of the earth to the falling object:

$$m_i\mathbf{a} = -\frac{GM_e m_G}{r^2}\hat{\mathbf{u}}_r. \tag{5}$$

To a surprising degree of accuracy (about 1 part in 10^{12}) the acceleration for all falling bodies in the vicinity of the earth is equal to $-GM_e/r^2$, more commonly designated as $g \cong 9.8$ Newtons/kilogram. It is the variation in r in the factor g and not a change in mass that causes the weight of a given object to be location dependent. This means that to the extent that all objects fall to the ground with the same acceleration, the ratio m_G/m_i, at fixed r, in Eq. (5) is constant so that m_i can be set equal to m_G by redefining the constant G. Einstein seized upon this apparent experimental equality of inertial and gravitational mass and made it absolute, thereby adopting the suggestion of Mach that inertial mass is simply the gravitational attraction of all the mass in the universe for the matter undergoing a change in its motion. This enabled him to reduce the number of fundamental undefinables of dynamics to two, namely length (three dimensions) and time. If we multiply the latter by the postulated invariant speed of light c, we obtain a fourth length or the fourth dimension. Thus, dynamics is reduced to four-dimensional geometry and the existence of mass is indirectly reflected by the warpage of this four-dimensional geometric structure. (The unusual behavior of black holes can be attributed to optical effects encountered under conditions of extreme warpage.) From a Newtonian standpoint, general relativity banishes absolute acceleration and quantifies the relativity of acceleration.

General relativity, in eliminating mass as a fundamental undefinable through the removal of any distinction between inertial and gravitational mass, redefines mass as a measure of the curvature of space-time. Despite many experimental confirmations involving matter and light; general relativity has resisted accommodation with electric charge, as well as with the related quantum of action h. Further, recent measurements of solar oblateness by Hill, if confirmed, would suggest that a small portion (~1.4%) of the advance of the perihelion of Mercury (43″/century), until now a stunning, unique and exact prediction of general relativity, may have to be attributed to some other mass effect. It therefore remains an open question whether a description of mass based upon the elimination of all distinction between inertia and gravitation can be maintained.

MASS SPECTROMETRY

Mass spectrometry is based on observations of the behavior of positive rays by Thomson and Wien. In 1919, Aston demonstrated the existence of isotopes by introducing neon gas into a mass spectrograph. Prior to 1940, mass spectrographs and spectrometers were used primarily for isotopic studies in university laboratories. Analytical spectrometers became commercially available during the early years of World War II when their use for the rapid analysis of hydrocarbon mixtures was recognized.

Mass spectrometry provides information concerning the mass-to-charge ratio and the abundance of positive ions produced from gaseous species. There are several techniques for the production and measurement of the ions, and the design of an instrument is determined by its proposed application. The mass spectrograph, using a photographic plate for ion detection, had been used primarily for isotopic studies but later was used for the analysis of trace constituents in solids. The mass spectrometer uses an electrical detection and recording system giving a metered output that provides a more accurate measure of the abundance of the ions than the photographic plate provides. The mass spectrometer is used primarily for the quantitative analysis of gases, liquids, and a limited number of solids.

The five basic components of the instrument are the sample introduction system, the ion source, the mass analyzer, the ion detector, and the recorder. A sample pressure of approximately 5×10^{-5} torr is generally required for a satisfactory analysis. An elevated temperature inlet system or other means of converting the sample into a gaseous state is required for less volatile species. Direct insertion probes for introducing samples directly into the region of ionization are available on many instruments.

The most common methods of producing positive ions are electron impact, thermal ionization, spark, field emission desorption, and chemical ionization. The electron impact source is the most widely used. Positive ions are produced by removing one or more electrons from the molecules. Thermal ionization produces positive ions by vaporizing a material directly into the ion source from a filament coated with the sample. With a spark source, the material under investigation must be a conductor, or else suitable means must be provided for initiating and maintaining a spark. Ions produced in the spark are taken directly into the mass analyzer. In the field emission source, a high potential is applied between the sample—generally deposited on the tip of a tungsten wire—and another electrode. Ionic species representative of the sample are removed by a high-intensity electric field. Chemical ionization involves the reaction, directly in the ion source, of ions from a reactant gas such as methane with molecules of the sample.

The three most widely used types of mass spectrometers are (1) the single-focusing, magnetic deflection, (2) the double-focusing, and (3) the quadrupole. These three types of instruments differ primarily in the method used for mass separation. The single-focusing analyzer achieves direction but not velocity focusing of the ions. Ions of the same mass-to-charge ratio, having slightly different velocities resulting from different kinetic energies imparted in the ionization process, will not be focused simultaneously, thus producing a broadening of the peak. The resolution of commercially available instruments of this type is generally limited to about one part in 500. That, is, mass 499 can be separated from mass 500 with about a 10% valley. With double-focusing instruments, an electric sector and a magnetic analyzer are placed in tandem to produce both velocity and direction focusing of the ions. Several commercial models of the double-focusing design are available having resolutions in excess of one part in 50,000 with an electron impact source, and greater than one part in 3000 with a spark source. The double-focusing geometry is necessary with spark source operation because of the wide energy spread of ions produced in the spark. With both single and double focusing, the resolution varies directly with the radius of the analyzer tube and inversely with the width of the slits located in the ion source and ion collector regions. Sensitivity, the abundance of the ions collected per unit sample charge, varies inversely with slit width, and a compromise must be made between resolution and sensitivity. Combined gas chromatography-mass spectrometry with appropriate data processing units is a popular type of instrumentation. Separation of complex mixtures into individual components as well as analysis is accomplished by mating these two types of instrumentation. Recently, two mass analyzers have been used in tandem for the technique termed MS/MS. The first analyzer is followed by a reaction region and then by a second analyzer. Chemical ionization is commonly used for the source of positive ions. In this technique, a spectrum is obtained of ions at a single m/e in the initial spectrum. A major advantage is the increased capability to detect individual organic compounds in complex mixtures.

The two types of ion detection and recording systems are the photographic plate and the electrical detector. The photographic method is commonly used with double-focusing instruments such as the Mattauch-Herzog design that focuses all ions simultaneously in one plane. The photographic plate records a complete spectrum (mass range ~ 36 : 1) in a time interval of a few seconds to 10 minutes. However, the response of the plate to the ion intensity is nonlinear and quantitative results are more difficult to obtain than by electrical detection. Electrical detection systems use an ion collector, amplifier (commonly an electron multiplier), and recorder.

Positive and negative ions and neutral species are produced by the electron bombardment of molecules. The mass spectrum of a compound is a record of the positive ions collected. Positive ions are produced by the removal of one or more electrons from the molecule and by the rupture of one or more bonds, fragmenting the molecule. While the majority of the positive ions are singly charged, doubly and triply charged ions are observed in many instances. Certain mass ions produced from organic molecules must be attributed to the rearrangement of hydrogen atoms during the ionization and fragmentation processes. Metastable ions, formed when ions decompose while traversing the path to the collector, are also frequently observed. Metastable ions generally appear at nonintegral mass units and produce broad, low-intensity peaks.

In the electron impact source, the electron energy is usually adjusted to 50–70 eV, which is considerably above the appearance potential for molecular and fragment ions. For simplification of a complex spectrum, the bombarding energy can be reduced to provide sufficient energy to ionize the molecule but not enough to rupture bonds, thus achieving a spectrum consisting primarily of molecular ions. Mass ions appearing in the normal mass spectrum correspond to the various atoms and combinations of atoms in the original molecule. The pattern of mass-ion intensities observed is independent of pressure. Differences in the patterns obtained for various compounds can be used as the basis for the analysis of complex mixtures. Quantitative analysis is based on the ion current varying linearly with the partial pressure of the gas.

Some of the common uses for mass spectrometry include analysis of petroleum products, identification of drugs, determination of the structure of organic molecules, determination of trace impurities in gases, residual vacuum studies and leak detection in high-vacuum systems, geological age determinations, tracer techniques with stable isotopes, determination of unstable ionic species in flames, identification of compounds separated by gas chromatography (combined gas chromatography-mass spectrometry), trace element analysis in metals and other solids, and microprobe studies of surfaces and of surface composition of various materials.

MATHEMATICAL PHYSICS

The term "mathematical physics" is almost synonymous with "THEORETICAL PHYSICS," but their difference is significant. It is like the difference between the descriptions of the electromagnetic field by Maxwell and by Faraday respectively. The theoretical (nonmathematical) description draws on analogies between elements of the field and familiar mechanical models—stretched strings, compressed fluids, vortex motion, etc.; the mathematical description made use of the abstract analytical properties of the elements of the field to set up a purely symbolic description without mechanical models. Classical theoretical physics was largely mathematical in content, but was nevertheless based on mechanical models in the spirit of Faraday's theory of the electromagnetic field. The atom and interactions between atoms were regarded as the "real," "external" objects in terms of which all physical phenomena could be explained. The mathematical formalism was merely a handy tool or language in terms of which to set up the explanation. The atoms themselves were not explained, but regarded as the fundamental "building blocks" of the physical world.

Einstein's theory of RELATIVITY is a magnificent historical example of mathematical physics we may cite to contrast with the classical atomic theory. Here mathematical abstractions, Minkowski space 4-vectors, Riemannian tensors, etc. were invented or adopted from the stock-in-trade of pure mathematicians, with analytical properties that were seen to match those of the data of experimental physics—velocities, forces, field variables, etc. Then the logical (i.e., mathematical) consequences of relations among these abstractions predicted new and unexpected relations among either already known or as yet undiscovered data of experimental physics. The construction of a self-consistent mathematical *description* of all physical phenomena, without the use of hypothetical building blocks of any kind, is the aim of mathematical physics as distinct from theoretical physics.

As a more recent example of this same concept, one may cite the deduction of conservation laws from generalized symmetry principles. The classically familiar conservation laws: energy, momentum, angular momentum, have for some time now been recognized as logical consequences of the homogeneity and isotropy of time and space. Interpreting these homogeneities and isotropy as meaning the invariance of physical laws under translation and rotation, one is led naturally to the theorem that each invariance principle corresponds to an appropriate conservation law. This theorem has yielded very significant discoveries in the study of elementary particles and nuclear structure where the most cunningly devised classical models have been not only fruitless but actually misleading. A non-technical account of this subject appears in Chapter 27 of R. K. Adair's text "Concepts in Physics," New York, Academic Press, 1969.

The activities of mathematical physicists have resulted in the invention of new mathematical abstractions some of which were at first rejected by pure mathematicians as illogical, only later to be granted a respectable status in the vocabulary of pure mathematics. Examples include Oliver Heaviside's operational calculus, J. Willard Gibbs' vector analysis, and P. A. M. Dirac's delta-function techniques. On the other hand, many branches of pure mathematics which initially had been regarded as so abstract as to be entirely "useless," have been found by mathematical physicists to serve as remarkably useful tools in describing physical phenomena. Examples include non-Euclidean geometry in the problems of COSMOLOGY; function space in modern QUANTUM MECHANICS; spinor analysis, or the theory of binary forms, in quantum FIELD THEORY. Again collaboration between mathematical physicists and mathematicians has in recent years resulted in the construction of new disciplines of great value, examples being group theory, operations analysis, the theory of random functions, information theory and CYBERNETICS. The names of many contemporary scientists are involved here, including Eugene P.

Wigner, John von Neumann, C. E. Shannon, Norbert Wiener and many others.

On closer examination it becomes difficult to distinguish clearly between mathematical physics and applied mathematics; very frequently the same individual may be responsible for discoveries in both areas. Classical examples of this may be cited: Isaac Newton, Laplace, Carl Friedrich Gauss, Henri Poincaré, David Hilbert, Ernst Mach, A. N. Whitehead. Evidently our attempt to define mathematical physics is degenerating into a simple catalog of items with only a vague hint of general characteristics common to all particulars. Physics has sometimes been defined as what physicists do, and one is expected to recognize the physicist without need for further definition than his own affirmation. Mathematical physics may then be defined as what physicists do with mathematics, or what mathematicians do with physics, or some superposition of the two. As the history of mathematical physics unfolds it becomes apparent that activity tends to cluster in a few fruitful directions at any one time. Current interests can be judged from the contents of the leading journals devoted to the subject; among these the reader should consult the *Journal of Mathematical Physics*, and the *Physical Review*, published by the American Institute of Physics; *The Proceedings of the Cambridge Philosophical Society; Comptes Rendus* (French Academy of Sciences); *Progress of Theoretical Physics* (Japan); *Nuovo Cimento* (Italy); *Indian Journal of Theoretical Physics; Zhurnal Eksperimental' noy i Teoreticheskoy Fiziki* (USSR) (in English Translation "JETP"); and other translations published by the American Institute of Physics. Probably the most popular fields in recent years have been in the wide application to solid-state physics and statistical mechanics of quantum field theoretical techniques introduced initially to deal with the phenomena of high energy physics—nuclear interactions, creation and destruction of particles, etc.

During the last decade the explosive growth in the availability of miniature computers and the wide accessibility of large computer facilities have had a revolutionary impact on the thinking of mathematical physicists, if not on mathematical physics itself. Exceptionally complicated problems that were easily proven "soluble in principle" have become soluble in practice, and this fact alone has freed creative thinkers to ask ever more elaborate and useful questions—e.g., finding the eigenvalues of very large matrices, solving nonlinear differential equations and adjusting parameters to make the solutions match experimental data, simulating the behavior of systems with many degrees of freedom* and the resulting understanding of shock formation in high-speed phenomena. For these purposes there are now several libraries of program subroutines useful in the study of literally thousands of unexplored problems. Computational projects that were never even contemplated because they would have taken decades to complete can now be undertaken and completed in hours or even minutes. The other side of the coin is: such masses of numerical data are generated that results can take years to digest and interpret. This difficulty is ameliorated in the simpler cases by the recently developed graphics display capability.

The most significant advance to date would seem to be the possibility of programming computers to perform abstract algebraic analysis without the use of purely numerical input. This may or may not help eliminate the one most serious weakness of computer science: computer programming is so absorbing an occupation that an expert can hardly be expected also to understand the historic significance, or even relevance, of the major problems at the frontiers of knowledge in mathematical physics. Perhaps the most serious error committed by schools of computer science has been to exempt their students from a solid course on mathematical physics. Physicists who wish to keep in touch with advances in computer science should watch the continuing series of annual volumes "Methods in Computational Physics" (Alder, Fernbach, Rotenberg, Eds.; Academic Press).

A philosophy of mathematical physics has gradually evolved with all this creative activity. For current thinking in this area, the reader is referred to two pertinent journals that have appeared in the past few years: "*Foundations of Physics*, and *International Journal of Theoretical Physics*, both from Plenum Press. Semipopular expositions are available in a number of recent texts in addition to the one by Adair, cited above: Kenneth W. Ford, "The World of Elementary Particles, 1967; F. A. Kaempffer, "The Elements of Physics," 1967; and Kenneth W. Ford, "Basic Physics," 1968; all from Blaisdell Publishing Co.

As for college level texts on mathematical physics, there are very few that are organized around physical concepts. We may refer to the classic series of volumes by Arnold Sommerfeld, and those by Slater and Frank, as prototypes. The standard modern work is the two-volume set by Morse and Feshbach, "Methods of Theoretical Physics," New York, McGraw-Hill, 1953. A less ambitious volume, William Band, "An Introduction to Mathematical Physics," New York, Van Nostrand Reinhold, 1959, served as an overall survey for advanced undergraduates. There is now a multitude of excellent texts whose major emphasis is the various mathematical techniques employed in theoretical physics, and we cite only three: Margenau and Murphy, "The Mathematics of Physics and Chemistry," New York, Van Nostrand Reinhold, 2 volumes, 1956 and 1964; George Arfken, "Mathematical

*A good example: Abraham, F. F., "Computer Simulation of Diffusion Problems . . . ," IBM Data Processing Division, and The Materials Science Department, Stanford University, Palo Alto, California, 1971.

Methods for Physicists," New York, Academic Press, 1966; and James T. Cushing, "Applied Analytical Mathematics for Physical Scientists," New York, John Wiley & Sons, 1975.

MATHEMATICAL PRINCIPLES OF QUANTUM MECHANICS

Classical Newtonian mechanics assumes that a physical system can be kept under continuous observation without thereby disturbing it. This is reasonable when the system is a planet or even a spinning top, but is unacceptable for microscopic systems such as an atom. To observe the motion of an electron, it is necessary to illuminate it with light of ultrashort wavelength (e.g., γ-rays); momentum is transferred from the radiation to the electron and the particle's velocity is therefore continually disturbed. The effect upon a system of observing it can never be determined exactly, and this means that the state of a system at any time can never be known with complete precision; this is *Heisenberg's uncertainty principle.* As a consequence, predictions regarding the behavior of microscopic systems have to be made on a probability basis and complete certainty can rarely be achieved. This limitation is accepted and is made one of the foundation stones upon which the theory of quantum mechanics is constructed.

Any physical quantity whose value is measured to determine the state of a physical system is called an *observable.* Thus, the coordinates of a particle, its velocity components, its energy, or its angular momentum components are all observables for the particle. A pair of observables of a system are *compatible* if the act of measuring either does not disturb the value of the other. The cartesian coordinates (x, y, z) of a particle are mutually compatible, but the x-component of its momentum p_x is incompatible with x (similarly, y, p_y are incompatible, etc.). $(p, q, \cdots w)$ constitute a *maximal set of compatible observables* if they are compatible in pairs and no observable is known which is compatible with every one of them. In quantum mechanics, the state of a system at an instant is fully specified by observing the values of a maximal set of compatible observables. Such a state is called a *pure state*. The act of observing a system in a pure state disturbs the system in a characteristic manner; the system is accordingly said to be *prepared* in the pure state by the observation. The cartesian coordinates (x, y, z) of a spinless (see below) particle form a maximal set, and if the position of the particle is known, it is in a pure state; similarly, the momentum components (p_x, p_y, p_z) form a maximal set and a particle whose momentum is known is also in a (different) pure state.

A pure state in which the observables of a maximal set S have known values is termed an *eigenstate* of S and the observable values are called their *eigenvalues* in the eigenstate. If $(p_0, q_0, \cdots, w_0)$ are the eigenvalues, the eigenstate is sometimes denoted by the symbol $|p_0, q_0, \cdots, w_0>$; in this article, pure states will be denoted more concisely by Greek letters. The eigenstates of S are represented by mutually orthogonal vectors, called the *base vectors*, defining a frame of rectangular axes F in an abstract *representation space*. The number n of such eigenstates is usually infinite, but for simplicity, it will first be assumed that each observable has only a finite number of eigenvalues and hence that the number n is finite; the representation space is then a straightforward generalization of ordinary space to n dimensions, with the additional requirement that the components of a vector will be permitted to take complex values. Any pure state of the system (not necessarily an eigenstate of S) is represented by a vector α in the representation space. If $(\alpha_1, \alpha_2, \cdots, \alpha_n)$ are the components of α with respect to F, and these components are arranged as a column matrix, this matrix is said to provide an S-representation of the state. The state, vector, and column matrix are all denoted by α.

The *scalar product* of two vectors α, β is denoted by (α, β) and is defined in terms of their components in F to be $\sum_{i=1}^{n} \alpha_i^* \beta_i$, where α_i^* is the complex conjugate of α_i. $\sqrt{(\alpha, \alpha)}$ is called the *norm* of α and corresponds to the length of an ordinary vector. All vectors representing pure states are taken to have unit norms and the S-eigenstates are accordingly represented in the S-representation by the columns $(1, 0, \cdots, 0)$, $(0, 1, \cdots, 0)$, etc.

Suppose a system is prepared in the state α at time t. The probability that the system can be observed in the state β at an instant immediately subsequent to t is taken to be $|(\alpha, \beta)|^2$. This event is termed a *transition* of the system from α to β. If β is identical with α, the probability of the transition is unity, as we expect. The probability of a transition from α into the eigenstate $(1, 0, \cdots, 0)$ is found to be $|\alpha_1|^2$. This provides a physical significance for the components of α in the frame F.

If the system is prepared in a state α on a number of occasions and an observable a is measured immediately after the preparation on each occasion, the values obtained will usually differ. If α is an eigenstate of a with eigenvalue a_1, then a will take this value with complete certainty. If, however, this is not the case, a will take all its possible eigenvalues a_i with associated probabilities p_i, and its *mean* or *expected value* $\bar{a}$ in the state α is given by $\bar{a} = \sum_i p_i a_i$. In the S-representation, an $n \times n$ matrix is associated with every observable a. This is said to represent a and is also denoted by a. Then, $\bar{a} = \alpha^\dagger a \alpha$, where α is the column matrix specifying the state and $\alpha^\dagger$ is its conjugate transpose. If a is a real observable, the matrix a is Hermitian (i.e., $a^\dagger = a$); this ensures that $\bar{a}$ is real. If a is one of the observables belonging to S, its matrix is diagonal, and the ith element in the principal diagonal is the eigenvalue a_i of a in the ith S-eigenstate; in this case, $\bar{a} = \sum_i \alpha_i^* \alpha_i a_i = \sum_i |\alpha_i|^2 a_i$, which is clearly correct, since $|\alpha_i|^2$ is the probability the system will be observed in the ith S-eigenstate.

A necessary and sufficient condition that the state α should be an eigenstate of a in which a takes the eigenvalue a_0 is that α should satisfy the matrix equation $a\alpha = a_0\alpha$. a is said to be *sharp* in the state α.

Observables are often introduced as functions of other observables, e.g., the kinetic energy T of a particle of mass m is defined in terms of its momentum by $T = (p_x^2 + p_y^2 + p_z^2)/2m$. If a is defined in terms of $u, v, \cdots$ by the equation $a = \phi(u, v, \cdots)$, then this equation also defines the matrix representing a in terms of the matrices representing u,v, etc. There is, however, a proviso: wherever a product uv occurs in ϕ, this must be replaced by $\frac{1}{2}(uv + vu)$ before matrices are substituted, whenever the matrices u,v are such that $uv \neq vu$; this is called *symmetrization*. If $uv \neq vu$, we say that u,v do not *commute* and it is then found that the observables u,v are incompatible.

Thus far, the evolution of a system with time has not been considered. Suppose a system is prepared in a state $\alpha(0)$ at $t = 0$ and is not thereafter interfered with by further observation. Its state $\alpha(t)$ at a later time t is then determined by the *Schrödinger equation*,

$$H\alpha = \iota\hbar \frac{d\alpha}{dt}, \quad \iota = \sqrt{(-1)}$$

where $\hbar = h/2\pi$ (h is Planck's constant). Using the S-representation, α is the column matrix $(\alpha_1, \alpha_2, \cdots, \alpha_n)$ and H is an $n \times n$ matrix, characteristic of the system, called its *Hamiltonian*. H is Hermitian, and in the case of an isolated system, represents the *energy observable* of the system. An important property of H is that, if a is the matrix representing some observable and a and H commute, then a is a *constant* of the system; this means that, if a has a sharp value at one instant, it keeps this sharp value for all t, and otherwise, its probability distribution over its eigenvalues never changes.

If S' is a maximal set of compatible observables different from S, an alternative S'-representation of the states and observables of a system can be developed. If α, α' are column matrices representing the same state in the two representations and a, a' are square matrices representing the same observable, the transformation equations relating the two representations take the forms

$$\alpha' = u\alpha, \quad a' = uau^{-1},$$

where u is a unitary $n \times n$ matrix (i.e., $u^{-1} = u^\dagger$) characteristic of the two representations. In particular, the Hamiltonian H transforms as an observable.

The type of representation we have been describing is called a *Schrödinger representation.* It is also possible, by rotating the frame in the representation space appropriately, to keep α constant as t increases. If this is done, the matrices $a, b, \cdots$ representing the observables of the system necessarily become functions of t and are not constants as assumed previously. This type of representation is called a *Heisenberg representation*. The Schrödinger equation above ceases to be valid and is replaced by equations of motion for the observable matrices $a, b, \cdots$ taking the form

$$\frac{da}{dt} = \frac{\iota}{\hbar}[H, a],$$

where $[H, a] = Ha - aH$ is called the *commutator* of H and a. If H and a commute, $[H, a] = 0$ and a is a constant of the system as already stated.

If the number of basic eigenstates of a representation is infinite but enumerable (i.e., they can be placed in a sequence $e_1, e_2, e_3, \cdots$), the matrices appearing in the theory will have an infinite number of rows. This creates convergence difficulties in most formulae (e.g., that for $\bar{a}$), but otherwise, the form of the theory is not affected. If, however, some of the observables upon which the representation is based have eigenvalues which are spread continuously over real intervals, the basic eigenstates will not be enumerable and the matrix-type representation must be abandoned. Such an observable is said to have a *continuous spectrum* of eigenvalues; examples are provided by the coordinates (x, y, z) of a particle. In these circumstances, the discrete sequence α_n of vector components is replaced by a function $\psi(p, q, \cdots)$ of the continuous eigenvalues $p, q, \cdots$ of the observables of the representation set S. ψ is called a *wave function*. If the system is in the state specified by ψ, the probability that if p, q, etc. are measured they will be found to have values lying in the intervals $(p, p + dp)$, $(q, q + dq)$, etc., respectively is $\psi^*\psi dp dq \cdots$. The representation space is now a function space called a *Hilbert space* in which each vector corresponds to a wave function and the scalar product of the vectors corresponding to the wave functions $\psi(p, q, \cdots)$, $\phi(p, q, \cdots)$ is defined by

$$(\psi, \phi) = \int \psi^* \phi dp dq \cdots,$$

the integration being over all possible eigenvalues of p, q, etc.

In this type of representation, observables are represented by *linear operators* which can operate upon the functions of the Hilbert space, transforming them into other functions belonging to the space. For example, if the system comprises a single particle and the representation being used is based on the particle's coordinates (x, y, z), its state is specified by a wave function $\psi(x, y, z)$ and its momentum components are represented by operators $p_x = (\hbar/\iota)(\partial/\partial x)$, $p_y = (\hbar/\iota)(\partial/\partial y)$, $p_z = (\hbar/\iota)(\partial/\partial z)$. This representation permits the immediate derivation of the important *commutation rules* for the coordinates and momenta, namely $[p_x, x] = \hbar/\iota$, $[p_x, y] = 0$, etc. Counterparts of all the results given earlier for a matrix representation can now be written down. Thus, if a is the operator representing some observable of a system which is in the state $\psi(p, q, \cdots)$, the expected value of a is given by

$$\bar{a} = \int \psi^* a \psi dp dq \cdots,$$

where a operates on the wave function ψ on its right. The necessary and sufficient condition for ψ to be an eigenstate of a with eigenvalue a_0 is $a\psi = a_0 \psi$. Finally, the Schrödinger equation remains valid, but H is now an operator and α is replaced by the wave function ψ; for a single particle moving in a conservative field in which its potential energy is $V(x, y, z)$, employing the coordinate representation, the total energy $H = V + (p_x^2 + p_y^2 + p_z^2)/2m$, Schrödinger's equation becomes

$$-\frac{\hbar^2}{2m} \nabla^2 \psi + V\psi = \iota \hbar \frac{\partial \psi}{\partial t}.$$

The simplest example of an observable with a discrete spectrum of eigenvalues is the *angular momentum* of a system about a point O. If (M_x, M_y, M_z) are the three components of angular momentum and $M^2 = M_x^2 + M_y^2 + M_z^2$ is the square of its magnitude, the following relations hold between the matrices or operators representing these observables

$$[M_y, M_z] = \iota \hbar M_x, \; [M_z, M_x] = \iota \hbar M_y,$$
$$[M_x, M_y] = \iota \hbar M_z.$$

These are the angular momentum *commutation rules*. M^2 commutes with each of the components. It follows that the components are mutually incompatible, but each is compatible with M^2. Simultaneous eigenstates of M^2 and M_z exist in which the eigenvalues of M^2 are $\ell(\ell + 1)\hbar^2$, where $\ell = 0, \frac{1}{2}, 1, \frac{3}{2}, \cdots$, and of M_z are $m\hbar$, where $m = -\ell, -\ell + 1, -\ell + 2, \cdots, \ell - 1, \ell$.

Part of the angular momentum of a system is due to the orbital motion of its particles about O and the remainder is contributed by the intrinsic angular momentum or *spin* of the particles. Let (s_x, s_y, s_z) be the components of spin of a particle and s^2 the square of its magnitude; then, if the particle is a fundamental one (e.g., an electron, proton, or vector meson), s^2 will have only one eigenvalue $\ell(\ell + 1)\hbar^2$ and the particle is then said to have spin $\ell\hbar$. For an electron or a proton, $\ell = \frac{1}{2}$ and for a vector meson $\ell = 1$. The eigenvalues of a spin component are then $-\ell\hbar, (-\ell + 1)\hbar, \cdots, \ell\hbar$. Thus, any spin component of an electron has but two eigenvalues, $-\frac{1}{2}\hbar, \frac{1}{2}\hbar$; a spin component of a vector meson has three eigenvalues $-\hbar, 0, \hbar$.

If all aspects of the state of a fundamental particle except its spin are ignored, (s^2, s_z) constitute a maximal set of compatible observables. Employing a representation based on this set, the number of basic eigenstates for a particle of spin $\ell\hbar$ will be $(2\ell + 1)$ and the general spin state of the particle will be represented by a column matrix $(\alpha_\ell, \alpha_{\ell-1}, \alpha_{\ell-2}, \cdots, \alpha_{-\ell})$; for a particle in this state, $|\alpha_k|^2$ is the probability of measuring s_z to take the value $k\hbar$. In the special case of an electron or a proton, $\ell = \frac{1}{2}$ and its spin state is specified by a column $(\alpha_{1/2}, \alpha_{-1/2})$ called a *spinor*; in this representation, the three components of spin are represented by 2 X 2 matrices, thus:

$$s_x = \tfrac{1}{2}\hbar \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \; s_y = \tfrac{1}{2}\hbar \begin{pmatrix} 0 & -\iota \\ \iota & 0 \end{pmatrix}, \; s_z = \tfrac{1}{2}\hbar \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The three 2 X 2 matrices appearing in these formulae are called the *Pauli matrices* and are denoted by $\sigma_x, \sigma_y, \sigma_z$.

In recent years, much thought has been given to the problem of constructing Schrödinger equations for the fundamental particles, which remain unchanged in form when subjected to the group of Lorentz transformations of special relativity theory. Dirac's equation for the electron is one such equation. The fields governed by these equations have themselves been treated as physical systems and quantized, thus leading to a quantum theory of fields. The symmetry of these fields under rotations and other transformations has been fully exploited by the application of group theory and the properties of Lie algebras. Details will be found in Ref. 10 of the bibliography below.

MATRICES

Matrix notation and operations are introduced into theoretical physics so that algebraic equations and expressions in terms of rectangular arrays of numbers can be systematically handled.

An $m \times n$ matrix $\mathbf{A} = (a_{ij})$ possesses m rows and n columns, having in double suffix notation the mn elements arranged to the form

$$\mathbf{A} = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ \cdot & \cdot & \cdots & \cdot \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{pmatrix}.$$

The general element a_{ij} may be a complex number. If all elements are zero, $\mathbf{A}$ is the null matrix $\mathbf{O}$ or 0. When $n = 1$, the matrix is a column vector $\mathbf{v}$. If $m = n$, $\mathbf{A}$ is square of order n; if all elements not on the leading diagonal a_{11}, a_{22}, $\cdots$, a_{nn} are zero, the matrix is a diagonal matrix $\mathbf{D}$, while $\mathbf{D}$ is the unit matrix $\mathbf{I}$ if

$$a_{11} = a_{22} = \cdots = a_{nn} = 1.$$

The sum or difference of two $m \times n$ matrices $\mathbf{A}$ and $\mathbf{B}$ is an $m \times n$ matrix $\mathbf{C} = \mathbf{A} \pm \mathbf{B}$, where $c_{ij} = a_{ij} \pm b_{ij}$. The elements of $\alpha\mathbf{A}$ are αa_{ij}.

The transpose of $\mathbf{A}$ is denoted by $\mathbf{A}^T$; this is an $n \times m$ matrix whose ith row and jth column are identical respectively with the ith column and jth row of $\mathbf{A}$. Hence $\mathbf{v}^T$ is a row matrix with m elements. For convenience, the column $\mathbf{v}$ is often printed as a row with braces, $\{v_1\ v_2 \cdots v_m\}$.

The product $\mathbf{C} = \mathbf{AB}$ is only defined when the number of columns of $\mathbf{A}$ equals the number of rows of $\mathbf{B}$; $\mathbf{A}$ and $\mathbf{B}$ are then conformable for multiplication. If $\mathbf{A}$ is $m \times n$ and $\mathbf{B}$ is $n \times p$, then $\mathbf{C}$ is $m \times p$, with

$$c_{ij} = \sum_{k=1}^{n} a_{ik}\, b_{kj}.$$

Generally, multiplication is not commutative, but it is always associative. The transpose of a product is given by $(\mathbf{ABC})^T = \mathbf{C}^T\mathbf{B}^T\mathbf{A}^T$.

If $\mathbf{A}$ is square, then $\mathbf{A}$ is symmetric if $\mathbf{A} = \mathbf{A}^T$, while if $\mathbf{A} = -\mathbf{A}^T$ it is skew-symmetric. A quadratic form S_A in the n variables contained in the column $\mathbf{x} = \{x_1\ x_2 \cdots x_n\}$ may be written as $S_A = \mathbf{x}^T\mathbf{A}\mathbf{x}$, where $\mathbf{A}$ is symmetric.

Let $\det \mathbf{A} \equiv |\mathbf{A}|$ denote the determinant of the square matrix $\mathbf{A}$. If $\det \mathbf{A} \neq 0$, $\mathbf{A}$ is non-singular. Then the definition of matrix multiplication ensures that

$$\det(\mathbf{AB}) = \det \mathbf{A} \det \mathbf{B}$$

where $\mathbf{A}$ and $\mathbf{B}$ are square matrices of the same order.

The cofactor of a_{ij} in the square matrix $\mathbf{A}$ equals $(-1)^{i+j}$ times the determinant formed by crossing out the ith row and jth column in $\mathbf{A}$. The sum of the n elements in any row (or column) multiplied respectively by their cofactors equals $\det \mathbf{A}$; the sum of the n elements in any row (or column) multiplied respectively by the cofactors of another row (or column) equals zero. We have

$$\det \mathbf{A}^T = \det \mathbf{A}; \qquad \det \alpha\mathbf{A} = \alpha^n \det \mathbf{A}.$$

The adjoint of $\mathbf{A}$, denoted by adj $\mathbf{A}$, is the transpose of the matrix formed when each element of $\mathbf{A}$ is replaced by its cofactor. We have

$$\mathbf{A}\ \mathrm{adj}\ \mathbf{A} = (\mathrm{adj}\ \mathbf{A})\mathbf{A} = (\det \mathbf{A})\mathbf{I}$$

and $\det(\mathrm{adj}\ \mathbf{A}) = |\mathbf{A}|^{n-1}$. The unique reciprocal or inverse of a non-singular matrix $\mathbf{A}$ is given by

$$\mathbf{A}^{-1} = (\mathrm{adj}\ \mathbf{A})/\det \mathbf{A}.$$

This has the property that $\mathbf{AA}^{-1} = \mathbf{A}^{-1}\mathbf{A} = \mathbf{I}$. It follows that

$$(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$$

and

$$(\mathbf{A}^{-1})^T = (\mathbf{A}^T)^{-1}.$$

Linear equations relating n variables x_i to n variables y_i may be expressed as $\mathbf{x} = \mathbf{Ay}$; if $\det \mathbf{A} \neq 0$, the unique solution for the y_i in terms of the x_i is $\mathbf{y} = \mathbf{A}^{-1}\mathbf{x}$.

The rank of an $m \times n$ matrix $\mathbf{A}$ is the order of the largest non-vanishing minor within $\mathbf{A}$; of the m linear expressions $\mathbf{Ax}$, the rank gives the number that are linearly independent. The m linear equations in n unknowns $\mathbf{Ax} = \mathbf{d}$, where $\mathbf{d}$ is a column with m elements, are consistent if the rank of $\mathbf{A}$ equals the rank of the augmented matrix $(\mathbf{A}\ \mathbf{d})$.

If the m linear equations $\mathbf{Ax} = \mathbf{d}$ are inconsistent in the n unknowns $x_1, x_2, \cdots, x_n$, where

$n < m$ and rank $\mathbf{A} = n$, there the "best" solution for these n unknowns in the least squares sense is given by the normal equations

$$\mathbf{A}^T\mathbf{A}\mathbf{x} = \mathbf{A}^T\mathbf{d}$$

$\mathbf{A}^T\mathbf{A}$ being non-singular when rank $\mathbf{A} = n$.

An $n \times n$ matrix Λ is orthogonal if $\Lambda^T\Lambda = \mathbf{I}$, that is, if $\Lambda^{-1} = \Lambda^T$. Clearly, $|\Lambda| = \pm 1$. If $\mathbf{c}_i$ denotes the ith column of Λ, then $\mathbf{c}_i{}^T\mathbf{c}_i = 1$ and $\mathbf{c}_i{}^T\mathbf{c}_j = 0$ if $i \neq j$; similar results hold for the rows. The transformation $\mathbf{x}' = \Lambda\mathbf{x}$ represents a rotation of rectangular Cartesian axes in three dimensions; $|\Lambda| = +1$ if the right-handed character is preserved. The element λ_{ij} equals the cosine of the angle between the $x_i{}'$ and x_j axes. If $\mathbf{N}$ is skew-symmetric, then

$$(\mathbf{I} + \mathbf{N})^{-1}(\mathbf{I} - \mathbf{N})$$

is orthogonal.

Matrices with complex elements are manipulated according to the same rules. A square matrix $\mathbf{H}$ is Hermitian if $\mathbf{H}^{*T} = \mathbf{H}$, and skew-Hermitian if $\mathbf{H}^{*T} = -\mathbf{H}$, a star denoting the complex conjugate. A unitary matrix $\mathbf{U}$ satisfies $\mathbf{U}^{*T} = \mathbf{U}^{-1}$, the columns (and rows) enjoying the properties $\mathbf{c}_i{}^{*T}\mathbf{c}_j = 1$ if $i = j$ and 0 if $i \neq j$. If $\mathbf{N}$ is skew-Hermitian, then $(\mathbf{I} + \mathbf{N})^{-1}(\mathbf{I} - \mathbf{N})$ is unitary.

First- and second-order tensors, arising in many physical problems, may be expressed in matrix notation. If $\mathbf{x}' = \Lambda\mathbf{x}$ denotes a rotation of rectangular Cartesian axes, Λ being orthogonal, then $\mathbf{f}' = \Lambda\mathbf{f}$ and $\mathbf{F}' = \Lambda\mathbf{F}\Lambda^T$ define Cartesian tensors of orders 1 and 2 respectively. Evidently, if $\mathbf{u}$ and $\mathbf{v}$ are vectors or tensors of order 1, then $\mathbf{u}^T\mathbf{v}$ is the invariant scalar product, $\mathbf{Fu}$ is a tensor of order 1 and $\mathbf{uv}^T$ is a tensor of order 2. For example, the vector product $\mathbf{u} \times \mathbf{v}$ may be written as $\mathbf{Uv}$, where

$$\mathbf{U} = \begin{pmatrix} 0 & -u_3 & u_2 \\ u_3 & 0 & -u_1 \\ -u_2 & u_1 & 0 \end{pmatrix}.$$

$\mathbf{U}$ is a tensor of order 2 if $\mathbf{u}$ is a vector; $\mathbf{U}^T$ is the dual of $\mathbf{u}$.

The differential operator (column)

$$\boldsymbol{\nabla} \equiv \left\{\frac{\partial}{\partial x_1}, \frac{\partial}{\partial x_2}, \frac{\partial}{\partial x_3}\right\}$$

is a vector or tensor of order 1; namely

$$\boldsymbol{\nabla} = \Lambda\boldsymbol{\nabla}.$$

Thus if ϕ is a scalar and $\mathbf{f}$ a vector,

$$\text{grad } \phi \equiv \boldsymbol{\nabla}\phi \text{ is a vector}$$

$$\text{div } \mathbf{f} \equiv \boldsymbol{\nabla}^T\mathbf{f} \text{ is a scalar}$$

$$\text{curl } \mathbf{f} \equiv \boldsymbol{\nabla}\mathbf{f} \text{ is a vector.}$$

But if $\mathbf{x}' = \mathbf{Ax}$, where $\mathbf{A}$ is not orthogonal, $\mathbf{f}' = \mathbf{Af}$ defines a contravariant vector, but $\mathbf{g}' = \mathbf{A}^{T-1}\mathbf{g}$ defines a covariant vector. The product $\mathbf{g}^T\mathbf{f}$ is now an invariant.

If $\mathbf{A}$ is square of order n, then the n homogeneous equations $\mathbf{Ak} = \lambda\mathbf{k}$ require

$$\det(\mathbf{A} - \lambda\mathbf{I}) = 0$$

for non-trivial solutions. This characteristic equation possesses n characteristic or latent roots; if they are all distinct, n corresponding characteristic or latent vectors exist. The vector $\mathbf{k}_i$ corresponding to the root λ_i may consist of the n cofactors of any row of $\mathbf{A} - \lambda_i\mathbf{I}$; at least one non-trivial row exists.

The Cayley-Hamilton theorem states that a square matrix $\mathbf{A}$ satisfies its own characteristic equation.

The following properties are important. If $\mathbf{A}$ is real and symmetric, and if λ_i and λ_j are distinct, then $\mathbf{k}_i{}^T\mathbf{k}_j = 0$; these two vectors are orthogonal. Again, if $\mathbf{A}$ is real and symmetric, the n values of λ are real, but if $\mathbf{A}$ is real and skew-symmetric, these n values are pure imaginary. For a real orthogonal matrix Λ, $|\lambda_i| = 1$ for all i. The characteristic roots of $\mathbf{A}^{-1}$ are $1/\lambda_i$, $\mathbf{k}_i$ still being the corresponding vectors. If $|\lambda_1|$ is the largest of the moduli of the n roots, then as $r \to \infty$, $\mathbf{A}^r\mathbf{x} \to \mathbf{k}_1$, where $\mathbf{x}$ is an arbitrary column.

If $\mathbf{A}$ is symmetric, n mutually orthogonal characteristic vectors may be found even if the roots are not all distinct. If each vector $\mathbf{k}_i$ is normalized, i.e., divided by $\sqrt{(\mathbf{k}_i{}^T\mathbf{k}_i)}$, then the matrix

$$\Lambda = (\mathbf{k}_1\ \mathbf{k}_2 \cdots \mathbf{k}_n)$$

is orthogonal, and the product $\Lambda^T\mathbf{A}\Lambda$ equals $\mathbf{D}$, the diagonal matrix consisting of the n roots arranged down its leading diagonal in order. The matrix $\mathbf{A}$ is said to be diagonalized, and $\mathbf{D}$ is the canonical form of $\mathbf{A}$.

More generally, if $\mathbf{A}$ is a general square matrix of order n, then n independent vectors $\mathbf{k}_i$ may be found corresponding to the n roots if the latter are distinct. Then

$$\mathbf{T} = (\mathbf{k}_1\ \mathbf{k}_2 \cdots \mathbf{k}_n)$$

transforms $\mathbf{A}$ into diagonal form, thus:

$$\mathbf{T}^{-1}\mathbf{AT} = \mathbf{D}.$$

If some of the characteristic roots are identical, it may or may not be possible to find n corresponding independent columns (though it is always possible when $\mathbf{A}$ is symmetric). If it is possible, $\mathbf{T}$ is non-singular, and as before

$$\mathbf{T}^{-1}\mathbf{AT} = \mathbf{D}.$$

If this is not possible, there still exists a distinct non-singular matrix $\mathbf{T}$ such that

$$\mathbf{T}^{-1}\mathbf{AT} = \mathbf{C},$$

where **C**, no longer diagonal, is the standard canonical form of **A**, containing submatrices of the form

$$\begin{pmatrix} \lambda & 1 & 0 \\ 0 & \lambda & 1 \\ 0 & 0 & \lambda \end{pmatrix}$$

corresponding to the repeated roots.

In each case, respectively,

$$\mathbf{A}^n = \mathbf{T}\,\mathbf{D}^n\mathbf{T}^{-1} \quad \text{or} \quad \mathbf{T}\,\mathbf{C}^n\mathbf{T}^{-1}.$$

This enables us to define functions of square matrices whose canonical forms are diagonal, namely, if $\mathbf{A} = \mathbf{T}\,\mathbf{D}\,\mathbf{T}^{-1}$. If

$$f(x) = \sum_{r=0}^{\infty} a_r x^r$$

is convergent for $|x| < R$, then define

$$\begin{aligned} f(\mathbf{A}) &= \sum_{r=0}^{\infty} a_r \mathbf{A}^r \\ &= \mathbf{T}\left(\sum_{r=0}^{\infty} a_r \mathbf{D}^r\right)\mathbf{T}^{-1} \\ &= \mathbf{T}\begin{pmatrix} f(\lambda_1) & 0 & \cdots \\ 0 & f(\lambda_2) & \cdots \\ \cdot & \cdot & \cdots \end{pmatrix}\mathbf{T}^{-1} \end{aligned}$$

provided $|\lambda_1|, |\lambda_2|, \cdots, |\lambda_n| < R$. Thus, for example, if

$$\mathbf{J} = \begin{pmatrix} 0 & \theta \\ -\theta & 0 \end{pmatrix}$$

then

$$e^{\mathbf{J}} = \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix}.$$

Similar remarks apply to Hermitian matrices **H**. If $\mathbf{Hk} = \lambda\mathbf{k}$, all the n values of λ are real and n vectors can always be found such that

$$\mathbf{k}_i{}^{*T}\mathbf{k}_j = \delta_{ij}.$$

The unitary matrix $\mathbf{U} = (\mathbf{k}_1\ \mathbf{k}_2 \cdots \mathbf{k}_n)$ transforms **H** into diagonal form.

Two quadratic forms $S_A = \mathbf{x}^T\mathbf{A}\mathbf{x}$, $S_B = \mathbf{x}^T\mathbf{B}\mathbf{x}$, where **A** and **B** are symmetric and of the same order, may be reduced simultaneously to sums of squares. The equations $\mathbf{Ak} = \lambda\mathbf{Bk}$ demand $\det(\mathbf{A} - \lambda\mathbf{B}) = 0$; this possesses n roots λ_i and n corresponding vectors $\mathbf{k}_i$. If

$$\mathbf{T} = (\mathbf{k}_1\ \mathbf{k}_2 \cdots \mathbf{k}_n)$$

then $\mathbf{T}^T\mathbf{A}\mathbf{T}$ and $\mathbf{T}^T\mathbf{B}\mathbf{T}$ are both diagonal. The transformation $\mathbf{x} = \mathbf{Ty}$ yields the two sums of squares $S_A = \mathbf{y}^T(\mathbf{T}^T\mathbf{AT})\mathbf{y}$ and $S_B = \mathbf{y}^T(\mathbf{T}^T\mathbf{BT})\mathbf{y}$. In particular, if S_A is positive definite, $\mathbf{T}^T\mathbf{AT}$ will equal **I** if new columns $\bar{\mathbf{k}}_i$ are used in **T**, where $\bar{\mathbf{k}}_i = \mathbf{k}_i/\sqrt{(\mathbf{k}_i{}^T\mathbf{A}\mathbf{k}_i)}$.

Necessary and sufficient conditions for the real quadratic form S_A to be positive definite for all real $\mathbf{x} \neq 0$ are that the n determinants

$$a_{11}, \quad \begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix}, \quad \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix}, \ldots, \det \mathbf{A}$$

should be positive. This ensures that the n characteristic roots of **A** are all positive.

Finally, matrices may often usefully be partitioned employing matrices within matrices. Multiplication may still be performed provided each individual matrix product is permissible. For example,

$$\begin{pmatrix} a & \mathbf{b}^T \\ \mathbf{c} & \mathbf{D} \end{pmatrix}\begin{pmatrix} e & \mathbf{f}^T \\ \mathbf{g} & \mathbf{H} \end{pmatrix} = \begin{pmatrix} ae + \mathbf{b}^T\mathbf{g} & a\mathbf{f}^T + \mathbf{b}^T\mathbf{H} \\ \mathbf{c}e + \mathbf{Dg} & \mathbf{c}\mathbf{f}^T + \mathbf{DH} \end{pmatrix}$$

where a, e are scalars, **b**, **c**, **f**, **g** are 1 × 3 columns and **D**, **H** are 3 × 3.

Applications *Differential Equations* If

$$d\mathbf{x}/dt + \mathbf{Ax} = \mathbf{f},$$

A being constant and

$$\mathbf{f} = \{f_1(t),\ f_2(t), \ldots,\ f_n(t)\},$$

then if **T** diagonalizes **A**, $\mathbf{x} = \mathbf{Ty}$ yields n non-simultaneous equations $d\mathbf{y}/dt + \mathbf{Dy} = \mathbf{T}^{-1}\mathbf{f}$. If $\mathbf{y}_0(t)$ is a particular integral,

$$\mathbf{x}(t) = \mathbf{T}\begin{pmatrix} e^{-\lambda_1 t} \cdots & 0 \\ \cdot \quad \cdots & \cdot \\ 0 \quad \cdots & e^{-\lambda_n t} \end{pmatrix}$$

$$\times\ [\mathbf{T}^{-1}\mathbf{x}(0) - \mathbf{y}_0(0)] + \mathbf{T}\mathbf{y}_0(t).$$

Geometry. In three-dimensional Cartesian coordinates,

$$\mathbf{a}^T\mathbf{x} + d = 0$$

represents a plane, the perpendicular distance from $\mathbf{x}_1$ being

$$(\mathbf{a}^T\mathbf{x}_1 + d)/\sqrt{(\mathbf{a}^T\mathbf{a})}.$$

The equation $\mathbf{x}^T\mathbf{A}\mathbf{x} = d$ represents a central quadric. If Λ diagonalizes **A**, the rotation

$$\mathbf{x} = \Lambda\mathbf{x}'$$

yields $\mathbf{x}'^T\mathbf{D}\mathbf{x}' = d$. The vectors $\mathbf{k}_1$, $\mathbf{k}_2$, $\mathbf{k}_3$ specify the three principal axes, of semi-lengths $\sqrt{(d/\lambda_i)}$ when $d/\lambda_i > 0$.

Dynamics. The rotational equations of motion of a rigid body with respect to moving axes fixed in the body and with the origin fixed in space or at the centre of mass are

$$\mathbf{g} = \mathbf{J}\dot{\omega} + \Omega\mathbf{J}\omega$$

where $\mathbf{g}$ = couple, ω = angular velocity, Ω^T = dual ω. $\mathbf{J}$ denotes the inertia tensor $-\Sigma m\mathbf{XX}$, where $\mathbf{X}^T$ = dual $\mathbf{x}$. Explicitly,

$$\mathbf{J} = \begin{pmatrix} A & -H & -G \\ -H & B & -F \\ -G & -F & C \end{pmatrix}.$$

The rotational kinetic energy is $\frac{1}{2}\omega^T\mathbf{J}\omega$. When principal axes of inertia are chosen, $\mathbf{J}$ is diagonal, yielding Euler's equations.

Small oscillations about a position of equilibrium are investigated by considering the second order approximations

$$K.E. = \dot{\mathbf{q}}^T\mathbf{A}\dot{\mathbf{q}}, \quad P.E. = \mathbf{q}^T\mathbf{B}\mathbf{q},$$

$\mathbf{q}$ containing n generalized coordinates measured from their equilibrium values. $\mathbf{A}$ and $\mathbf{B}$ are constant symmetric matrices. If the n roots of $\det(\mathbf{A} + \lambda\mathbf{B}) = 0$ are considered, and if $\mathbf{q} = \mathbf{Tx}$, where $\mathbf{T} = (\mathbf{k}_1 \ \mathbf{k}_2 \cdots \mathbf{k}_n)$ reduces $\mathbf{A}$ to the unit matrix $\mathbf{I}$, the equations of motion are

$$\ddot{x}_i + (1/\lambda_i)x_i = 0.$$

The elements of $\mathbf{x}$ are the *normal coordinates*; each individual solution x_i in terms of the q's is a *normal mode of* period $2\pi\sqrt{\lambda_i}$.

Electromagnetic Theory. Maxwell's 3 × 3 stress tensor in matrix notation is

$$\mathbf{T} = \tfrac{1}{2}\left[2\epsilon\mathbf{ee}^T + 2\mu\mathbf{hh}^T - \epsilon(\mathbf{e}^T\mathbf{e})\mathbf{I} - \mu(\mathbf{h}^T\mathbf{h})\mathbf{I}\right]$$

in mks rationalized units. The field exerts a force across an area element $\mathbf{n}\delta S$ equal to $\mathbf{Tn}\,\delta S$.

When electromagnetic waves are propagated in an ionized medium the equation

$$\text{curl curl } \mathbf{e} = k^2(\mathbf{I} + \mathbf{M})\mathbf{e}$$

arises, where

$$\mathbf{M} = -X(Y^2\mathbf{nn}^T + iY\mathbf{N} - \mathbf{I})/(Y^2 - 1)$$

in the usual notation with collisions neglected; here, $\mathbf{n}$ = unit vector directed along the external magnetic field, $\mathbf{N}_T$ = dual $\mathbf{n}$. These equations may be rearranged in terms of the matrix

$$\mathbf{f} = \{E_x, -E_y, Z_0H_x, Z_0H_y\}$$

giving $d\mathbf{f}/dz = -ik\mathbf{Tf}$, where $\mathbf{T}$ is a 4 × 4 matrix. If the characteristic roots $\lambda_i(z)$ of $\mathbf{T}$ are found, and if $\mathbf{R}$ diagonalizes $\mathbf{T}$, then the transformation $\mathbf{f} = \mathbf{Rg}$ yields

$$\frac{d\mathbf{g}}{dz} = -ik\mathbf{Dg} - \mathbf{R}^{-1}\frac{d\mathbf{R}}{dz}\,\mathbf{g}.$$

When $\mathbf{k}$ is large, approximate solutions are possible if the terms of $\mathbf{R}^{-1}(d\mathbf{R}/dz)\,\mathbf{g}$ arising from the non-diagonal elements of $\mathbf{R}^{-1}(d\mathbf{R}/dz)$ are much smaller in magnitude than the corresponding elements of $k\mathbf{Dg}$. Then

$$\frac{dg_j}{dz} \doteqdot -ikD_jg_j - \left(\mathbf{R}^{-1}\frac{d\mathbf{R}}{dz}\right)_{jj} g_j$$

and

$$g_j \doteqdot \exp\left(-ik\int D_j\,dz\right) \cdot \exp\left[-\int\left(\mathbf{R}^{-1}\frac{d\mathbf{R}}{dz}\right)_{jj} dz\right]$$

giving rise to the characteristic waves propagating in the medium.

Special Relativity. If $\mathbf{x} = \{ict, x, y, z\}$ refers to an inertial frame S, and if a second parallel frame S' has uniform relative velocity U along Ox, the Lorentz transformation is $\mathbf{x}' = \Lambda_U\mathbf{x}$, where

$$\Lambda_U = \begin{pmatrix} \beta & -iU\beta/c & 0 & 0 \\ iU\beta/c & \beta & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Λ is orthogonal, and $\beta = 1/\sqrt{(1 - U^2/c^2)}$. We have $\Lambda_V\,\Lambda_U = \Lambda_W$, where

$$W = (U + V)/(1 + UV/c^2).$$

For the general velocity $\mathbf{v}$ relating parallel frames,

$$\Lambda = \begin{pmatrix} \beta & -i\beta\mathbf{v}^T/c \\ i\beta\mathbf{v}/c & \mathbf{I} + (\beta - 1)\mathbf{vv}^T/v^2 \end{pmatrix}.$$

The operator $\square = \{\partial/ic\partial t, \partial/\partial x, \partial/\partial y, \partial/\partial z\}$ is a four vector satisfying $\square' = \Lambda\square$; so are the four-current $\mathbf{i}$ and the four-potential $\mathbf{b}$,

$$\mathbf{i} = \begin{pmatrix} ic\rho \\ \mathbf{j} \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} i\phi/c \\ \mathbf{a} \end{pmatrix}$$

where $\mathbf{a}$ is the vector potential. They satisfy $\square^T\mathbf{i} = 0$ (conservation of charge), $\square^T\mathbf{b} = 0$ (the Lorentz relation). Maxwell's equations in mks units in free space take the form

$$\square^T\mathbf{F} = -\mathbf{i}^T/\epsilon_0c^2$$

$$\square^T\mathbf{G} = 0$$

where

$$\mathbf{F} = \square\mathbf{b}^T - (\square\mathbf{b}^T)^T = \begin{pmatrix} 0 & i\mathbf{e}^T/c \\ -i\mathbf{e}/c & -\mu_0\mathbf{H} \end{pmatrix}$$

and

$$\mathbf{G} = \begin{pmatrix} 0 & \mu_0 \mathbf{h}^T \\ -\mu_0 \mathbf{h} & -i\mathbf{E}/c \end{pmatrix}$$

are tensors of order 2 under a Lorentz transformation. $\mathbf{E}^T$ and $\mathbf{H}^T$ are the respective 3 X 3 duals of **e** and **h**. All tensor equations are invariant in form in all frames of reference.

The tensor of order 2

$$\begin{aligned} \mathbf{T} &= \tfrac{1}{2}\epsilon_0 c^2 \mathbf{F}\,\mathbf{F} - \tfrac{1}{2}\mu_0{}^{-1}\mathbf{G}\,\mathbf{G} \\ &= \tfrac{1}{2}\begin{pmatrix} \epsilon_0\,\mathbf{e}^T\mathbf{e} + \mu_0\mathbf{h}^T\mathbf{h} & -2i\mathbf{e}^T\mathbf{H}/c \\ -2i\mathbf{E}\mathbf{h}/c & \epsilon_0\mathbf{e}\mathbf{e}^T + \epsilon_0\,\mathbf{E}\mathbf{E} + \mu_0\,\mathbf{h}\mathbf{h}^T + \\ & \mu_0\,\mathbf{H}\mathbf{H} \end{pmatrix} \end{aligned}$$

contains the energy density, Poynting's vector, the momentum density and Maxwell's stress tensor in partitioned form.

Applications may likewise be made to circuit theory, to elasticity where 3 X 3 stress and strain tensors are defined, and to quantum mechanics, embracing, for example, matrix mechanics and the Dirac wave equation of the electron.

MEASUREMENTS, PRINCIPLES OF

Measurement is the process of quantifying our experience of the world around us. It can be as simple as an elementary event-counting process (the number of automobiles passing a certain point per day or the number of β-particles entering a certain radiation detector in a certain time interval) but it is usually a more complex process involving comparison with some reference. For example, how many handspans wide is my desk? This is an elementary example, but even such a simple question reveals many of the essential and fundamental characteristics of measuring processes. First, the search for improved precision quickly makes desirable the acceptance of a standard reference quantity. Second, the primitive process of comparison makes it clear that we can make statements about the measurement only within certain limits. (My desk is between 6 and 7 handspans wide). Our fundamental inability to make exact measurements leads to the concept of uncertainty, and a very extensive theory of the uncertainty of measurement exists.

Measurement Standards Standard, defined units of measurement have been in use for many thousands of years and the situation has been in continuous flux up to the present day. Every country maintains standards of measurement, not only of the basic quantities such as mass, length and time, which we normally think of in this context, but also of a large number of other items (such as the optical reflectivity of paper) which have been identified as important for trade and commerce. We shall restrict ourselves here to a few physical quantities which are important in scientific work. It will turn out that it may be a relatively simple matter to define a unit; it is usually a much more difficult problem to realize that unit in the laboratory so as to make possible the calibration of other instruments.

(a) *Mass.* The kilogram was defined in 1889 as the mass of a certain piece of metal (platinum-iridium) still preserved at the International Bureau of Weights and Measures near Paris, France. Copies of this prototype kilogram, compared with the original by carefully refined beam balance techniques, are kept in most countries to serve as that country's definition of a kilogram. The normal process of comparison using beam balances allows a precision for mass standards of around one part in 10^8, making mass standards substantially less precise than those of length and time.

(b) *Length.* The original 1889 definition of the meter (chosen to be one ten millionth part of the quadrant of the earth's surface at the longitude of Paris) was realized initially using engraved marks on a platinum-iridium bar. However, it very soon thereafter became clear, on the basis of the pioneering work of A. A. Michelson on optical interferometry, that a much much more precise, stable, and easily realizable standard was available using the wavelength of carefully selected spectrum lines. Despite Michelson's early suggestions to that effect it was not until 1960 that an international standard of length was defined in terms of the wavelength of a certain line in the spectrum of krypton-86. Recently, however, it has become clear that even the precision available from the krypton-86 line has been surpassed by precision in two other areas, measurements of the velocity of light and the standard of time. As a consequence it is now possible to define a unit of length in terms of the unit of time and the measurement of the velocity of electromagnetic waves. As accepted by the General Conference of Weights and Measures in 1983, the unit of length is the distance traveled in a time interval of 1/299,792,458 of a second by plane electromagnetic waves in a vacuum. Such a unit will be realizable in any laboratory with precise time standards, and will be translatable into actual distance measurements using standard techniques of interferometry.

(c) *Time.* For hundreds of years the most precise measurements of time were made by the astronomers, whose observations served to define the basic unit of time, the second, in terms of the axial rotation of the earth. When terrestrial clock systems achieved the precision required to show that the earth's rotation rate is not constant it became clear that replacement of the defined standard was necessary. Observations on the radiation frequency in atomic transitions can be made with very high precision and the present definition of the second (adopted in 1967) is the duration of 9,192,631,770 periods of the radiation associated with a certain transition in the cesium-113 atom. Cesium beam clocks now provide a realizable standard of time, not only for time-keeping, but also for practical purposes such as radio navigation systems and for experimental work like long baseline interferometry in radioastronomy.

(d) *Temperature.* The definition of temperature is based on the triple point of water, which was defined in 1954 to have a temperature of 273.16 K. The unit of temperature, the kelvin, is thus defined (since 1967) is as 1/273.16 of the temperature of the triple point of water. The realization of a temperature scale, particularly over wide temperature ranges, is a much more difficult matter. In practice the standards laboratories maintain a working scale called the International Practical Temperature Scale, 1968 (abbreviated IPTS-68). In this, thirteen fixed points have temperatures assigned to them and specified methods of measurement are used to provide intermediate temperatures for calibration purposes. Above the temperature of freezing gold (1337 K) optical pyrometry is used; between 903 K and 1337 K the standard measuring device is a thermocouple of platinum and an alloy of platinum with 10% rhodium; between 14 K and 903 K it is a platinum resistance thermometer. Standard temperatures are also available in the liquid helium temperature range between 0.5 K and 4.2 K using the vapor pressure of helium.

(e) *Electrical Quantities.* Once again we have a distinction between the fundamental definition of a standard quantity and its practical realization. In principle the fundamental electrical quantity is the unit of current (the ampere), which is defined in terms of the force between adjacent current-carrying conductors. In practice it is too difficult to implement this definition with sufficient precision, and the practical standards are those of potential difference and resistance. The unit of potential difference (the volt) is defined in terms of the Josephson effect, a phenomenon occurring in superconducting junctions, which provides an extremely sensitive, precise, and stable connection between potential difference and frequency. The practical realization of the volt is a bank of carefully preserved electrolytic cells which can be moved for international comparison and which are checked periodically for drift using a Josephson source. The standard of resistance (the ohm) is realized using a bank of 1 ohm resistors which can be compared internally and internationally.

Measurement Uncertainty As was mentioned earlier the primitive act of comparison between an object and a reference quantity leads to a value which is known only within a certain interval. No matter how sophisticated the measuring process we cannot evade this fundamental limitation; we can be confident about measurements only within a certain interval. The way in which we handle these uncertainties mathematically depends on the way in which our confidence varies along the scale.

(a) *Estimated Uncertainty.* If we are making our measurements by a personal, visual method, the outcome of the measuring process should be an interval, outside which we are certain the value does not lie. If, by careful examination of a scale, we feel confident that the value we seek does not lie below 24.6 and does not lie above 24.8, we can state that we are confident that our desired value lies inside the interval 24.6–24.8, although we can say nothing about its location within the interval. The interval is usually renamed 24.7 ± 0.1, and we call the quantity ±0.1 the *uncertainty* of the reading. Frequently it is instructive to compare this uncertainty with the reading itself, and we call the ratio 0.1/24.7, usually expressed as a percentage, the *precision* of the measurement. This question of the uncertainty in reading a scale is only one contribution to our lack of exact knowledge of the value. There may be other effects, like calibration errors in the instrument, which affect all the readings in a similar way and constitute systematic errors in addition to reading uncertainty. To make satisfactory measurements we must always be aware of the presence of the reading uncertainty and also alert to the possible presence of systematic errors. These last must be identified and corrected if possible but, at the end of the whole process, it is important to express the reading in such a way that the quoted value provides a realistic appraisal of the complete range of uncertainty.

It is rarely sufficient to make such a measurement of a single quantity and we are more commonly faced with the problem of calculating some final quantity z as a function of a number of measured quantities x, y, etc., each of which has its own uncertainty Δx, Δy, etc. If

$$z = f(x, y, \ldots),$$

the value of Δz will be calculated from

$$\Delta z = (\partial f/\partial x)\Delta x + (\partial f/\partial y)\Delta y + \ldots.$$

If we were confident that the values of x and y lay within the measured intervals $x_0 \pm \Delta x$, $y_0 \pm \Delta y$, etc., then we can be equally confident that the value of z lies within the calculated interval $z_0 \pm \Delta z$, where $z_0 = f(x_0, y_0, \ldots)$. This general method of calculating uncertainties will be found to be useful for a wide range of functions.

Statistical Uncertainty Circumstances frequently do not permit the subjective estimation of an uncertainty interval as considered in the preceding section. Many measurement processes give results which are influenced by random fluctuations and we must resort to statistical treatment of the observations. Instead of identifying an interval within which we are confident our quantity lies we must be content with statements about probabilities. To make this possible we must build up experience of a fluctuating phenomenon by repeatedly making the measurement. We shall thereby obtain a sample of readings whose characteristics will give us as much information as is available from the system. This sample will have a certain frequency distribution along the scale of values and the uncertainty of the measuring process is related to the breadth of the distribution. One suitable measure of the breadth is the standard deviation of the sample, defined to be

$$S = \sqrt{\left[\sum (\bar{x} - x_i)^2 / N\right]},$$

where $\bar{x}$ is the mean of the sample, x_i are the individual readings, and N is the number of readings in the sample. By making suitable assumptions about the basic distribution from which the sample was taken (often assumed to be Gaussian), we can now make numerical assertions about the sample. It turns out that any one reading has a 68% probability of falling within the interval $\bar{x} \pm S$ and a 95% probability of falling within $\bar{x} \pm 2S$. Rather than make assertions about single readings it is more useful to be able to make statements about probabilities for the sample mean. We calculate the standard deviation of the mean

$$S_m = S/\sqrt{N}$$

and we are then able to assert that the value we seek in the measuring process has a 68% chance of falling within the interval $\bar{x} \pm S_m$ and a 95% chance of falling within $\bar{x} \pm 2S_m$. The mean and the standard deviation of the mean thus provide us with measures of probability which take us as far as randomly fluctuating phenomena allow.

The statistically determined interval serves as the measure of uncertainty for processes governed by random fluctuation so that, irrespective of the type of measurement, the outcome of the measuring process is an interval which has a certain probability of containing the value we seek. The measurements are now in suitable condition for the next step in a complete measuring process.

Systems and Models A measuring process is almost never a primitive process of simply comparing an object with a scale (unless we are satisfied simply to measure something with a ruler or read a temperature on a mercury-in-glass thermometer); the situation is almost invariably more complicated. Even if we are doing something as simple as comparing the weight of an object with that of a standard mass using a beam balance we have to make the assumption that the balance beam arms are of equal length. Our measuring process almost invariably involves some complete system and the result of our measuring process is dependent on the properties of the system. Since we can never know these exactly we are dependent on the set of assumptions we make about the system (like the equality of the balance beam arms), and this set of assumptions constitutes a model of the system. Our process of measurement almost invariably requires us, therefore, to consider the model of the system, and it is an integral part of all satisfactory measuring processes to check, not that the model is "correct" or "true," because all models are in principle oversimplified, but that the correspondence between the model and the system is good enough, at least at the level of precision under consideration.

Sometimes this process of testing the model of a measuring system will have been done for us if we buy an expensive piece of apparatus. If we buy a good quality slide-wire potentiometer from a reputable manufacturer it may be satisfactory to assume that the set of assumptions which constitute the model of the system (such as linearity of the slide wire resistance) has been adequately tested. But if we are making up our own measurement system, it is vital to include in the process adequate provision for testing the model on which our work with the system is predicated.

It is common to do the model testing graphically. For example a measurement of the resistance of an electrical component is incomplete without a study of the complete variation of the current through and the potential difference across the component. Only if the plotted values of V and i turn out to be compatible with a straight line can we assert that the resistance of the component is constant, with a value specified by the slope of the line. Usually the model of the system is more complicated than $V = iR$ and more complicated graphical methods of checking the model against the system are needed. In compensation, however, the value we seek as the objective of the experiment will usually be obtained from the graph, so that drawing the graph serves the dual purpose of checking the compatibility of the system and the model and of providing a computational procedure for obtaining the answer. Even when the measurements in an experiment are processed completely analytically (using a least squares procedure, for example, to fit a function to the observations), it is important not to forget the basically graphical nature of the process.

Measurement Systems The demands of modern experimenting and the availability of automatic data processing methods have recently revolutionized measuring methods. It is now common to think of a complete measuring system containing: (a) a conversion stage which may be desirable to convert the basic quantity under investigation into some other form more amenable to measurement; (b) a sensor, detector, or transducer stage to provide for conversion into an electrical signal; (c) a signal processing system to perform on the signal any necessary mathematical computations; (d) an output stage for display, storage, or telemetry of the information. Let us consider each of these stages in turn.

(a) *Conversion Stage.* This is not always present but is frequently necessary if it is impossible or inconvenient to work directly with the phenomenon under investigation. For example a gas thermometer bulb converts temperature into pressure, a moving coil ammeter converts currents into angles, a slide wire potentiometer converts values of potential difference into lengths, a prism, diffraction grating, or crystal converts the wavelength of electromagnetic radiation into angles, a digital voltmeter uses a ramp method to convert a potential difference into a time measurement, a mass spectrometer converts atomic masses into magnetic field values, etc.

(b) *Sensor, Detector, or Transducer Stage.* Almost invariably we wish to process our signal by electrical methods and so some process for converting the basic phenomenon into an electrical signal is required. Sensors are found in enormous variety depending on the type of physical phenomenon involved.

(i) Strain is measured using strain gauges, a small length of metallic or semiconducting material glued to the component under stress. Changes in length of the material are detected from the consequent alteration in electrical resistance.

(ii) Force or pressure transducers may rely on some elastic component (cantilever beam for force, membrane for pressure) to convert the force into a displacement which is then detected using strain gauges. Alternatively, a piezoelectric crystal may be used to obtain an electrical output directly.

(iii) Temperature sensors use a variety of phenomena. Gas thermometers use the change in pressure with temperature of a gas, often helium. Thermocouples produce an electrical emf directly but require careful calibration. From low temperatures up to 500 or 600 K the most commonly used junction materials are copper and constantan (an alloy of copper and nickel). At higher temperatures tungsten and tungsten alloys are used. Resistance thermometers use the change in electrical resistance with temperature of metals or semiconductors, the choice of material depending on the temperature range. Pure platinum gives high precision over a wide temperature range; germanium or ordinary carbon resistors are widely used at low temperatures; and thermistors, in which a sintered powder, generally of metallic oxides, provides rapid variation of resistance with temperature, can be made to suit a wide range of temperatures. The change in resistance which provides a measure of the temperature is commonly measured using some kind of bridge circuit. Temperatures too high for normal sensors are measured by pyrometers in which an absolute measure of the intensity of radiation at some fixed wavelength is interpreted using Planck's radiation equation to give values of temperature. Liquid-in-glass thermometers, although commonly used as an indicator of temperature, only rarely qualify for precise measurement and cannot be used as a transducer to supply an electrical output.

(iv) Optical sensors may be of several different types. The vacuum photodiode contains a surface, generally of some cesium compound, which reacts to illumination by emitting electrons which are collected by an anode. The photomultiplier tube uses successive stages of secondary electron emission in an avalanche process to provide amplification of the current. Solid state devices may be of the photoconductive type, in which the resistance of a semiconducting material such as selenium or cadmium sulfide changes with illumination, or the photovoltaic type in which a semiconducting junction produces its own emf in response to the light. The familiar "solar cell" is of this variety and usually contains a junction between silicon and a metal. Infrared detectors may be of the photoconductive or photovoltaic type. They normally use semiconducting materials or junctions involving compounds like indium antimonide or alloys containing such materials as lead, tin, and tellurium. For wavelengths which do not excite photoelectrons or for cases in which absolute measurements of intensity are required, a bolometer can be used. This device is constructed to absorb all the incident radiation, regardless of wavelength, and convert it into a temperature increase which can be measured using a thermocouple or resistance thermometer.

(v) Acoustic transducers take various forms depending on the frequency of the radiation. For ultrasonic applications at frequencies of tens of kilohertz up to megahertz a piezoelectric transducer, commonly of quartz, is used to convert the pressure fluctuation in the sound wave to an electrical signal. At the lower frequencies of the auditory region microphones can use the piezoelectric effect in materials like lead titanate ceramic or the electrostatic properties of electrets, materials possessing permanent electric polarization.

(vi) Transducers for magnetic field measurements frequently use the Hall effect, in which a current-carrying conductor exhibits a transverse potential difference when placed in a magnetic field. Hall effect probes make a sturdy component for many common measurements of magnetic field but for other applications higher sensitivity may be required. For example, airborne surveys of the earth's magnetic field are commonly carried out using a flux-gate magnetometer, which detects the out-of-balance signal produced by an external field in a carefully balanced magnetic circuit. Still higher sensitivity is available from the proton precession magnetometer. This relies on the relationship between the frequency of proton precession (often in a water sample) and the magnitude of the surrounding magnetic field, and can supply a sensitivity as low as 10^{-5} of the external field. Still higher sensitivity is available from the magnetic dependence of optical transitions in rubidium and cesium atoms in the form of the optically pumped rubidium or cesium magnetometer. For the very lowest values of magnetic field the Josephson effect in superconductors has extended the range of magnetic field measurements by many orders of magnitude. Such devices require cooling to liquid helium temperatures but make possible the measurement of magnetic field changes of the order of 10^{-12} tesla.

(vii) The various forms of ionizing radiation encountered in nuclear physics are detected by a large variety of techniques, of which some of the more common are described below.

Gas-filled tubes containing electrodes can be used under various conditions of pressure and potential difference to detect the ionization produced by fast particles or high-energy radiation photons. An ionization chamber can provide steady monitoring of particle flux densities and a similar gas-filled tube operated at higher potential constitutes a Geiger counter which provides a pulse of current for a single particle entering the counter. Scintillation counters detect individual photons of γ-rays or x-rays from the flash of visible light which is produced by passage through certain solid crystals or liquids. The solid materials are generally single crystals of organic materials such as anthracene or inorganic crystals of sodium iodide (doped with thallium). The light pulses emitted by the scintillation material are normally detected using photomultipliers. An enormous advantage of the use of a scintillation counter lies in the fact that the magnitude of the current pulse is closely proportional to the energy of the x-ray or γ-ray photon. These crystals thereby permit the analysis of such a beam into a spectrum of its energy components. X-ray and γ-ray beams can also be detected directly and analyzed using semiconducting crystals. Lithium-drifted germanium and silicon crystals, although requiring cooling to liquid air temperature, provide current pulses from individual x-ray or γ-ray photons which are accurately proportional to the photon energies.

Signal Processing Systems Signal processing procedures have been available since the introduction of electronic circuitry but were initially restricted to such elementary operations as amplification or heterodyning (the generation of a beat frequency to expedite the tuning and amplification of radio-frequency signals). Rather more sophisticated processing became available with the development of analog computers but was still limited to relatively simple arithmetic operations or integration and differentiation. The real revolution came with the development of digital data processing, and the availability of fast and powerful computers now makes it possible, in "real time," to perform almost any desired mathematical operation on the observations as they are made. If, as is frequently the case, the output of the sensor stage is in analog form, it is necessary to pass the signal through some form of analog-digital (a-d) converter. Examples of on-line signal processing procedures are given below.

(a) *Basic Arithmetic Operations.* Division, for example, can be used to calculate resistance directly as V/i or velocities from values of distance and time.

(b) *Statistical Operations.* These include calculation of such distribution parameters as mean, standard deviation, and correlation coefficient. Comparison with a prescribed function, linear or otherwise, can be carried out by least squares methods, or, in the absence of a specified function, a generalized polynomial fit can be obtained. In all cases progressive improvement of the accuracy of the calculations will result from continued revision as new observations become available.

(c) *Time Averaging.* This is a very powerful method to improve signal-to-noise ratios. If some phenomenon such as a resonance peak or a spectrum line is hidden in noise, we can carry out a process of repeated scans over the range of variable containing the signal. If we have some way of storing the information and averaging the results of the repeated scans, we shall find that the random noise will give, ultimately, an average of zero. The desired signal, on the other hand, will add positively on every scan and eventually appear free of the noise which formerly masked it.

(d) *Fourier Analysis.* It is very frequently desirable to analyze a time-varying phenomenon into a frequency spectrum by the method of

Fourier analysis. Such computation has recently been greatly facilitated by the development of the fast Fourier transform methods and is now commonly used in a wide range of applications. Typical is the Fourier transform spectrometer, in which optical spectra are processed in an interferometer. The resulting variation of fringe intensity with order of interference is analyzed to yield the frequency components of which the original beam was composed.

(e) *Optical Image Enhancement.* A two-dimensional picture can be converted into digital data by a scanning process, thereby becoming susceptible to computer processing. Photographs showing such defects as lack of contrast, out-of-focus, or smearing from camera movement can be analyzed to determine the precise nature of the defect and subsequently corrected to construct an improved image. Many of the most spectacular results of space exploration among the planets would not have been visible without various processes of image enhancement to emphasize detail in particular ways, and similar improvement is available for microscopic images of biological material. Computer processing can also be used to create "false-color" images of normally invisible phenomena such as infrared emission, accoustic signals, and others. These are now familiar in many applications, such as the thermographs which identify poorly insulated houses or human breast cancer and the satellite-based photography which is used to study earth resources such as crops.

(f) *Pulse-Height Analysis.* This is a process in which separate storage is provided for pulses of differing height. The resulting display can then give a direct picture of, for example, a spectrum of γ-ray energies from a scintillation counter or x-ray energies from a Li-drifted silicon counter. This very powerful technique can be used to record any phenomenon in which the quantity in which we are interested can be converted into pulses with height dependent on the original variable. For example, lifetime studies on excited atoms will use a time-to-pulse height converter to provide a direct picture of the decaying radiation.

(g) *Others.* Other examples of on-line signal processing too complex to be described here but of too great importance to omit include pattern recognition and the various procedures for clinical examination by tomography. In these a signal, derived usually from x-ray absorption but occasionally from other phenomena, is analyzed to provide a picture of a cross-section of the human body as an aid to diagnosis.

Display and Storage Systems The traditional methods of needle and scale are now less frequently encountered, except as indicators. For time-varying phenomena the strip-chart recorder remains useful at low rates of change and the cathode ray oscilloscope is absolutely irreplaceable for rapidly changing phenomena. The addition of digital processing and memory to the CRO has made it a uniquely powerful and versatile instrument for the display and study of oscillations or time-varying phenomena over a wide range of frequencies and times.

Digital data processing makes possible the presentation of output information using digital numerical displays, based often on neon tubes or light-emitting diodes. These offer the convenience of direct access to output information without need for further interpretation, e.g., a range scale on a laser range finder. Similar convenience is available from the two- or three-dimensional cathode-ray tube displays in which the output of computer processing of observations can be viewed directly in pictorial form.

For cases in which later use of the results is intended, digital storage methods using magnetic tape and disc or punched paper tape permit vast quantities of information to be stored and easily retrieved. If onward transmission of the information is required, the use of digital techniques makes possible the rapid and accurate transfer of observations over interplanetary distances.

MECHANICAL PROPERTIES OF SOLIDS

When a material is in the solid phase, its constituent particles, which may be atoms, ions, or chemical molecules, vibrate about fixed equilibrium positions in which the interparticle force is zero. In most solids composed of small constituent particles, e.g., metals and ionic solids, these interparticle interactions produce an internal atomic or molecular arrangement which is regular and periodic in three dimensions over intervals which are large compared with the unit of periodicity. Such solids are called crystals.

Solids composed of larger units, e.g., polymers, can be crystalline, though the crystallinity is usually rather imperfect, or they can be amorphous.

When a solid is deformed by external forces, the constituent particles have their separations changed from the equilibrium values. The resultant of the interparticle forces acting on a particular particle is then no longer zero, but acts to restore the particle to its original position relative to its neighbors. When the solid is in equilibrium under the action of external forces, the interparticle (or internal) forces must be in equilibrium to give continuity of the material and must also be equal to the external forces, i.e., any element of the body must be in equilibrium. These internal forces are maintained as long as the external forces are applied. When the external forces are removed the internal forces restore to the constituent particles their original separations.

If, after unloading, the body returns exactly to its former size and shape its behavior is called perfectly elastic. If it retains completely its altered size and shape it is a perfectly plastic body. In general, the behavior of real bodies lies between these two extremes.

Stress and Strain Two types of forces may act on any element of a body: (a) surface forces, exerted by the surrounding material, which are proportional to the surface area of the element and (b) body forces, which are proportional to the volume of the element, e.g., gravitational forces. The effects of body forces are usually negligible compared with those resulting from surface forces.

For a body to be deformed and not merely accelerated when forces are applied to it the body must be in statical equilibrium under the action of the applied forces. The conditions of equilibrium are (a) there must be no unbalanced applied forces and (b) there must be no unbalanced applied couples. Further, the internal and external force equilibrium can be equated.

The effect produced in a given material by forces of given magnitudes depends on the size of the body to which they are applied, and hence, to enable a comparison to be made of the reaction to external loading of bodies of different size, the concept of *stress* is introduced.

The stress in an element is defined as force divided by area over which the force acts. It is described as a homogeneous stress if, for an element of fixed shape and orientation, the value is independent of the position of the element in the body. Usually the term stress is taken to mean stress at a point, and is the limiting value of force divided by area over which the force acts as the area tends to zero. If a force δF acts over a surface of area δA and makes an angle ϕ with the normal to the surface, the normal stress σ is

$$\sigma = \lim_{\delta A \to 0} \left(\frac{\delta F \cos \phi}{\delta A} \right)$$

and the tangential or shearing stress τ is

$$\tau = \lim_{\delta A \to 0} \left(\frac{\delta F \sin \phi}{\delta A} \right)$$

The stress is, of course, transmitted through the solid.

The change in the separation of the constituent particles of the solid produced by the applied forces is seen on the macroscopic scale as a change in the size and shape of the body. Since the deformation of different bodies of a given material subjected to a particular load is a function of the size of body, comparisons are made using the relative deformation, or strain, defined as

$$\text{strain} = \frac{\text{change in dimension}}{\text{original dimension}} .$$

A strain is homogeneous if, after deformation, lines of the body that were originally straight remain straight and lines that were originally parallel remain parallel.

The following strains are found to be convenient in describing the behavior of a body in various states of stress.

When a rod of unstretched length ℓ_0 has its length increased to ℓ by the application of external forces, the conventional, engineering, or nominal tensile strain ϵ is defined as

$$\epsilon = \frac{\ell - \ell_0}{\ell_0} .$$

Sometimes it is more convenient to use the true, natural, or logarithmic strain ϵ^*, defined as

$$\epsilon^* = \sum \frac{\delta \ell}{\ell} = \log_e \left(\frac{\ell}{\ell_0} \right) .$$

Clearly

$$\epsilon^* = \log_e (1 + \epsilon)$$

If, as the result of the application of a uniform hydrostatic force, the volume of a solid changes from V_0 to V, the bulk strain θ is defined as

$$\theta = \frac{V - V_0}{V_0} .$$

When a solid is sheared by the application of couples, the angle of shear is taken as a measure of the strain, in this instance a shear strain.

Elastic Behavior For very small strains ($< \sim 0.1$ per cent) the behavior of many solid materials is almost perfectly elastic. In this strain range a specimen will exhibit a linear relationship between the magnitude of the applied forces and the deformation produced. This relationship is known as the Hooke law and in terms of stress and strain it may be stated in the form

$$\text{stress} = \text{constant} \times \text{strain}.$$

The constant in this equation is called a modulus of elasticity. Each strain has a corresponding modulus of elasticity. These moduli are temperature-dependent, and in general, depend on the direction of measurement, but if elastically isotropic solids are considered, the value of a particular modulus is independent of the direction in which it is measured. A solid is effectively isotropic if it is composed of grains whose size is small compared with the smallest dimension of the solid and if the orientations of the grains are randomly distributed.

Consider a bar of uniform area of cross-section A and unstretched length ℓ_0 acted upon by forces F applied uniformly at the ends. If ℓ is the length when this load is applied, the stress σ is given by $\sigma = F/A$ and the strain ϵ is $\epsilon = (\ell - \ell_0)/\ell_0$. (Tensile stresses are counted positive.) When the Hooke law is obeyed, $F/A = E(\ell - \ell_0)/\ell_0$ where E is a constant for a given material at a given temperature and is known as the Young modulus of the material.

When a solid has a hydrostatic stress σ applied to it, the volume changes from V_0 to V so that if the Hooke law is obeyed

$$\sigma = \frac{K(V - V_0)}{V_0}$$

where K is a constant at a given temperature and is known as the bulk modulus of the material.

When a solid is deformed by couples producing a shear stress τ, the angle of shear γ is taken as a measure of the strain so that, if the Hooke law is obeyed,

$$\tau = G\gamma$$

where G is a constant at a given temperature and is known as the rigidity modulus for the material.

The axial deformation of a prismatic bar with unloaded prismatic surfaces is accompanied by a change in the cross-sectional area. Experiment shows that the ratio

$$\text{lateral strain/axial strain}$$

is a constant known as the Poisson ratio ν. For the small strains encountered in pure elastic behavior the change in cross-sectional area is very small, so the difference in the stress calculated using the original area of cross-section and using that when the load is applied is negligible.

Elastic shear deformation, in constrast, takes place at constant volume. The elastic moduli are not independent and it can be shown that, for an isotropic solid,

$$E = 3K(1 - 2\nu)$$

and

$$G = \frac{E}{2(1 + \nu)}.$$

Plastic Behavior When a solid is deformed under an increasing stress, a stage is reached when the further deformation produced by a slight increase in stress, though still elastic, does not obey the Hooke law. The stress at which the departure from linearity of the stress-strain curve first occurs is called the proportional limit or elastic limit. If the stress is increased beyond the elastic limit, a value is reached at which permanent deformation occurs, i.e., the specimen does not recover completely its original size and shape on unloading. The stress at which permanent deformation is first detected has, for very many materials, a value characteristic of the material at that temperature and is called the yield stress. The corresponding point on the stress-strain curve is the yield point. For many materials the elastic limit and yield stress have almost the same value and are not readily distinguished. The deformation not recovered on unloading is called the permanent set and the specimen is said to have suffered plastic deformation.

Plastic Deformation of Simple Crystalline Solids, e.g., Metals and Ionic Solids. The simplest mechanical test that can be performed on a solid is the tension test, and measurements made during such tests are often used to characterize particular materials.

Many simple crystalline solids are ductile at temperatures greater than about 0.3 to 0.4 of the melting temperature in kelvins. The plastic deformation of such materials takes place at approximately constant volume, and hence, for a specimen tested in tension, the cross-sectional area decreases as extension proceeds. This change in cross-sectional area with strain necessitates a more careful definition of stress. Two definitions are in common use, namely, conventional stress σ_c, sometimes called the nominal or engineering stress, defined by

$$\sigma_c = \frac{\text{load}}{\text{original area of cross section}}$$

and true stress σ_t, defined by

$$\sigma_t = \frac{\text{load}}{\text{area of cross section under that load}}$$

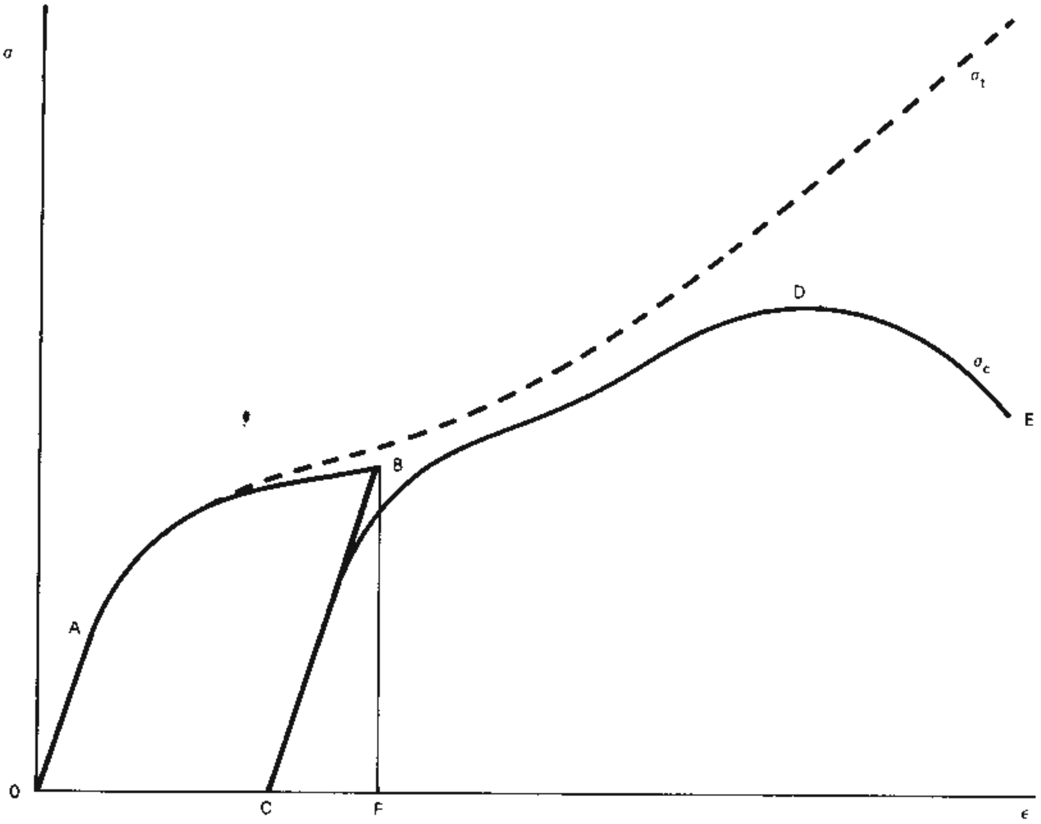

FIG. 1

When a tensile test is carried out on a fine-grained sample of a ductile material the conventional stress σ_c vs engineering strain ϵ graph has the form shown by the solid line in Fig. 1. The actual shape of the curve depends on many variables, e.g., purity of the material, temperature of testing, and rate of straining.

Over the region OA the graph is a straight line passing through the origin, the behavior is perfectly elastic, and the Hooke law is obeyed. When the stress exceeds that at A macroscopic permanent deformation occurs and the curve bends towards the strain axis; the stress at A is the yield stress σ_y and A is the yield point. However, the stress needed to produce further plastic deformation increases with strain and the material is said to work-harden or strain-harden. If the specimen is unloaded when B is reached, the unloading path is BC, which has almost the same slope as OA; the elastic properties of the material are little affected by plastic deformation. The elastic strain FC is recovered, but the material retains the plastic strain OC, which is the permanent set. The plastic strain becomes an increasing fraction of the total strain as the latter increases. When the test is continued the stress rises along CB (ignoring a small amount of hysteresis which is sometimes observed), but before B is reached the curve bends towards the strain axis and then continues to rise as if unloading had not taken place. σ_c continues to rise until D is reached and then starts to fall. The load corresponding to D on the σ_c vs ϵ curve is the maximum load that the specimen can withstand in tension, and the value of σ_c corresponding to this load is called the ultimate stress or ultimate tensile strength σ_u.

For deformations represented by OD on the σ_c vs ϵ graph the extension is homogeneous, i.e., on the macroscopic scale the deformation is the same for all cross sections. At D, however, a neck forms in the specimen, all subsequent plastic deformation is restricted to this neck, and the load needed to produce further extension falls. The neck gets progressively narrower until fracture occurs at a strain corresponding to E.

When σ_t is plotted instead of σ_c, the curve has the form shown by the dotted line in Fig. 1. If, when the neck forms, σ_t is measured in the neck, σ_t continues to increase with strain up to fracture.

Mild steel and some other materials show a different behavior. The elastic range is terminated when the stress reaches a value known as

TABLE 1

Material	E (Nm^{-2})	K (Nm^{-2})	G (Nm^{-2})	ν	σ_y (Nm^{-2})	σ_u (Nm^{-2})
Al	71×10^9	75×10^9	26×10^9	0.33	26×10^6	60×10^6
Cu	130×10^9	138×10^9	46×10^9	0.34	40×10^6	160×10^6
Steel	210×10^9	168×10^9	83×10^9	0.28	0.4×10^9 (σ_{UYS}) 0.3×10^9 (σ_{LYS})	460×10^6

the upper yield stress σ_{UYS}. There is an abrupt partial unloading and macroscopic plastic deformation occurs locally in regions called Lüders bands. These bands spread along the specimen and the value of σ_c oscillates about a relatively constant value known as the lower yield stress σ_{LYS}. When the Lüders bands cover the whole specimen, further deformation is macroscopically homogeneous and σ_c rises as the material work-hardens.

The stress-strain curves usually plotted use the engineering strain, but it should be noted that if true stress is plotted against true strain the resulting curve is the same for both compression and tension tests.

Some typical values of elastic moduli and yield stresses are given in Table 1. These values refer to measurements on fine-grained wires at room temperature.

The Deformation of Solid Polymers Polymer molecules consist of very long chains of atoms, often containing short side groups at regular intervals. In many of the common polymers the linking between neighboring chains is weak. This type of polymer is rigid at low temperatures and soft and rubbery at high temperatures, the transition being reversible. Such long-chain polymers, whose properties are strongly temperature-dependent, are called *thermoplastics*.

Polymers in which there are frequent strong links between neighboring long chains are said to be *crosslinked*. Crosslinked polymers have properties that are rubberlike.

Crosslinking is also found in the thermosetting plastics, in which nonlinear structures are formed. When these materials polymerize, a process accelerated by raising the temperature, the monomers group themselves into a rigid framework that is not softened when the temperature is raised again. These materials show brittle behavior under an applied stress.

Thermoplastics can be either *amorphous* (or glassy), in which state the polymer chains are randomly oriented and intertwined, or *crystalline*, in which small regions of the structure exhibit a definite arrangement of the polymer chains.

At very low temperatures both amorphous and crystalline polymers show essentially brittle behavior, having a Young's modulus of about 10^9–10^{10} N m^{-2} and breaking at a strain of about 5%. When tested at temperatures close to the melting point the deformation of both types of material is dominated by the sliding of polymer chains over each other, large irreversible strains are produced, and the behavior is termed *viscofluid*.

Between these extremes of behavior is an intermediate temperature range, the *glass transition range*, in which the mechanical behavior is strongly time dependent and is called *viscoelastic*. One manifestation of the glass transition is a fairly abrupt change in volume expansivity, and this can be used to define a glass transition temperature T_g. At temperatures above T_g the polymer chains have a certain freedom of movement relative to each other, whereas at temperatures well below T_g there is a complete locking of the polymer chains and their individual segments.

At temperatures up to T_g amorphous polymers deform elastically under tension until the so-called *yield stress* σ_y is reached, when the stress drops to a lower value σ_d (the *draw stress*) and a neck appears in the specimen (see Fig. 2). With further deformation this neck propagates along the specimen and the stress only rises again when the complete gauge length has been drawn down to a neck. In this process the polymer chains are oriented in the direction of the applied stress and the material becomes

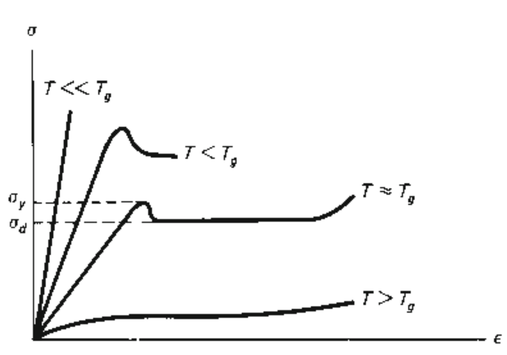

FIG. 2.

TABLE 2

Material	State at Room Temperature	E (MN m^{-2})	T_g (K)
Polyethylene	partially crystalline	70-280	153
Polyvinylchloride	amorphous/slightly crystalline	2500-3500	353
Polymethylmethacrylate	amorphous	2500-4000	380
Nylon 6	crystalline	2000-3000	323
Phenol formaldehyde resin	thermosetting glass	7000	–

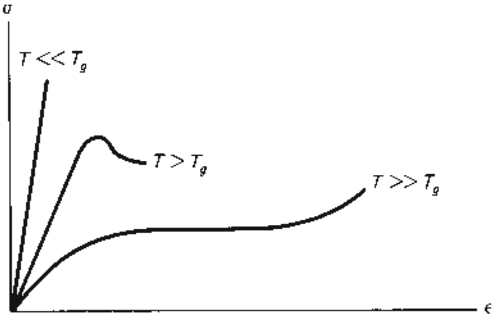

FIG. 3.

stronger. At temperatures above T_g large strains develop from the start of the test and no yield stress drop is observed. In both these regimes the strain can be recovered completely by heating the material at a temperature above T_g.

Crystalline polymers show rather similar curves (Fig. 3), but brittle behavior is observed for temperatures up to T_g. Above T_g a neck is produced in tensile deformation, but it results from recrystallization of the polymer chains in the direction of the stress, since the melting point of the aligned chains is higher than that of the unaligned chains. Consequently, no recovery of the strain takes place when the material is heated. At temperatures around T_g the propagation of the neck is usually terminated by flaws in the material, but well above T_g the neck propagates along the entire length of the specimen and the stress rises when the aligned polymer chains become strained.

Some data for common polymeric materials are given in Table 2.

MECHANICS

"Give me matter and motion," proclaimed René Descartes, "and I will make the Universe." And what the renowned 17th-Century philosopher meant by that bold and somewhat cryptic remark was that at the very primal heart of things physical, there is *matter in motion*. Understanding the marveolus subtleties, the unity of that fundamental reality, is essential to knowing the Universe on any level. In its broadest sense *mechanics* is just that: *it is the study of the relative movement of objects* (actual and impending), or, if you will, *the study of motion and rest*, the latter merely being a special case of the former.

The subject developed historically along several different lines driven by very different practical concerns. For the most part, the descriptive aspects of the study evolved more successfully earlier on, followed only later by an effective explanatory capability. The result was an almost natural partition of mechanics into several broad subdivisions which are usually (though not universally) designated as kinematics, dynamics, and statics.

The description of every sort of motion, without regard to either the cause thereof or to the physical nature of that which is moving, is known as *kinematics*. Insofar as it deals with the changing locations of objects in space and time, it can be regarded as the geometry of motion.

By contrast, *dynamics* (sometimes referred to in part as *kinetics*) is the study relating motion and the changes therein with the corresponding causative interactions. Dynamics seeks to explain the motion described by kinematics.

As a special case of dynamics, *statics* relates specifically to the conditions governing constant relative motion (including "rest"). Historically the discipline evolved simply as the study of objects at rest and that is still the quintessence of the business; but insofar as we now know that absolute rest is a fiction, the purview of statics is specified more appropriately as that of objects in unchanging motion. Loosely speaking, statics deals with systems that can be imagined to be motionless (like the Brooklyn Bridge). It is the study of the balance of interactions operating on and within any material system which results in its effectively being at rest. Unlike dynamics, wherein time is central, the imagery of statics is quite independent of time—presumably nothing changes.

Kinematics The primary goal of kinematics is to provide a quantified description of motion, one in which the necessary concepts are inherently measurable. The formulation begins naturally enough with the familiar ideas of *space* and *time*. Even so, it is an illusion to think that we can satisfactorily define these most basic underlying concepts. Pragmatically we must content ourselves with measuring intervals of space and time with meter sticks and clocks, relying on intuition for conceptual meaning.

Clearly the faster an object moves, the farther it will travel in a given amount of time. That's the crucial insight that leads to a definition of *speed*, the measure of "how fast." The oldest surviving thoughts on the subject are those of Aristotle (384–322 B.C.) and, like his fellow Greeks of the era, he specified speed as the distance traversed in a given amount of time. And that's just the way it was framed for well over a thousand years—a thing traveled with a speed of "so many miles in so many hours." Nowadays we say almost, but not quite, the same thing defining *average speed* (v_{av}) *as the interval of distance traveled* (Δl) *divided by the interval of time* (Δt) *it took to do the traveling:* $v_{\text{av}} \equiv \Delta l/\Delta t$. However close the ancients got to the idea, they never actually carried through the division, apparently because of a hesitance to divide the "unlike" notions of space and time.

The scholars of the mid-1300s, especially at the University of Paris and Merton College, Oxford, dealt quite successfully with the idea of constant speed. But when they attempted to define the speed of an object at any given moment, the *instantaneous speed,* they failed. That was not surprising, for they lacked the mathematical imagery of motion, a calculus of change, something Newton would create just for the purpose centuries later. As the time interval Δt over which v_{av} is determined is made smaller and smaller, the ratio of $\Delta l/\Delta t$ approaches a value known as the instantaneous speed, or what we nowadays just call the speed (v). That limiting process actually defines the derivative and so in the notation of calculus, $v = dl/dt$: *speed is the time rate of change of distance*, the derivative of distance with respect to time.

If, instead of the distance traveled, we consider the *displacement* (**s**), which is the vector drawn from some origin to the moving body, we can express in a single concept both the speed and the direction of motion. Accordingly, *velocity* (**v**) *is the time rate of change of the displacement*, $\mathbf{v} = d\mathbf{s}/dt$, and the magnitude of the velocity is the speed.

Variations in motion are commonplace; change is the rule rather than the exception and the measure of this change is called *acceleration.* Aristotle considered the concept, hinting at it in his book *Physics*, but never quite grasping it clearly. His follower Strato (ca. 340–270 B.C.) seems to have been the first person to appreciate the real-world importance of the idea. He suggested that a body was accelerating when it traversed equal increments of distance in shorter and shorter times. During the 12th-Century revival of science, the alternative formulation was set forth that acceleration obtained when a body traveled greater and greater distances in successive equal intervals of time. Only later, in the 14th Century, did the realization begin to emerge that variations in the speed itself were the essence of the concept. Today we define *acceleration* (**a**) *as the time rate of change of velocity:* $\mathbf{a} \equiv d\mathbf{v}/dt$.

Along with the notions of displacement and time, velocity and acceleration complete the vernacular of kinematics. Constructing the *equation of motion* of the system (the expression of displacement as a function of time) becomes the primary task of the discipline.

Dynamics The explanations of dynamics go beyond the descriptions of kinematics, requiring additional concepts which reflect the physical nature of mover and moved. Perhaps the richest and, at the same time, most elusive of these notions is that of *mass*.

The idea that there had to be another measure of matter, in addition to the old standbys of weight and volume, was first proposed by the theologian Aegidius Romanus (ca. 1247–1316). In an effort to resolve some complex religio-philosophic questions concerning the Eucharist, he suggested that the true measure of a substance, the "how much" of a material entity, was its *quantity-of-matter*. Though in the end it had little or no influence on theology, the new insight, however undefined, found a welcome place in medieval dynamics. The Parisian physicist Jean Buridan (ca. 1300–1385) utilized the conception of quantity-of-matter in his highly influential *impetus theory*. By the 17th Century, the phrase *quantity-of-matter* and the term *mass* (already long in common unscientific usage) had become synonymous—Newton used them interchangeably.

Buridan is responsible for conceiving one of the most important dynamical ideas to come out of the Middle Ages. He began with a question which is essentially equivalent to this: "Given that both are traveling at the same speed, which would you rather get hit by, a firefly or a fire engine?" Obviously the firefly, but why? What aspect of motion, above and beyond just speed, is involved? He suggested that the essential measure of motion was proportional to both quantity-of-matter and speed, that is, it depended on their product. This new metaphor of motion would soon come to be known as the *quantity-of-motion* and ultimately it would be reinterpreted and renamed *momentum*. Momentum ($m\mathbf{v}$) has proved to be one of the fundamental characteristics of the movement of all things.

Since the time of Aristotle, it had been widely assumed that the sustained motion of an object required the action of a sustained force. It was Galileo Galilei (1564–1642) who most convincingly challenged this seemingly reasonable view. Still, it should be pointed out that there were others before him who had thought, if somewhat tentatively, along similar lines. The Tuscan master performed a series of experiments which led him to conclude that an object once set in motion and left alone will continue in motion all by itself forever. That was the *law of inertia*, one of the first grand insights into the long hidden workings of the Universe. On a sizable planet like Earth, gravity and all sorts of friction conspire to obscure this all-important underlying principle—that is why it remained unrevealed for 2000 years. Had we been dwellers on a far smaller vessel in space, the natural tendency for things in motion to continue in motion would have been quite obvious. As it is, we are not, and it is not, and it took the genius of Galileo to see beyond the Scholastic fiction, the age-old error that the natural tendency of matter was to rest.

When Isaac Newton (1642–1727) came to codify motion in his masterpiece, the "Mathematical Principles of Natural Philosophy," he began with a series of definitions. The first was a rather unsatisfactory attempt at defining quantity-of-matter, while the second was a clear statement of quantity-of-motion framed as the product of mass and velocity. Newton then set out the three "axioms or laws of motion" which form the basis of dynamics (and statics) even to this day. The *first* of these was the law of inertia: *Every body continues in its state of rest, or of uniform motion in a straight line, except insofar as it is compelled to change that state by forces impressed upon it.* Force is the agent of change; it does not sustain motion, it changes it.

Newton's *second law* is a quantified recasting of the first law. Modernized somewhat in its language, it reads: *The rate of change of the quantity-of-motion (i.e., the momentum) of a body is equal to, and occurs in the same direction as, the net applied force*, $\mathbf{F} = d(m\mathbf{v})/dt$. From the first law we have that that which changes motion is force and now, more specifically, *force equals the change in the motion per unit time* (the measure of motion being the quantity-of-motion or the momentum).

If mass is taken to be constant, $\mathbf{F} = m d\mathbf{v}/dt$ and so $\mathbf{F} = m\mathbf{a}$. This is the hallmark of Newton's theory and yet it does not appear anywhere in his work. In fact, it actually was introduced decades later by the Swiss mathematician Leonhard Euler. It is a real tribute to Newton's vision that his formulation in terms of momentum is in perfect accord with modern relativity theory, whereas $\mathbf{F} = m\mathbf{a}$ is not. Mass is a function of speed and therefore not constant in time—but that would not be shown until 1905 and Einstein.

Sir Isaac's third axiom, his *third law* of motion, completes the logical picture of force which is the very pillar of his dynamics. An isolated body follows the law of inertia. It cannot alter its own motion; that requires some *outside* intervention called *force*. And when two bodies, like billiard balls, interact, it's only reasonable to assume that both will be affected, both motions will be altered, *both will experience a force*. Leonardo de Vinci (1452–1519) had pointed the way long before. "An object offers as much resistance to the air," he wrote, "as the air does to the object. You may see that the beating of an eagle's wings against the air supports its heavy body in the highest and rarest atmosphere. . . ." Whatever the source of inspiration, and others had grasped the essence of it, too, Newton provided the final link: "To every action there is always opposed an equal reaction: or the mutual actions of two bodies upon each other are always equal, and directed to contrary parts." *The interaction of two entities always occurs via an equal action-reaction pair: force and counterforce.* There is no such thing as a single force; force is a thing of pairs.

The second and third laws combine to reveal one of the guiding principles of modern physics, the *law of conservation of momentum.* If two objects interact, the forces acting on each will be equal and opposite and so, too, will be their resulting changes in momentum. In terms of the system as a whole, these paired opposite momentum changes cancel each other, leaving the net or combined momentum unaltered. *The total momentum of a system of interacting masses must remain unchanged provided that no net external force is applied.* As Newton put it, "the quantity-of-motion . . . suffers no change from the action of bodies among themselves." Amusingly, the idea had been speculatively anticipated by René Descartes (1596–1650), who wrote of the Creator: "He conserves continually . . . an equal quantity-of-motion" in the Universe.

To the kinematical ideas of time, displacement, velocity, and acceleration had been added the dynamical concepts of mass, momentum, and force, all united in the credo of the three laws. Brilliant physicists would spend the next two hundred years mathematically honing the fine edge of Newton's force-dynamics. And all the while another complementary piece to the scheme, another powerful vision, was slowly evolving—the concept of *energy*.

The necessity to formally quantify *work* came out of the practical needs of the engineers and scientists of the late 18th Century at the start of the Industrial Revolution. Work ≡ force X distance; work equals the force applied to an object multiplied by the distance through which it moves, a quantity easily measured with scales and meter sticks and just as easily bought and paid for. *Power*, the amount of work done per unit time, was also a practical measure dictated by the demands of the new machine age.

In "The Two New Sciences," Galileo had long before shown some grasp of the key idea. He talked about the physics of pile drivers and recognized that the weight of the hammer and the distance through which it fell determined its effectiveness—force and distance related in a crucial way.

Suppose we do work on a hammer, exert a force on it and cause it to accelerate, and then slam it down on a nail bringing it to rest, thereby doing work on the nail; we have work-motion-work. And if we recognize that work is the changer of energy, then the hammer apparently has some sort of *energy of motion*.

Interestingly, the underlying insight to all of this actually began to evolve roughly a hundred years before it reached maturity in the 19th Century. Christian Huygens (1629–1695) never cared much for Descartes's reliance on the idea of quantity-of-motion. Momentum to be really meaningful must be framed as a directional quantity, a vector, like force. A body at rest could explode into two pieces violently flying in opposite directions and yet the total momentum would remain zero throughout. That bothered Huygens, who suggested a different measure of the motion, one which would be independent of the direction of the velocity, one which would only vanish when all the motion actually ceased. He subsequently decided on the product of the mass and speed *squared*. Gottfried Leibniz (1646–1716), Newton's bitter rival, picked up the idea, calling mv^2 the *vis viva* or living force. The great and meaningless vis viva controversy between the followers of Descartes and Leibniz roared on for decades as each side claimed the fundamental notion.

It was not until the beginning of the 1800s that Thomas Young (1773-1829) shifted the imagery and spoke of mv^2 as *energy*. "Labour expended in producing any motion," he wrote, "is proportional . . . . to the energy which is obtained." Then Gaspard de Coriolis (1792–1843), using Newtonian mechanics, showed that the work done on a system was equivalent to a change in the quantity $\frac{1}{2}mv^2$. Lord Kelvin (1824–1907), years later, dubbed this the *kinetic energy*. Vis viva was forgotten, drowned out by the roar of the Industrial Revolution, and in its place stood its lookalike, kinetic energy.

Suppose that there is some sort of driving force constantly exerted on a body, like its weight. To move against that pull requires the application of a counterforce and the doing of work. The crucial point is that the force—be it elastic, electric, magnetic, gravitational, whatever—continues to act even after the displacement. Once let loose, that force will drive the body back, imparting kinetic energy in the process. Clearly it is possible to do work and not have it immediately appear as kinetic energy, and yet the potential for generating that energy is there. This retrievable stored energy, *energy by virtue of position in relation to a force*, is known as *potential energy*, a name given it by William Rankine (1820-1872).

When we consider the kinetic and potential energy of a body as a whole, it is understood that all of its atoms act together in an organized fashion. Alternatively, it is possible to impart motion to the individual constituent atoms which is disorganized, motion not of the body, but within the body. A pendulum swings until it ultimately comes to rest—organized kinetic energy is transformed into disorganized kinetic energy or, as it's called nowadays, *thermal energy*. The ubiquitous agent of that transformation is known as *friction*.

One of the great revelations of the previous century was the *law of conservation of energy* opened out to include both thermal and mechanical processes: *Energy can neither be created nor destroyed, but only transformed from one form to another*. Whatever energy is (and we have no satisfactory conceptual definition of that underlying quantity, although we know its various manifestations) it is conserved.

To the force-time-momentum imagery of the 18th Century was added the force-space-energy vision of the 19th Century. And then in the 20th Century Albert Einstein (1879-1955), questioning the very basic understanding of space and time, profoundly recast kinematics and dynamics in his *special theory of relativity*. Newtonian mechanics turned out to be the low-speed approximation of the new vision whose real significance becomes apparent only at speeds that are appreciable in comparison to the speed of light.

The theory builds from two basic postulates. The first is known as the *principle of relativity*, which states that *all the laws of physics are the same for nonaccelerating observers*. The second, the *principle of the constancy of the speed of light*, maintains that *light propagates in free space with a speed* ($c \simeq 300{,}000{,}000$ m/s) *that is independent of the motion of the source (and of the observer)*. The speed of light in vacuum is absolute.

Among the many surprises provided by the new vision was the realization that rest, motion, simultaneity, time, length, and mass are not absolutes as had long been thought. Instead these fundamental quantities are relative, they depend on the motion of the observer.

The result, which Einstein himself thought was "the most important," was the *equivalence of mass and energy*. These two seemingly different concepts are actually manifestations of one single entity: *mass-energy*, $E = mc^2$, *the total energy E of an object equals its mass m multiplied by the speed of light squared.*

Statics The central problem that was never far from the surface in the early days of the development of kinematics and dynamics, was the motion of the heavens. Aristotle had woven his theory of motion into his cosmography to form a single fabric that would stand for two thousand years. By contrast, the motivation behind the development of *statics* was far more mundane and pragmatic. The ancients, who weighed out their goods on balances, who raised stone, hauled ships and pitched tents were all practitioners of statics, even before the formal body of knowledge evolved.

An object experiencing no change in its motion, *no acceleration*, is said to be in *equilibrium*. Hence it follows from Newton's second law that *translational equilibrium* ($\mathbf{a} = 0$) *obtains when the sum of the forces acting on a body is zero*, $\Sigma\ \mathbf{F} = 0$. If the two teams in a tug of war pull equally hard in opposite directions, the net force is zero and the rope remains motionless. This is the first of the two conditions of equilibrium.

The simple equal-arm balance was already in widespread use well over 4000 years ago. It is not surprising then, that Aristotle, in his "Mechanica," attempted to analyze the important practical problem represented by balances, levers, and seesaws (which are just variations on one theme). When equal downward forces are applied to each end of the centrally pivoted rod, the system remains motionless, balanced horizontally. Any tendency to rotate clockwise is canceled by an equal tendency to rotate counterclockwise, and we say that the system is in *rotational equilibrium*. In fact, the word *equilibrium* derives from the Latin *aequus*, even or equal, and *libra*, a scale or balance.

It was the great Archimedes of Syracuse (287–212 B.C.) who, in his treatise "On Equilibrium," framed the *law of the lever* in a satisfactory way. *Unequal forces (of magnitudes F_1 and F_2) acting perpendicularly on a bar at unequal distances from the pivot (r_1 and r_2, respectively) balance each other provided that* $F_1r_1 = F_2r_2$. It is not enough to be concerned only with the sizes of the forces; the distances from the pivot at which they act are crucial, as well.

Da Vinci, aware that the human body achieved its mobility via a system of various kinds of levers, set himself to the study of these simple machines. He was among the first to recognize the significance of the idea of the *moment of a force*.

Envision a force **F** acting on a body which is pivoted at a point O: *The lever or moment-arm of the force* **F** *with respect to the axis passing through O is the perpendicular distance* ($r_\perp$) *drawn from O to the line of action of* **F**. *The moment of the force about O is then defined as the product of the magnitude F and* $r_\perp$. Nowadays it is common practice to symbolize this quantity by the Greek letter *tau*, τ, and refer to it as *torque* (from the Latin, *torquere*, to twist). The law of the lever is then simply a requirement that the two opposing torques be equal. Formulated as a vector, torque becomes $\boldsymbol{\tau} = \mathbf{r} \times \mathbf{F}$.

In the case of a rigid body (viewed as a collection of interacting point masses) Newton's second and third laws lead to the *second condition of equilibrium: For a rigid body in equilibrium the sum of the torques about any point (due to all the externally applied forces acting on it) must be zero*, $\Sigma\tau = 0$.

The two conditions of equilibrium provide a basis for the analysis of the forces at work in all sorts of mechanical systems from trusses and bridges to the muscle-bone structure of the human body.

Mechanics, the tap root of physics, is the seminal discipline, whether it is general relativity on the cosmic scale, quantum mechanics in the micro-domain of the atom, or Newtonian mechanics in the macro-world of baseballs and ballistic missiles. "Give me matter and motion and I will make the Universe."

MEDICAL PHYSICS

That physics has an important place in medicine can scarcely be denied. A physician's first move in examining a patient is to measure his temperature, count his pulse, listen to his heart sounds and take his blood pressure. Only much later does the physician get around to chemical and laboratory tests. Yet every hospital of any stature has a laboratory or a department of clinical chemistry. Laboratories of clinical physics are virtually nonexistent. While physics plays a large role in medical diagnosis and treatment, physicists have largely neglected the field.

Some of the earliest applications of the principles of physics to problems in medicine were in the fields of optics and sound. An early contributor was H. L. F. von Helmholtz; a physician as well as a physicist. His work in physiological optics and that on the sensations of tone are considered classics. Even earlier, J. L. M. Poiseuille, a French physician and physicist, seeking a better understanding of the flow of blood, studied the flow of water in rigid tubes. His work not only contributed to physiology but also established an important relation in the physics of viscous fluids. D'Arsonval, a French physicist, pioneered in the therapeutic use of high frequency electric currents and measuring instruments. Much earlier, that unusual artist, inventor and physicist, Leonardo da Vinci, had shown a keen interest in the fascinating mechanics of human locomotion.

With the intensive development of the sciences of physics and medicine in the latter part of the nineteenth century, the two drew further apart. This period also saw rapid development in the science of physiology which is concerned not only with chemical but also with physical processes in the body. Clinical physiology abounds with such concepts as the pressure-velocity relationships in the flow of blood, the mechanics of the cardiac cycle, the work of breathing, gas exchange in the lungs, voltage gradient in cellular membranes, and cable properties of nerves, to name but a few. These concepts have, of necessity, been worked out by scientists with training and experience in the basic biological and clinical procedures. Physicists have been inactive in the field and have made very little contribution to its development. But there is a growing awareness among physiologists of the importance of physical principles and the need for precise statement of physical law. An example of this conviction is Howell's Textbook of Physiology in which editions since the eighteenth have carried the title, "Physiology and Biophysics."[1]

A phenomenon of the mid-twentieth century has been the development of interdisciplinary fields of science. BIOPHYSICS combines the most fundamental of the biological and physical sciences. It has had an extremely rapid growth, with something like 30 to 40 university Departments of Biophysics in America alone. Its emphasis has been on the application of physical principles to all aspects of biology—cellular, botanical, zoological as well as clinical.

An even more recent phenomenon has been the development of biomedical engineering. Its basis has been the application of the tremendous developments in electronics to medical measurements and instrumentation. In fact, the field is frequently referred to as biomedical electronics. Such recent developments as vector electrocardiography, implantable pacemakers for the heart, and intensive-care physiological monitors and recorders are examples of the impact of electronics on medicine. While these fields border on medical physics, none are concerned primarily with the application of physical principles to clinical problems. Yet they compete so effectively with medical physics that it is difficult to delineate the boundaries of the latter.

The discovery of X-RAYS by Roentgen in 1895 had an immediate impact upon medicine. Within a few months, the new rays were used both diagnostically and therapeutically. Indirectly, their application set the stage for the development of medical physics. Therapeutic application of x-rays raised questions concerning their quality and quantity—both of which are important in accurate dosimetry. Evaluation of early successes and failures indicated the importance of the proper distribution of dose between neoplasm and normal tissue. The physician turned to the physicist for assistance. The late Otto Glasser was one of the early radiological physicists; he and Fricke in 1924 constructed an air wall ionization chamber for the measurement of radiation dose.[2] Their construction eliminated some of the nonlinear effects due to quality, i.e., photon energy distribution, in the evaluation of biological response. Other early workers in America were Edith Quimby and G. Failla. In England, L. H. Gray and W. V. Mayneord were active. In 1936, Gray proposed the Bragg-Gray formula for determining the absolute amount of energy delivered to a medium from ionization measurements.[3] The work of Fricke, Glasser, and Failla along with that of L. S. Taylor[4] and others contributed to the establishment in 1928 by the Second International Congress of Radiology of the roentgen as a unit of radiation dose based on the amount of ionization generated in a standard volume of air. The use of higher energies and ionizing radiations other than x-rays led during the 1950's to the abandonment of the roentgen as a unit of absorbed dose. Dissatisfaction with the roentgen was also due to a growing realization that biological response was more nearly related to the energy absorbed in a medium. The Bragg-Gray formula permitted the calculation of absorbed dose in a medium, and the work of J. S. Laughlin[5] established the dosimetry of high-energy radiations in energy units by calorimetric methods. While radiological physics is clearly a part of the broader discipline of medical physics, it included in the early days practically all that was organized of the later subject.

For many years there were no organizations of workers in the field of medical physics. In America, radiological physicists were associate members of the Radiological Society of North America, naturally dominated by radiologists. First in Britain (The Hospital Physicist's Association) and later in America specialty groups were organized. The American Association of Physicists in Medicine (AAPM) brings together those physicists working in hospitals and medical schools, and interested in an understanding of the physical side of medical problems. The membership has been largely drawn from those working in radiological physics, but an interest in all areas of the application of physics to medical problems is rapidly developing. The A.A.P.M. became affiliated with the American Institute of Physics in 1958 and is now showing the most rapid growth of its nine member organizations.[6] In 1973, the A.A.P.M. began publication of its own journal, *Medical Physics*. A further indication of the developing awareness of this field are the International Conferences on Medical Physics, which meet every three years (the Sixth met with the International Conference on Medical and Biological Engineering in Hamburg, Federal Republic of Germany in 1982).

One last word about a related field: Radiation protection was in the early days a part of radiological physics. In America, L. S. Taylor was active for many years at the Bureau of Standards in setting up guidelines for protection from radiation. During World War II, the Manhattan Project required large numbers of workers in the field of protection, and the term HEALTH PHYSICS was introduced. Since the war, the field has grown with the growth of the area of atomic energy. The Health Physics Society is a large and growing group with many local chapters and an international organization. The field seems, though, to be becoming more closely aligned with the area of public health than with clinical medicine.

When the first edition of the "Encyclopedia of Physics" was issued, the viability of medical physics as a profession was uncertain. It appeared that any breakthrough in the cure of cancer, eliminating radiation therapy as a modality of treatment, would also eliminate the livelihood of medical physicists. But much was already happening and the results that have changed the picture are now apparent. Electronics and nuclear physics have made many previously unmeasurable variables in medicine accessible to quantification. The introduction of the concept of modulation transfer function has made a science of the evaluation of diagnostic imaging quality. Nuclear medicine has had wide applications and attracted many physicists into the field. Ultrasound and computed tomography have had spectacular successes in improving medical diagnostics. And now nuclear magnetic resonance imaging is beginning to be applied. During the 1970s, with shrinking financial support for physics, many recent PhDs entered the field of medical physics as postdoctoral trainees. Physicists in general became more aware of the opportunities and the need to apply physical principles to the many problems in medicine. Many large physics accelerator installations developed programs for the treatment of cancer. Even the largest accelerator in America, Fermilab, has a large and continuing program for cancer treatment with high-energy neutrons. The award of a Nobel prize in Physiology and Medicine in 1977 to Roslyn S. Yalow[7] for the development of radioimmunoassay served notice to the world that physicists are contributing to the solution of problems in medicine. This was followed two years later by the award of Nobel prizes to a physicist, Allan M. Cormack,[8] and an engineer, Godfrey N. Hounsfield,[9] for the development of computed tomography. Certainly, one can now state that the new discipline of Medical Physics is healthy, growing and showing unmistakable signs of survival. And one can find few areas of physics where the challenge is greater, or the rewards more satisfying, than in making accurate evaluation of physical variables in the living human patient.

METALLURGY

The metallurgical industry is one of the oldest of the arts, but one of the youngest of the subjects to be investigated systematically and considered analytically in the tradition of the pure sciences. It is only in comparatively recent times that any fundamental work has been carried out on metals and alloys, but there are now well-established and rapidly growing branches of science which are related to the metallurgical industry.

Extraction Metallurgy Extraction metallurgy, or the science of extracting metals from their ores, is broadly divided into two groups.

Ferrous. This branch is concerned with the production of *iron* (normally from iron ore, with coke and limestone in a blast furnace) and its subsequent refining into *steel*, by oxidizing the impurities either in an electric arc furnace by means of an appropriate slag on the surface or in a "converter," by blowing oxidizing gas through the molten iron. The most striking recent developments in this field have been the increasing use of pure gaseous oxygen in steelmaking, and the increasing size of furnaces, with a resultant improvement in efficiency, rate of production, and quality of product. Over 500 million tonnes or 70% of the worlds's annual steel production is now made using oxygen converters.

Nonferrous. Some metals such as chromium, cobalt, and manganese, for example, are principally produced as alloying elements to improve the properties of steels. The nonferrous metals manufactured in greatest quantity include aluminum, copper, nickel, zinc, magnesium, lead, and tin, with titanium being an important newcomer in view of its low density, high melting point (1943 K) and resistance to corrosion. The precious metals, and the "refractory metals" of very high melting point (e.g., tungsten and molybdenum) are other important families.

Shaping of Metals This may be carried out in three main ways.

Casting. Most metals are initially cast into *ingots*, which may be subsequently forged to shape. The technique of *continuous casting* is increasingly used in this context to improve efficiency and to increase the rate of production. By 1990 it is expected that one-half of the world's steel output will be continuously cast. Many alloys are designed to be cast into their final shape by pouring the molten alloy into an appropriate mold. These may be sand molds if only a small number of objects are required, and very massive castings (e.g., over 10^6 Kg in mass) may also be produced in this way. A permanent mold, or die casting, is employed if large numbers of the object are required (particularly in alloys of low melting point, such as zinc-based alloys), and high dimensional accuracy can be achieved by these means. Cast iron is the cheapest metallic material. The microstructure of "gray cast iron" is shown in Fig. 1. It consists of flakes of graphite in a two-phase matrix of iron and iron carbide (Fe_3C). The brittleness of this material arises from the weakness of the graphite flakes, which act like cracks in the structure.

Forging. This entails shaping of the metal by rolling, pressing, hammering, etc., and may be carried out at high temperatures, when the metal is soft (hot-working), or at lower temperatures (cold-working) where deformation leads to progressive hardening of the metal (work-hardening). In contrast with casting, forgings usually exhibit differing physical and mechanical properties in different directions, due to the directional nature of the shaping operation.

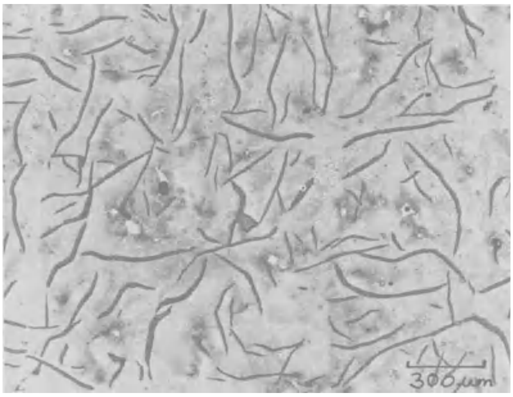

FIG. 1. The microstructure of gray cast iron: the black lines are flakes of graphite.

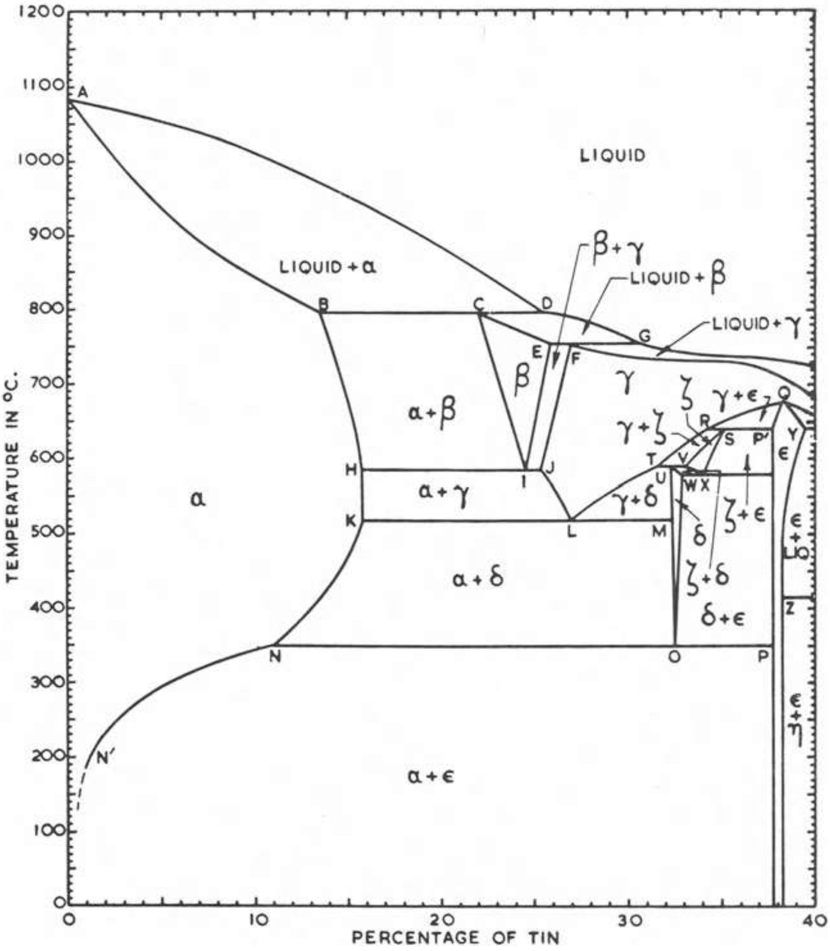
Much modern research in physical metallurgy is concerned with investigating the plastic flow and work-hardening behavior of metals and alloys. Metal crystals yield plastically at stresses several orders of magnitude lower than the theoretical value for the deformation of perfect crystals. This discrepancy is accounted for by the presence of linear imperfections known as "dislocation lines" within the crystals. Plastic flow takes place in metal crystals by "slip" or "glide" in definite crystallographic directions on certain crystal planes, due to the movement of dislocation lines under the applied stress. Dislocations multiply and entangle as deformation proceeds, thus making further flow increasingly difficult (work-hardening)–the density of dislocations rising from about $10^5 mm^{-2}$ in soft (annealed) metal to about $10^{10} mm^{-2}$ in work-hardened material. These and other types of crystal defect (such as *stacking faults*, which are planar in geometry) can be studied by x-ray diffraction and also by means of the electron microscope and the field-ion microscope (q.v.).

Powder Metallurgy. This is a method of shaping by pressing finely powdered metal into an appropriately shaped die. The "green compact" thereby produced is of low strength and is subsequently heated in an inert atmosphere ("sintered"); the pressing and sintering may be repeated until strong, dense products are obtained. The technology was first developed for metals which were of too high a melting point for conventional casting and forging methods, and tungsten lamp filaments were first produced by this means. Other refractory metals and hard metal-cutting alloys may thus be shaped, and some magnetic and other special alloys are prepared in this way by suitable blending of powders, which avoids any contamination that may be associated with the melting process. The pressing and sintering conditions may be arranged to leave some residual porosity in the structure of, for example, bronze bearing alloys. The pores are filled with oil, thus producing the so-called oil-less bearings which can operate without further lubrication.

Joining. The three important methods of joining metals are riveting, soldering or brazing (in which metal components are joined by means of a layer of alloy of lower melting point), and welding (in which the metal itself is fused). *Weldability* is often the critical factor in the selection of an alloy for a given purpose, since the metallurgical changes produced by localized heating are often associated with the development of deleterious properties at, or adjacent to, the weld.

Alloy Constitution Phase equilibria in alloy systems are represented on *phase diagrams*, which represent the temperature ranges of phase stability as a function of composition. An example of such a diagram is given in Fig. 2; they are experimentally established by, e.g.,



Point	A	B	C	D	E	F	G	H	I	J	K	L	M	N′
° C.	1083	798	798	798	755	755	755	586	586	586	520	520	520	200
Sn, %	0	13·5	22·0	25·5	25·9	27·0	30·6	15·8	24·6	25·4	15·8	27·0	32·4	1·2
Point	N	O	P	P′	Q	R	S	T	U	V	W	X	Y	Z
° C.	350	350	350	640	676	640	640	590	590	590	582	582	640	415
Sn, %	11·0	32·55	37·8	37·8	38·3	34·2	35·2	31·6	32·3	33·1	32·9	34·1	39·5	38·3

FIG. 2. The copper-tin phase diagram. (G. V. Raynor, "Institute of Metals Annotated Equilibrium Diagram," Series No. 2, 1944.)

thermal analysis, dilatometry, microscopical, and x-ray diffraction methods. Phase diagrams can also be calculated by computation of the Gibbs free energy minimum, if the thermodynamic functions of observable phases are determined by experiment. Diagrams such as that in Fig. 2 are invaluable in the interpretation of the structures of alloys observed under the microscope.

The microstructure of an alloy (and hence its properties) will be determined not only by its composition, but also by its thermal and mechanical history. Of particular importance is the metallurgical control of the mechanical properties of an alloy by *heat-treatment*, which affects the distribution of the phases present. Hardness, for example, will depend upon the state of deformation (i.e., the density of dislocations) and upon the composition of the alloy. Pure metal crystals can be hardened by other atoms in solid solution (solute hardening) as well as by finely dispersed particles of a hard second phase (precipitation, or dispersion hardening) which are effective in impeding the motion of dislocations when the crystal is stressed. Fig. 3 is an electron micrograph showing dislocations on the slip plane of a copper alloy crystal, and it illustrates how the presence of hard particles has caused local entanglement of the dislocations. The relationship between the microstructure and properties of metals and alloys is of fundamental importance and is a field of intense scientific activity.

Although many common alloys were not developed scientifically, a considerable theory of alloys is developing, springing from empirical rules and principles (notably those due to W. Hume-Rothery) which have generalized the facts and enabled predictions to be made. The early theories of the metallic state, due to Drude and Lorentz, and later to Sommerfeld, were developed and discussed by N. F. Mott and H. Jones in their book "The Theory of the Properties of Metals and Alloys." A great increase in our knowledge of transition metals and alloys has taken place, and some signs of general principles have begun to appear, although there is yet little theoretical knowledge enabling one to calculate properties or structures of alloys from fundamental principles. The propensity to form deleterious phases in nickel-based materials has been related empirically to the average number of electron vacancies (N_V) in a given alloy. Computer calculations, using a system known as PHACOMP, have identified the critical value of N_V above which such phases form.

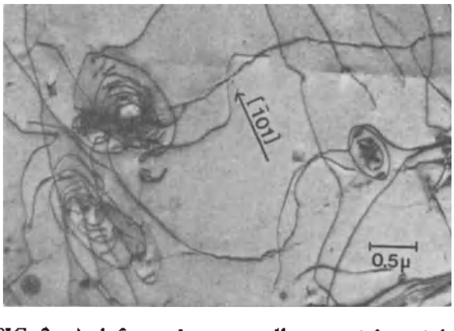


FIG. 3. A deformed copper alloy crystal containing hard particles. Electron micrograph showing interaction of dislocation lines with the second phase.

The Effect of Environment Upon the Behavior of Metals *Low Temperature*. Some metals and alloys exhibit a spectacular change in mechanical behavior with decrease in temperature. Many metals of body-centered cubic crystal symmetry (e.g., iron and mild steel) which are tough and ductile at ordinary temperatures become completely brittle at subzero temperatures, the actual transition temperature depending upon the metallurgical condition of the alloy, the state of stress, and the rate of deformation. Some metals of hexagonal symmetry (e.g., zinc) exhibit this effect, but metals of face-centered cubic symmetry (e.g., copper) remain ductile to the lowest temperatures. This transition in behavior is clearly of critical importance in the selection of materials for low-temperature application.

High Temperature. Apart from problems of oxidation (discussed below), metals tend to deform under constant stress at elevated temperatures (the deformation is known as "creep"), and creep-resistant alloys are designed to provide strength at high temperatures. These are essentially alloys in a state of high thermodynamic stability, usually containing finely dispersed particles of a hard second phase which impede the movement of dislocations. Grain boundaries may be a source of weakness at elevated temperatures, and turbine blades in the form of alloy single crystals have recently been employed in engines of advanced design.

Fatigue. Metals break under oscillating stresses whose maximum value is smaller than that required to cause rupture in a static test, although many ferrous alloys show a "fatigue limit," or stress below which such fracture never occurs, however great the number of cycles of application. The phenomenon is associated with the nucleation of submicroscopic surface cracks in the fatigued component early in its life, which initially grow very slowly. Eventually a crack grows until the effective cross section of the piece is reduced to such a value that the applied stress cannot be supported, and rapid failure occurs. A typical fatigue fracture surface is shown in Fig. 4, in which two distinct zones are apparent. These correspond to the period of slow growth (left-hand side) and final failure, respectively.

Oxidation and Corrosion. With the exception of the "noble metals," which are intrinsically resistant to attack by the environment, metals

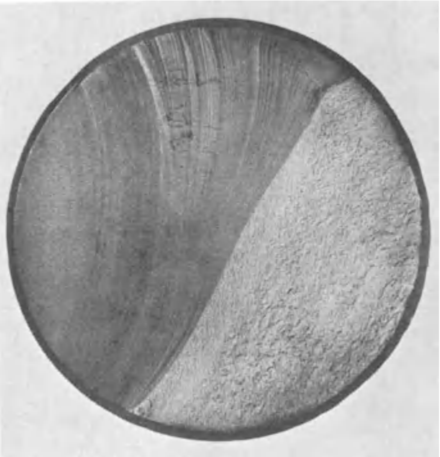

FIG. 4. A fatigue fracture surface upon a large steel shaft. (Courtesy of British Engine Insurance Ltd.)

in general owe their oxidation resistance, when they are heated in air, to the presence of impervious oxide films on their surfaces. Those which develop porous oxides (e.g., the refractory metals tungsten and molybdenum) oxidize very rapidly at high temperatures. Oxidation resistant alloys are designed to maintain a protective film under these conditions.

Corrosion occurs under conditions of high humidity or immersion in aqueous media. The phenomenon can be interpreted electrochemically—local anodes form at the region of metal dissolution, and local cathodes form where the electrons are discharged. "Galvanic corrosion" is encountered where dissimilar metals are in electrical contact under these conditions. Of particular importance is the *conjoint* action of stress and corrosion, where "stress corrosion" or (under fluctuating stresses) "corrosion fatigue" cracking may be encountered, in situations where no failure would occur under the action of the stress or the corrosive environment applied separately. Electrochemical principles are applied in the protection against corrosion.

Materials Technology The scientific principles which govern the behavior of metals are, of course, applicable to a wide range of other technologically important materials, such as polymers, ceramics, and glasses. In recent years many centers of metallurgical research both in industry and in universities have broadened their approach in this way and are often described as Departments of Materials Technology.

METEOROLOGY

Meteorology is the study of the atmosphere. The word is derived from the classical Greek *meteoros* meaning "things lifted up." As early as 250 B.C. Aristotle wrote extensively about these topics in his treatise "Meteorologica." Meteorology, as practiced today, is broadly interdisciplinary, drawing extensively from the fields of hydrodynamics, thermodynamics, optics, chemistry, and mathematics. It has applications in industry, agriculture, transportation, economics, resource management, and many other human activities.

Almost every branch of physics and chemistry is in some way involved in atmospheric phenomena. This article is confined to brief overviews of modern methods of weather prediction, climatology, cloud physics (including attempts at weather modification), and boundary-layer processes.

Atmospheric Circulation and Weather Prediction The basic state of the atmosphere is described by seven variables: three components of velocity; temperature; pressure; density; and the water-vapor concentration (usually called the *mixing ratio*). The changes of these variables are governed by seven well known equations. The accelerations in the three principal directions are given by three differential equations based on Newton's second law. These were written in their hydrodynamic form by Euler about 200 years ago. Temperature changes are governed by the first law of thermodynamics. The other equations are the equation of state and the equations for the conservation of mass of the dry air and water vapor. The complete set of equations has been established for well over 100 years, but because of their complexity, their application to weather prediction has become a reality only during the last 25 years as modern computers have become available.

The numerical problems involved in solving these equations for the future values of weather elements are far from trivial. Essentially, the changes must be calculated for periods of a few minutes at a time based on the global distribution of the elements derived from observation or calculated during earlier time steps, and moved forward step by step. This method was first studied by L. F. Richardson in the early 1920s, but had to be abandoned because of inadequate computational capability. The problems were successfully confronted by John von Neumann and his colleagues in Princeton about 1950. In 1955 the U.S. Weather Bureau began numerical weather prediction on a twice-daily basis. Today, numerical weather prediction is being carried out routinely from greatly improved global models at several national and international centers. The use of models has brought about a considerable increase of predictive skill (measured by the degree to which accuracy exceeds that attainable using climatological averages). The skill achieved for two- to three-day forecasts by computer models is about that formerly attainable one day in advance by subjective methods. Demonstrable skill has been achieved out to ten or twelve days, but five days is a more realistic limit in temperate latitudes on a routine basis.

The use of circulation models in weather prediction requires upper-air observational input over at least the entire Northern Hemisphere (current models are now global in extent). The data are provided each 12 hours by several hundred soundings of pressure, temperature, humidity, and winds observed from balloons and telemetered to ground stations. The specifications for these data and their distribution are coordinated by the World Meteorological Organization (WMO). Data from several thousand surface stations and ships are also used.

Meteorological satellites have been employed extensively to supplement surface based data. Geostationary satellites, hovering at a height of 35,000 km above a fixed point on the equator provide quasi-hemispheric visible and infrared images every half hour. These are valuable for short-range prediction of thunderstorms, tornados, and other localized phenomena. They also provide important surveillance of tropical and extratropical cyclones in data-sparse areas, particularly in the southern hemisphere. Winds derived from satellite cloud-image motions have made important inputs to numerical prediction models. Also for this purpose, much effort has been devoted to developing methods of deriving temperature soundings remotely from polar-orbiting satellites. The inversion technique for reconstructing the temperature distribution from infrared fluxes observed at different wavelengths has been solved, but the technique can be used only in cloud-free regions.

Because of the global extent of the atmospheric circulation, much of the research is carried out in international programs. The most recent of these is the Global Atmospheric Research Program (GARP), planning and coordination of which is done jointly by the International Union of Geodesy and Geophysics (IUGG) and WMO. The program seeks to provide a better understanding of the large scale atmosphere, to define better the data requirements of atmospheric prediction models, and to exploit the fullest observational capabilities of modern technology.

Climatology Climate may be defined as the statistical summary of past weather at a fixed place. It is most often thought of as a running average using a fixed time interval, the length of which may be as little as a month in some conceptions or indefinitely large in others. Usually a period of about thirty years is preferred in order to filter out annual and shorter-term fluctuations while still allowing longer period variations to be studied. Strictly speaking, one cannot observe the climate of the present. However, the study of past climates and their changes provides a basis for projections into the present and the future, and such studies are receiving intensive effort and support at the present time.

Research in climatology may be subdivided into three main categories: (1) the reconstruction of past climates from weather observations and proxy data; (2) the understanding of the physical and mathematical bases of climate and its changes; and (3) assessment of the impact of climate on society. Contributions to the study of climate have been and are being made by scientists in a wide range of disciplines.

Instrumental records of weather go back for about two centuries at most. Therefore, the reconstruction of climates depends mainly on the analysis and interpretation of proxy data, such as tree rings, glacier ice cores, and ancient descriptions of the distribution of plants.

Geological evidence long ago indicated the occurrence of large variations of climate during the history of the earth. At least four major glaciations occurred in Europe and North America during the Pleistocene. Within the last ten years, a reasonably reliable chronology began to become available from isotope analyses of cores extracted from the deep ocean bottom. From these and other data is emerging an interesting pattern. The mean temperature of the earth declined significantly during Tertiary times and there may have been as many as 17 major glaciations during the last 1.7 million years. A period of about 100,000 years between major episodes is quite conspicuous, and the spectrum over the last 400,000 years also shows significant peaks near 41,000 and 22,000 years. The last glaciation reached its climax about 16,000 years ago and was followed by a warm extreme about 6,000 years ago. Since then the mean temperature has gradually declined, with numerous short-term fluctuations on many time scales.

Rapid strides have been made during the last decade in understanding the physical and mathematical basis of climate. This understanding is greatly complicated by the large number of interactions that occur between different components of the atmosphere-ocean-earth system and by the response of such a complex system to perturbations imposed on it. As an example of such interactions or feedbacks, picture the effect of a temperature perturbation resulting possibly from some minor disturbance of the sun's atmosphere. An increase of surface temperature would increase evaporation from the ocean's surface, affecting in turn the mean cloudiness, snow cover, and probably the circulation pattern; these changes would in turn affect the distribution of absorption of solar radiation and thereby result in further changes of the temperature distribution. The complexity of the climate system has prompted the development of computer models capable of incorporating them. Such models are currently severely limited by the insufficient understanding of the physics and chemistry of some of these interactions, and also the difficulty of evaluating the covariances that appear when the atmospheric equations are averaged over long periods of time. One of the interesting suggestions emerging from mathematical and computational studies of climate models is the possibility that the system may spontaneously oscillate between two or more quite different states without any external forcing.

Many possibilities exist for both external and internal forcing of climate changes. Observations of solar energy output over the last 50 years have shown it to be remarkably steady; nevertheless, it is scientifically plausible that significant variations of this output rate may have occurred over longer time scales. It is also likely that the prevalence of suspended dust from volcanoes has varied widely. The impact of such dust on the terrestrial heat budget is not clear and may not have been great. It is becoming rather well accepted that on a time scale of tens of millions of years, continental displacements are effective causes of change; the major glaciations that occurred in India and Australia during Permian times, and probably also the Tertiary cooling, can be attributed to this cause. The presence of 22-, 41-, and 100-thousand-year periods in the Pleistocene chronology gives strong support to the astronomical theory proposed originally by Milankovitch. According to this theory, changes in the orbital elements of the earth caused by the Moon and planets give rise to variations of solar insolation with precisely these periods. The amplitude of these variations is rather small, and the mechanism by which they would produce the observed climatic response is not understood. However, on the basis of past relationships, it is possible to project that in the absence of anthropogenic influences, the mean temperature of the earth will decline over the next 60,000 years.

It is estimated that about half of the carbon dioxide given off from the burning of fossil fuels resides in the atmosphere and the rest is dissolved in the upper layers of the ocean. This atmospheric residue interacts with the infrared radiation in the atmosphere in such a way as to increase the surface temperature. At present the atmospheric content is increasing about 0.4% a year, and it is estimated that this increase, acting alone, would raise the mean temperature about 0.3 C over the next 50 years. The observational verification of carbon dioxide warming of the atmosphere has not been possible because of numerous other factors that cannot be controlled.

Cloud Physics and Weather Modification The water vapor saturation required for the formation of clouds and precipitation normally comes from upward motion and accompanying adiabatic cooling of the air. Condensation actually begins at humidities slightly less than 100% on small, suspended hygroscopic nuclei derived from such sources as sea spray and combustion products. Because of the strong curvature of the surface of the growing droplets, a slight supersaturation is required for continued growth. Freezing nuclei are rare, and cloud droplets normally remain in the liquid phase at subfreezing temperatures down to −40 C.

Cloud droplets range in diameter from 1 to 50 μ depending mainly on the size of the original nucleus and the extent of coalescence with other droplets. An average raindrop contains about a million times the water mass of a single cloud droplet and cannot be formed in a reasonable time by the ordinary droplet growth mechanism. Two processes are believed to act naturally if the required circumstances are met. The first of these is coalescence of colliding droplets that fall at different speeds; such a process requires a broad spectrum of droplet sizes. The second mechanism is the Bergeron-Findeisen process, which requires the presence of a few ice crystals in a predominantly liquid cloud at subfreezing temperatures. The difference between the saturation vapor pressures over liquid and ice at low temperatures causes a rapid transfer of water from the liquid to the ice. Because the requirements for these processes are rather stringent, most clouds do not precipitate.

In principle it should be possible to trigger the first process by artificially injecting into the cloud liquid water masses, which fragment immediately into drops of a wide range of sizes. Each of these should then grow by coalescence and fracture into a large number of new seeds, effecting a chain reaction that can ultimately produce beneficial amounts of precipitation. The second process has been stimulated in natural clouds by seeding with freezing nuclei such as silver iodide or with "dry ice," which produces ice crystals by the sudden chilling of droplets.

Both of these methods have been employed widely in rain-making operations and experiments. These techniques appear to have been effective in a few experiments, but the amounts of augmentation have usually been too small to demonstrate conclusively under statistically controlled conditions. In most (but probably not all) cases where there is sufficient liquid water in the cloud to produce a significant amount of precipitation and sufficient vertical motion to sustain it once it begins, the precipitation forms naturally. In a few conditions the artificially created latent heat of sublimation may provide enough additional buoyancy to trigger a large amount of additional cloud growth and precipitation.

Injection of silver iodide into cumulonimbus clouds has also been attempted for the purpose of preventing hail. By increasing the number of ice seeds that compete for the available cloud water it is hoped that one can substitute for a small number of large hail stones a vastly increased number of small stones that melt before reaching the ground.

Boundary Layer Meteorology The atmospheric boundary layer comprises the lowest kilometer (more or less), where the air properties are directly influenced by interactions with the surface of the earth. The layer is intensively studied for several reasons. Nearly all of the heat and water vapor that generate kinetic energy and precipitation pass through this layer and are controlled by processes near the earth's surface. The greater part of the kinetic energy that is generated by storms is dissipated within this layer. Finally, pollutants enter the atmosphere near the surface, and they are transported by the winds in this layer, undergo chemical transformations with other species, and are diffused by turbulence in varying degrees.

Boundary layer processes must be included in numerical prediction models. Without the inclusion of friction, storms tend to overintensify. It has also been found that longer period prediction of precipitation requires the inclusion of evaporation and the transfer of water vapor through the boundary layer into the free atmosphere.

Legislation has made it necessary to find and use working theories for relating ambient air quality to the industrial emissions that affect it. The pressure imposed by regulation authorities and the requirements of legislation have been a strong stimulus for research to develop better theories for transport, modification, and diffusion in natural environments. The problems are compounded by the fact that many industrial operations are situated near coastlines or in complex terrain that defy the application of simple theories. Moreover, the chemical transformations involve a large number of possible reactions under very low concentrations, often involving heterogeneous phases. Of particular importance is the conversion of SO_2 to sulfate and the precipitation of the resulting acidic ions (along with products derived from oxides of nitrogen) in what is commonly called *acid rain*. Natural rain is slightly acidic due to the presence of carbon dioxide. Rain downstream of pollutant sources sometimes reaches pH values of 4.0 or less.

Dilution of pollutant concentrations by turbulent diffusion has been intensively studied for more than 50 years, both in the laboratory and in field experiments. Turbulence in the atmospheric environment is more complicated than in the laboratory, and the challenge of these complications has attracted the attention of a number of prominent hydrodynamicists. During the last 25 years the emphasis has been directed mainly at observing the distribution of mean wind and turbulence on towers within the lowest 300 meters above the surface. The main efforts are now shifting toward computer modeling of turbulence throughout the entire boundary layer.

Research and Publications Research is meteorology is carried out in many countries and results are published in a variety of specialized journals. A partial list of these includes the *Journal of the Atmospheric Sciences*, *Journal of Climate and Applied Meteorology*, *Journal of Atmospheric and Terrestrial Physics*, *Quarterly Journal of the Royal Meteorological Society*, *Tellus*, *Izvestiya–Atmospheric and Oceanic Physics*, *Journal of Geophysical Research*, and *Atmospheric Environment*. A complete list of publications in this field can be found in *Meteorological and Geoastrophysical Abstracts* published by the American Meteorological Society.

MICHELSON-MORLEY EXPERIMENT*

Introduction The revival and development of the wave theory of light at the beginning of the nineteenth century, principally through the contributions of Young and Fresnel, posed a problem which proved to be of major interest for physics throughout the entire century. The question concerned the nature of the medium in which light is propagated. This medium was called the "aether" and an enormous amount of experimental and theoretical work was expended in efforts to determine its properties. On the experimental side, a long series of electrical and optical investigations were carried out attempting to measure the motion of the earth through the ether medium. For many years, the experimental precision permitted measurements only to the first power of the ratio of the speed of the earth in its orbit to the speed of light ($v/c \simeq 10^{-4}$), and these "first-order experiments" uniformly gave null results. It became the accepted view that the earth's motion through the ether could not be detected by laboratory experiments of this sensitivity. With the development of Maxwell's electromagnetic theory of light, and especially with its extensions by Lorentz in his electron theory, theoretical explanations for the null results obtained in the early ether drift experiments were provided. These results were in harmony with the Galilean-Newtonian principle of relativity in mechanics, which explains why the essential features of all uniform motions are independent of the frame of reference in which they are observed. In Maxwell's electromagnetic theory, however, the situation was altered when quantities of the second order in (v/c) were considered. According to the Maxwell theory, effects depending on $(v/c)^2$ should have been detectable in optical and electrical experiments. The presence of these "second-order effects" would indicate a preferred reference frame for the phenomena in which the ether would be at rest. At first, this feature of Maxwell's theory implying observable ether drift effects of the second order in (v/c) raised a purely hypothetical question, since the accuracy needed for such experiments was a part in a hundred million, and no experimental techniques then known could attain this sensitivity.

Michelson pondered this problem and it led him to invent the Michelson interferometer, which was capable of measurements of the required sensitivity, and to plan the ether drift experiment which he carried to completion in collaboration with Edward W. Morley at Cleveland in 1887. This famous optical interference experiment was devised to measure the motion of the earth through the ether medium by means of an extremely sensitive comparison of the velocity of light traveling in two mutually perpendicular directions. The experiment, when completed in 1887, gave a most convincing null result and proved to be the culmination of the long nineteenth century search for the ether. At that time, the definitive null result of the Michelson-Morley experiment was a most disconcerting finding for theoretical physics, and indeed for many years repetitions of this experiment and related ones were performed with the hope of finding positive experimental evidence for the earth's motion through the ether. These later experiments, however, have all been shown to be consistent with the original null result obtained by Michelson and Morley. In the years following 1887, their experiment led to extensive and revolutionary developments in theoretical physics, and proved to be a major incentive for the work of FitzGerald, Lorentz, Larmor, Poincaré, and others, leading finally in 1905 to the special theory of relativity of Albert Einstein.

The optical paths in the Michelson-Morley interferometer are shown in plan in Fig. 1. Light from a is divided into two coherent beams at the half-reflecting, half-transmitting rear surface of the optical flat b. These two beams travel at 90° to each other and are multiply reflected by two systems of mirrors d − e and $d_1 - e_1$. On returning to b part of the light from e − d is reflected into the telescope at f, and light from $e_1 - d_1$ is also transmitted to f. These two coherent beams of light produce interference fringes. These are formed in white

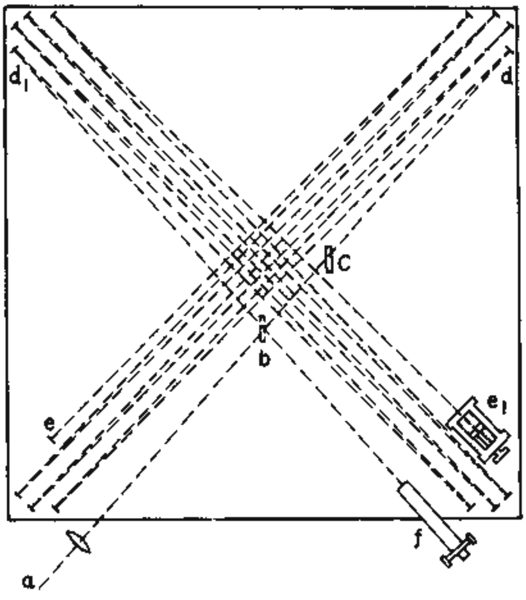

FIG. 1. Optical paths in the Michelson-Morley interferometer.

*The author passed away on March 5, 1982, after preparing this article.

only when the optical paths in both arms are exactly equal, a condition produced by moving the mirror at e_1 by a micrometer. c is an optical compensating plate. The effective optical path length of each arm of the apparatus was increased to 1100 cm by the repeated reflections from the mirror system.

Figure 2 is a perspective drawing of the Michelson-Morley interferometer showing the optical system mounted on a 5 foot square sandstone slab. The slab is supported on the annular wooden float, which in turn fitted into the annular cast-iron trough containing mercury which floated the apparatus. On the outside of this tank can be seen some of the numbers 1 to 16 used to locate the position of the interferometer in azimuth. The trough was mounted on a brick pier which in turn was supported by a special concrete base. The height of the apparatus was such that the telescope was at eye level to permit convenient observation of the fringes when the instrument was rotating in the mercury. While observations were being made, the optical parts were covered with a wooden box to reduce air currents and temperature fluctuations.

This arrangement permitted the interferometer to be continuously rotated in the horizontal plane so that observations of the interference fringes could be made at all azimuths with respect to the earth's orbital velocity through space. When set in motion, the interferometer would rotate slowly (about once in 6 minutes) for hours at a time. No starting and stopping was necessary, and the motion was so slow that accurate readings of fringe positions could easily be made while the apparatus rotated.

The experiment to observe "the relative motion of the earth and the luminiferous ether" for which this instrument was devised, was planned by Michelson and Morley as follows. When the interferometer is oriented as in Fig. 3 with the arm L_1 parallel to the direction of the earth's velocity v in space, the time required for light to travel from M to M_1 and return to M in its,new position is,

$$t_{\|}(1) = \frac{L_1}{c-v} + \frac{L_1}{c+v} = \frac{2L_1}{c}\,\frac{1}{1-\beta^2} \quad \left(\beta = \frac{v}{c}\right)$$

The time for light to make the journey to and from the mirror M_2 in the other interferometer arm L_2 is,

$$t_{\perp}(1) = [2L_2(1+\tan^2\alpha)^{1/2}/c]$$

and since $\tan^2\alpha = v^2/(c^2 - v^2)$

$$t_{\perp}(1) = \frac{2L_2}{c}\,\frac{1}{(1-\beta^2)^{1/2}}.$$

When the interferometer is rotated through 90° in the horizontal plane so that the arm L_2 is parallel to v, the corresponding times are,

$$t_{\|}(2) = \frac{2L_2}{c}\,\frac{1}{1-\beta^2}$$

$$t_{\perp}(2) = \frac{2L_1}{c}\,\frac{1}{(1-\beta^2)^{1/2}}$$

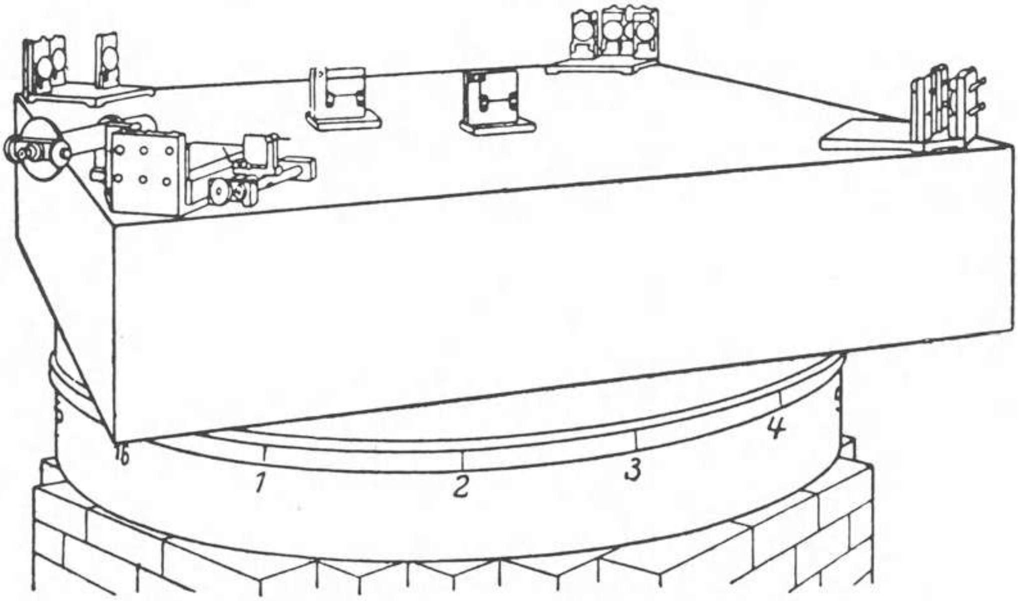

FIG. 2. Michelson-Morley interferometer used at Cleveland in 1887.

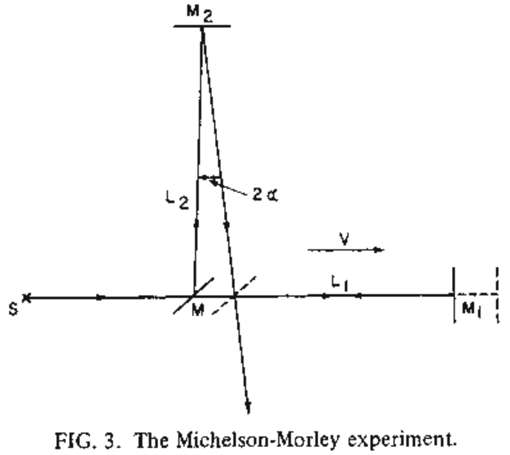

FIG. 3. The Michelson-Morley experiment.

Thus, the total phase shift (in time) between the two light beams expected on the ether theory for a rotation of the interferometer through 90° is,

$$\Delta t = \frac{2L_1}{c}\left[\frac{1}{1-\beta^2} - \frac{1}{(1-\beta^2)^{1/2}}\right] + \frac{2L_2}{c}\left[\frac{1}{1-\beta^2} - \frac{1}{(1-\beta^2)^{1/2}}\right] = \frac{2(L_1+L_2)}{c}\left[\frac{1}{1-\beta^2} - \frac{1}{(1-\beta^2)^{1/2}}\right]$$

For equal interferometer arms, as used in this experiment,

$$L_1 = L_2 = L, \text{ and, since } \beta \ll 1,$$

$$\Delta t \simeq \frac{2L}{c}\beta^2$$

The observations give the positions of the fringes, rather than times, so the quantity of importance for the experiment is the change in optical path in the two arms of the interferometer.

$$A = c\,\Delta t = 2L(v/c)^2$$

This is the quantity of second order in (v/c) referred to above.

With the Michelson-Morley interferometer, the magnitude of the expected shift of the white-light interference pattern was 0.4 of a fringe as the instrument was rotated through an angle of 90° in the horizontal plane. Michelson and Morley felt completely confident that fringe shifts of this order of magnitude could be determined with high precision.

In July of 1887, Michelson and Morley were able to make their definitive observations. The experiments which gave their final measurements were conducted at noon and during the evening of the days of July 8, 9, 11, 12 of 1887. Instead of the expected shift of 0.4 of a fringe they found "that if there is any displacement due to the relative motion of the earth and the luminiferous ether, this cannot be much greater than 0.01 of the distance between the fringes."

The result of the Michelson-Morley experiment has always been accepted as definitive and formed an essential base for the long train of theoretical developments that finally culminated in the special theory of relativity. The first important suggestion advanced to explain the null result of Michelson and Morley was G. F. FitzGerald's hypothesis that the length of the interferometer is contracted in the direction of its motion through the ether by the exact amount necessary to compensate for the increased time needed by the light signal in its to-and-fro path. This contraction hypothesis was made quantitative by H. A. Lorentz in further development of his electron theory in which he introduced the formalism which has since been known as the "Lorentz transformation" for the analysis of relative motions.

H. Poincaré also contributed greatly to both the philosophical and mathematical developments of the theory. As early as 1899, he asserted that the result of Michelson and Morley should be generalized to a doctrine that absolute motion is in principle not detectable by laboratory experiments of any kind. Poincaré further elaborated his ideas in 1900 and in 1904 and gave to his generalization the name "the principle of relativity." He also completed the theory of Lorentz and it was he who named the essential transformation "the Lorentz transformation."

In 1905 Einstein published his famous paper on the "Electrodynamics of Moving Bodies" in which he developed the special theory of relativity from two postulates: (1) the principle of relativity was accepted as the impossibility of detecting uniform motion by laboratory experiments, and (2) the constancy of the speed of light was generalized to a postulate that light is always propagated in empty space with a velocity independent of the motion of the source. Both postulates have a close relationship to the Michelson-Morley experiment, which Einstein knew through his study of the work of Lorentz. Einstein's paper is generally considered as the definitive exposition of the special relativity principle, and the climax of the century-long developments which had begun with Young and Fresnel to explain the electrical and optical properties of moving bodies.

At all times the Michelson-Morley experiment continued to have great interest and was repeated many times throughout more than a half century. In 1904 Morley and Miller[4] showed that the Fitzgerald-Lorentz contraction is the same in several materials. All repetitions after 1887 failed to find the full expected "aether-drift," although Dayton C. Miller's trials on Mount Wilson (1921–1926) gave a small effect, later shown to be due to temperature gradients.[5] The most certain null result was that obtained by Joos[6] using an interferometer built by Zeiss of Jena. Finally, experiments by Townes[7] with very sensitive laser techniques, gave definitive confirmation of Michelson and Morley's work.

In 1922 at the height of his fame for relativity, Einstein lectured widely in Japan. A reprint and discussion of these lectures has recently become available.[8] In his lecture on December 14, 1922 at Kyoto University, Einstein referred several times to the interferometer experiment, stating that he "had thought about the result even in his student days." In 1950 Einstein told the writer[1] that after 1905 he and Lorentz had discussed the Michelson-Morley experiment many times while he was working on the general theory of relativity. Today, both the experiment and the theories are among the prized achievements of Physics.

MICROPARACRYSTALS

Most noncrystalline matter consists of microparacrystals (mPCs). They can be identified by X-ray, neutron, and electron diffraction patterns. The reflections of microparacrystals show a characteristic broadening (see, for example, Figs. 8, 9, and 11 of the article DIFFRACTION BY MATTER AND DIFFRACTION GRATINGS. Plotting for instance the integral width $\delta\beta$ of the reflections ($h00$) against h we can calculate the number N of netplanes and the paracyrstalline distortion g by means of the following theoretical relationships:[1]

$$\begin{aligned}\delta\beta &= \frac{1}{\bar{d}}\left[\frac{1}{N} + (\pi g h)^2\right]\\ g &= \Delta_1/\bar{d} \qquad\qquad (1)\\ \Delta_1 &= (\overline{d^2} - \bar{d}^2)^{1/2},\end{aligned}$$

where d is the distance between atoms of neighboring netplanes orthogonal to their surfaces and Δ_1 the variance of these distances d. Figure 1 shows a two-dimensional paracrystalline lattice, where 3% larger coins are mixed statistically with 97% smaller ones. At the center of the lattice there exist some crystalline-like domains. Near the boundaries the netplanes become more and more distorted until finally they are destroyed at some places. Similar phenomena exist in atomic dimensions. From statistical laws it is known that the distance variance Δ_N increases with $\sqrt{N}$ orthogonal to the surface between atoms of the first and $(N+1)$th netplanes. When Δ_N reaches $100\alpha^*$% of $\bar{d}$, then the valence bonds between atoms or molecules within the Nth netplane are strongly overstrained so that the netplane suffers a break. This leads to the so-called "α^*-relation:"

$$\begin{aligned}&\Delta_N = \sqrt{N}\,\Delta_1 = \alpha^*\bar{d}, \quad \text{hence} \quad \sqrt{N} = \alpha^*/g\\ &\alpha^* = 0.15 \pm 0.03.\end{aligned} \qquad (2)$$

In Fig. 2 is plotted $\sqrt{N}$ against $1/g$ for numerous different colloids. α^* always has values between 0.12 and 0.18. Another example is given by the steel-ball model (cf. the article DIFFRACTION BY MATTER AND DIFFRACTION GRATING, dotted line, Fig. 11). The α^*-relation was firstly published in 1967.[2] At that time its fundamental importance for the whole world of noncrystalline matter was not recognized. F. J. Baltá-Calleja[3] stimulated the publication of diagrams like Fig. 2. Nevertheless, the importance of the α^* = relation is rarely understood nowadays. On the right-hand side of Fig. 2, for instance, an example is given of the ammonia contact catalysts. Their microparacrystals are, on account of relation (2), very small compared with crystals and therefore build up a large thermostable "inner" surface of some 100 m^2 per 1 cm^3. This large surface is important in synthesizing ammonia (NH_4OH) from hydrogen (H_2), nitrogen (N_2), and water (H_2O) in a rational technical way:

$$3H_2 + N_2 + 2H_2O = 2NH_4OH.$$

In Figure 12 of the article on PARACRYSTALS it is shown that the microparacrystals of this catalyst consist of α-Fe lattices into which $FeAl_2O_4$ molecules are statistically imbedded and destroy the crystalline order of the Fe atoms. Here $g \sim 1$% and $\sqrt{N} \sim 15$. At temperatures higher than 400°C some $FeAl_2O_4$ molecules slowly begin to emigrate, the g-value therefore becomes smaller, and $\sqrt{N}$ reaches

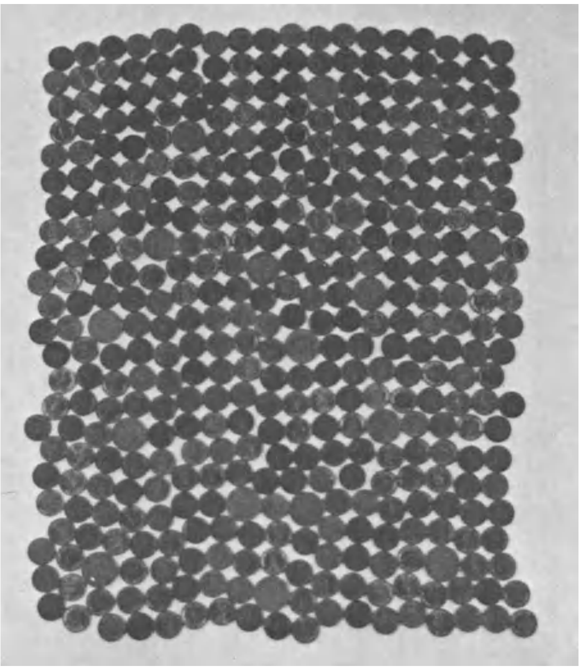

FIG. 1. Two-dimensional model of a paracrystalline lattice with quadratic lattice cells. 97% smaller coins are mixed statistically with 3% larger ones.

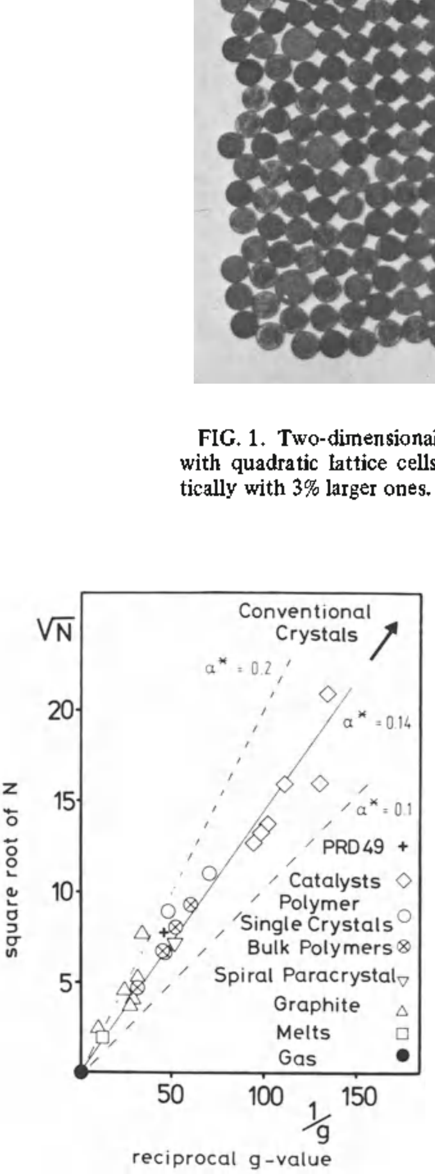

FIG. 2. The α^*-law of colloidal systems. The relation of Eq. (2) gives the theoretical background for noncrystalline matter independent of its chemical composition.

values up to $\sqrt{N} = 20$. With higher annealing temperature the microparacrystals more nearly approach the crystalline state in the direction of the arrow until the catalyst loses its favorable properties. A new example of the existence of microparacrystals was found recently in the $NiAl_2O_3$ catalyst.[4] Adjacent to the catalyst in Fig. 2 are plotted mPCs ("single crystals" and bulk material) in polymers. Their g-values lie between 2 and 5%. The example for "crystalline" polymers is given in Fig. 9 of the article on PARACRYSTALS, where some microparacrystals can be recognized. They are linked together by long molecules and work therefore as knots of a three-dimensional network. During strain the chains glide along each other, each moment building up new microparacrystals which, step by step, become smaller until finally every microparacrystal is disintegrated into 30 smaller ones [Fig. 3(b)]. The most disordered microparacrystals are to be found in melts (left corner of Fig. 2). There they have values $g \sim 8\%$ and $\sqrt{N} \sim 2$. Figure 4 shows as an example a microparacrystal of molten Fe or Pb which builds up a cubic face-centered lattice similar to that below the melting point. In contrast to the solid state, the atoms have a high mobility and can move over to other nuclei building up icosahedra in some

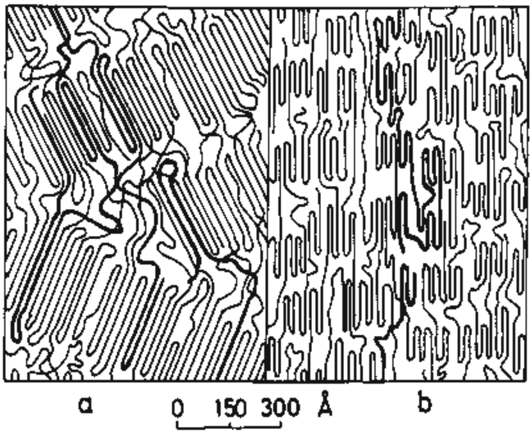

FIG. 3. Microparacrystals in polymers are the knots of a three-dimensional network: (a) before and (b) after stretching eight-fold.

cases.[5] Equation (2) is not only an empirically detected relation but *the fundamental law* of colloid and surface science. It manifests an equilibrium state of microparacrystals which is unknown in conventional solid state physics of condensed matter. For details see the article MICROPARACRYSTALS, EQUILIBRIUM STATE OF.

MICROPARACRYSTALS, EQUILIBRIUM STATE OF

The physical meaning of the α^*-law is that the mean number $\bar{N}$ of netplanes in an ensemble of microparacrystals (the so called mPCs) depends only on the relative distance fluctuation g of atoms belonging to neighboring netplanes (see also the article MICROPARACRYSTALS. Here,

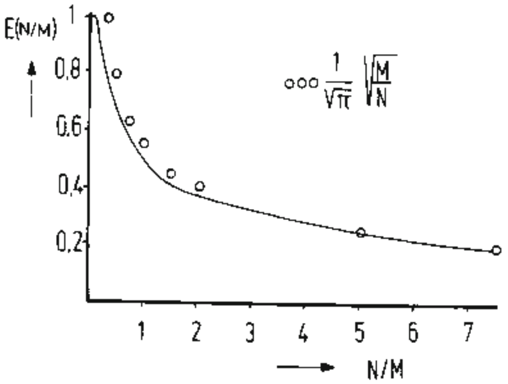

FIG. 1. The probability $E(N)$ of further growth of a microparacrystal consisting of N netplanes.

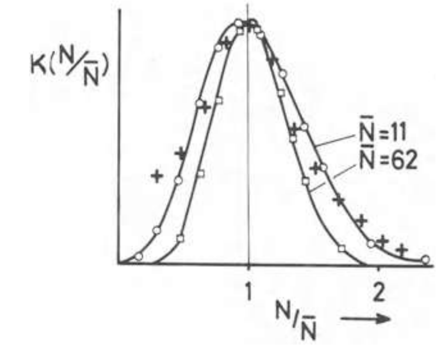

FIG. 2. Frequency distribution $K(N)$ of microparacrystals with $N + 1$ netplanes. Open circles and squares plot $K(N)$ by computer calculation; solid lines drawn by Maxwell approximation. Crosses indicate distribution as directly observed for $\bar{N} = 11$ microparacrystals in DuPont PRD 49 fibers.

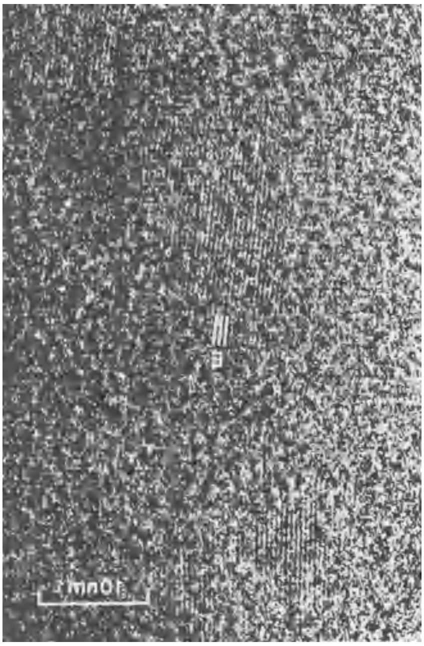

FIG. 3. High-precision transmission-electron-microscopic picture of DuPont PRD 49 fibers.

from the probability $E(N)$, what amount of microparacrystals with $N - 1$ netplanes aggregate the next netplane (see Fig. 1), can be calculated by statistical mechanics. As in biology, where the expectation of surviving the next day decreases continuously day by day, here $E(N)$ begins with a plateau $E = 1$ which suddenly changes to a smooth decay. The frequency $K(N)$ of microparacrystals meeting $N + 1$ netplanes is given by

$$K(N) = E(1)\,E(2)\,E(3)\ldots \cdot E(N - 1)\,(1 - E(N)). \tag{1}$$

$K(N)$ is plotted in Fig. 2 for $\bar{N} = 11$ (open circles) and $\bar{N} = 62$ (open squares) and can be approximated by Maxwellian functions.[2] The crosses in Fig. 2 show the $K(N)$ distribution directly observed[3] from high-precision transmission-electron-microscopic diagrams, with $\bar{N} = 11$ (Fig. 3). This agreement proves directly that the equilibrium state of microparacrystals is of utmost importance for the understanding of noncrystalline condensed matter.[4]

MICROWAVE SPECTROSCOPY

Microwaves are electromagnetic waves which range in length from about 30 cm to a fraction of a millimeter or in frequency from 10^9 to 0.5×10^{12} cps. This corresponds to the rotational frequency range of a large class of molecules. Thus, microwave radiation passing through a gas can be absorbed when the rotating electric dipole moment of the molecule interacts with the electric vector of the radiation. Likewise, absorption can take place if the rotating magnetic moment of the molecule interacts with the magnetic vector of the radiation.

Most microwave spectroscopy is based on a study of transitions induced by interaction of the molecular electric dipole with the incident radiation.

A microwave spectrometer consists basically of a monochromatic microwave source (klystron), an absorption cell, and a detector. The absorption cell must transmit the microwave of interest and in the centimeter region may have cross-sectional dimensions of 1×4 cm and may be a few meters in length. Normally a metal strip is inserted along the length of the cell and is insulated from the cell. In this way, an auxiliary, spatially uniform electric field may be established in the absorption cell without affecting the microwaves. The Stark effect thereby produced splits the molecular energy levels into a series of levels and enables one to identify the transition.

The Hamiltonian for a rotating rigid asymmetric molecule including possible fine and hyperfine structure terms is given in Eq. (1). It is assumed, as is most commonly so, that the molecule is in a $^1\Sigma$ state, i.e., that there is no net electronic angular momentum and no net electron spin (singlet state). The Hamiltonian written is quite general and in many cases not all of the terms shown in Eq. (1) need be included to account for spectra observed under normal resolution.

A brief description will be given of each term in order that one may most simply understand the kinds of interactions which may occur and which may be pertinent to an understanding of the spectra of rotating molecules.

$$H = H_{\mathrm{R}} + H_{\mathrm{dist.}} + H_{\mathrm{S}} + H_{\mathrm{ze}} + H_{Q} + H_{\mathrm{zi}} + H_{\mathrm{D}} \quad (1)$$

1. H_{R} is the framework rotational kinetic energy and may be written

$$H_{\mathrm{R}} = \frac{\hbar^2}{8\pi^2}\left[\frac{J_a{}^2}{I_a} + \frac{J_b{}^2}{I_b} + \frac{J_c{}^2}{I_c}\right]$$

where J_a, J_b, and J_c are the components of the total angular momentum in units of $\hbar$ referred to body-fixed principal axes. I_a, I_b, and I_c are the moments of inertia about the respective principal axes. The Hamiltonian may be written

$$H_{\mathrm{R}} = AJ_a{}^2 + BJ_b{}^2 + CJ_c{}^2$$

or displaying the total angular momentum J

$$H_{\mathrm{R}} = AJ^2 + (B - A)J_b{}^2 + (C - A)J_c{}^2$$

A, B and C are rotational constants with $A > B > C$. In this form, units can be chosen so as to give energy levels directly in megacycles per second. H_{R} describes a rigid symmetric top if I_a is equal to I_b. For a diatomic molecule, $I_a = I_b$ and $I_c \cong 0$. ($1/I_c$ becomes very large, and the rotational levels about the c axis are too far apart to become excited by microwaves). For the spherical rotor, $I_a = I_b = I_c$, but this implies no dipole moment and therefore no observable rotational spectrum.

Energy levels for the symmetric top may be determined by analytical methods,[1] by factorization methods[2], or by using the commutation properties of the angular momenta.[3] In Eulerian coordinates, the wave equation separates, and the wave function has the form

$$\psi_J = N(JKM)e^{iK\phi}e^{iM\psi}\Theta_{JKM}(\theta)$$

where Θ_{JKM} is the solution to the differential equation in the polar angle θ which results after separation of the simple terms in the azimuthal angle ϕ and the angle ψ which defines the direction of the line of nodes. The equation for Θ_{JKM} with appropriate change of variable becomes the equation for the Jacobi polynomials.

The solution ψ is characterized by three quantum numbers: J, the total angular momentum; K the component of angular momentum along the symmetry axis of the molecule; and M, the magnetic quantum number or projection of J along an arbitrary space axis. The energy does not depend on M in the absence of external electric or magnetic fields. The energy levels for the symmetric top have the form

$$E_{J,K} = BJ(J + 1) + (C - B)K^2$$

The rotational constants $A = B$ and C may typically range from 2000 to 300 000 MHz for presently observable spectra. A hertz is one cycle per second. A megahertz (MHz) is one million cycles per second.

Selection Rules In all but the accidentally symmetric top, the permanent dipole will be along the symmetry axis. In this case, the selection rules for absorption of radiation through rotation are:[4]

$$J \rightarrow J \pm 1, K \rightarrow K$$

For a component of the dipole moment perpendicular to the symmetry axis, the selection rules are

$$\Delta J = \pm 1, 0 \text{ and } \Delta K = \pm 1$$

In both cases, $\Delta M = \pm 1, 0$.

The wave functions of the asymmetric top are expressed as linear combinations of symmetric top functions. The energy remains diagonal in J but not in K. One must, therefore, arbitrarily label the energy levels and determine the selection rules. This will not be done here. In order to do this, however, one needs to know only the nonvanishing matrix elements of the three components of the dipole moment for the symmetric top given above.

The selection rule for diatomic molecules is simply $J \rightarrow J \pm 1, M \rightarrow M, M \pm 1$.

2. $H_{\mathrm{dist.}}$ describes centrifugal stretching corrections to the energy levels which for an asymmetric molecule can be quite complicated. Corrections for a symmetric top molecule are easily derived, and the framework energy in this case including centrifugal stretching is given by:

$$E_{J,K} = BJ(J + 1) + (C - B)K^2 - D_J J^2(J + 1)^2 - D_{JK}J(J + 1)K^2 - D_K K^4$$

For a non-rigid diatomic molecule or linear polyatomic molecule, $K = 0$, and the energy is given by:

$$E_J = B_v J(J + 1) - D_v J^2(J + 1)^2$$

and since $J \rightarrow J + 1$, for absorption the line frequencies are:

$$\nu_r = 2B_v(J + 1) - 4D_v(J + 1)^3$$

where B_V is the "effective" spectral constant, $h(8\pi^2 I_V)$, for the particular vibrational state for which the rotational spectrum is observed, and where D_V is the centrifugal stretching constant for that state.

In terms of the constants B_e and D_e for the hypothetical vibrationless state, B_V and D_V for diatomic molecules are:

$$B_V = B_e - \alpha(v + \tfrac{1}{2})$$

$$D_V = D_e + \beta(v + \tfrac{1}{2})$$

where α and β are interaction constants which are very small in comparison with B and D, respectively, and where v is the vibrational quantum number. For linear polyatomic molecules, there is more than one vibrational mode, and the above equations must be written in the more general form

$$B_V = B_e + \sum_i \alpha_i \left(v_i + \frac{d_i}{2}\right)$$

$$D_V = D_e + \sum_i \beta_i \left(v_i + \frac{d_i}{2}\right)$$

where the summation is taken over all the fundamental modes of vibrations. The subscript i refers to the ith mode, and d_i represents the degeneracy of that mode.

In analysis of spectra, the variations of the stretching constants D_J and D_{JK} with vibrational state are customarily neglected. It is seldom possible to obtain sufficient data for the evaluation of these effects upon B and for determination of B_e even for the simpler symmetric tops.

Centrifugal stretching constants may typically range from 8.5 to 0.002 MHz or less.[6]

3. The third term H_S is the contribution to the Hamiltonian arising from the Stark effect and may be written as

$$H_S = \mu_e \cdot \mathcal{E}$$

where μ_e is the vector dipole moment and $\mathcal{E}$ is the external electric field.

If the dipole moment lies along the "c" body-fixed principal axis, H_S has the form

$$H_S = \mu_e(A_x{}^c\mathcal{E}_x + A_y{}^c\mathcal{E}_y + A_z{}^c\mathcal{E}_z)$$

where $A_x{}^c$, $A_y{}^c$, $A_z{}^c$ are the direction cosines of the c principal axis with space-fixed axes xyz. $\mathcal{E}_x$, $\mathcal{E}_y$, and $\mathcal{E}_z$ are the components of the electric field along the space-fixed axes. Additional terms will be added to this expression if the dipole moment has components along the remaining two principal axes. In order to obtain the contribution to the energy from this part of the Hamiltonian, one must evaluate matrix elements of the direction cosines with respect to symmetric top wave functions. Methods described in reference 5 enable one to do this.

In the case of a symmetric top, the dipole moment will have a component only along the c axis so that H_S consists of the single term $A_z{}^c\mathcal{E}_z$ when $\mathcal{E}_x = \mathcal{E}_y = 0$.

In this case, the energy associated with H_S is diagonal in all three quantum numbers JKM and has the form

$$E_S = -\mathcal{E}_z\mu_e \frac{MK}{J(J+1)}$$

where M, the "magnetic quantum number," measures the component of J along $\mathcal{E}_z$ and can take the values $M = J, J-1, \cdots, -J$. The selection rules for M are $M \rightarrow M$; $M \rightarrow M \pm 1$, depending on the polarization of the microwaves.

For asymmetric molecules, μ_e will in general have components along the A and B axes as well as C. The A and B components give rise to matrix elements off diagonal in J, K and M. For a dipole moment of 1 debye and an electric field of 1 volt/cm, $\mu_e\mathcal{E}$ is 0.5 MHz.

4. H_{Ze} is the contribution to the Hamiltonian due to the interaction of the external magnetic field with the magnetic moment which is created by rotation of the molecule.

We also include the interaction of the external magnetic field with the dipole moment of individual nuclei. For a molecule with two nuclear spins, I_1 and I_2, this may be written

$$H_{Ze} = \sum_{j,k} \mu_n(J)_{jk}J_jH_k + \mu_n g_1(I_1 \cdot H) + \mu_n g_2(I_2 \cdot H)$$

where $g(J)$ is in general a tensor, J_j are components of J along axes to which H is referred, H_k are the components of the field H usually referred to the space-fixed axes, and g_1 and g_2 are called the nuclear magnetic g factors. The interaction between J and H is the same order as that between the nuclear spin and H. Therefore, we introduce the term μ_n so that g coefficients are of the order of unity. Thus for a field of one gauss, the quantity $\mu_n gH$ is 0.7 kHz.

For molecules with electronic angular momentum, μ_n in the first term is replaced by μ_0, the Bohr magneton which is 1836 times larger than μ_n. Thus, in this case $\mu_n gH$ is ~ 1.4 MHz for a field of one gauss. For a discussion of the problem of determining molecular g values, as well as magnetic susceptibility anisotropies and molecular quadrupole moments, see Ref. 5.

5. H_Q is the energy of interaction of the nuclear electric quadrupole with the gradient of the electric field produced by the electrons in the molecule at nucleus with spin I. For a nucleus on the axis of a symmetric top, the quadrupole operator is ordinarily considered to be of the form:

$$H_Q = \frac{-eQq}{2I(2I-1)(2J-1)(2J+3)}\left\{1 - \frac{3K^2}{J(J+1)}\right\} \left[3(J+1)^2 + \frac{3}{2}(J \cdot I) - J^2I^2\right]$$

This operator yields only those matrix elements of the quadrupole interaction which are diagonal in J. The diagonal contributions are sufficient for most cases.

In the expression above, eQ is defined by

$$eQ = (I, I | \int \rho_n [3z_n{}^2 - r_n{}^2] d\tau_n | I, I)$$

where ρ_n is the nuclear charge density at a distance r_n from the center of charge of the nucleus and $d\tau$ is the differential volume element for the nuclear volume. z_n is the position coordinate along the direction of the nuclear spin I. The matrix element considered is that for which $M_I = I$.

The quantity q is defined as

$$q = \left[\frac{\partial^2 V}{\partial c^2}\right]_{(r_n = 0)}$$

where V is the electrostatic potential due to the electronic cloud and other nuclei surrounding the nucleus and c is the axis in the body-fixed system which is parallel to the symmetry axis of the molecule. The quantity eqQ varies from - 1000 to 1000 MHz although the intermediate values are more common.[6] A tabulation of matrix elements for quadrupole interaction is given in Ref. 7. For a general discussion, see the book, Ref. 8.

6. H_{zi} represents the interaction between the magnetic field caused by rotation of the charged particles which make up the molecule and the nuclear magnetic moments of the nuclei. For the case of 2 nuclei, this takes the form

$$H_{zi} = \sum_{j,\,k} C(1)_{jk} J_j I_{1k} + \sum_{j,\,k} C(2)_{jk} J_j I_{2k}$$

$C(1)$ and $C(2)$ represent the internal magnetic moment tensors for the two nuclei. The C coefficients are of the order of 10^{-2}MHz.[9] J and I are pure numbers. This correction will therefore be unimportant for the large majority of molecules. For values of the coefficients as determined by molecular beam work, see Ref. 7 and 10.

7. H_D is the dipole interaction between the two nuclei which may be written in the form

$$H_D = \frac{g_1 g_2 \mu_n{}^2}{R^3}\left[I_1 \cdot I_2 - \frac{3(I_1 \cdot R)(I_2 \cdot R)}{R^2}\right]$$

where g_1 and g_2 are the nuclear gyromagnetic ratios of the nuclei, μ_n is the nuclear magneton and R is the distance between the two nuclei.

The operator which is usually used to represent this interaction is

$$H_D = \frac{g_1 g_2 \mu_n{}^2}{R^3} \cdot \frac{[3(I_1 \cdot J)(I_2 \cdot J) + 3(I_2 \cdot J)(I_1 \cdot J) - 2I_1 \cdot I_2 J^2]}{(2J - 1)(2J + 3)}$$

This operator, like that given for the quadrupole interaction above, and usually quoted in the literature, will yield only those matrix elements which are diagonal in the quantum number J. The coefficient $g_1 g_2 \mu_n{}^2/R^3$ may be of the order of a kilocycle. This correction is observed only in very rare cases.[9]

Matrix elements for all of the above-mentioned components of the Hamiltonian may be evaluated by the methods in references 11. The matrix elements themselves are too lengthy to be tabulated here.

There is an additional interaction which, for completeness, should be mentioned. The nuclear spins may interact with one another through mutual coupling with the surrounding electron cloud. This gives a correction of the form $CI_1 \cdot I_2$. The coefficient C may be larger than that in the dipole-dipole interaction term. In TlI, C has the value of 6.57 kHz.[7]

The preceding discussion emphasizes the interpretation of microwave absorption spectra. One is thereby led to a knowledge of the structure of the molecule, the value of nuclear spins, and various coupling constants. For a short review which emphasizes the experimental aspects of microwave spectroscopy see Ref. 12.

Microwave spectroscopy is also an effective technique for determination of barrier heights associated with internal rotation.[13,14,15] It may also yield the barrier to ring puckering and also the barrier to inversion, the earliest example of the latter being the inversion of nitrogen through the plane of the three hydrogens in ammonia; see Rudolph review.[23]

For a discussion of and references to microwave pressure broadening, line shape, and intensities see G. Birnbaum.[16] Among other things line width is related to the rate of energy transfer between molecules. The shape of a microwave line is broadened as pressure increases and this can camouflage fine structure.

We have not discussed electron spin resonance (ESR), also called electron paramagnetic resonance.[17] (See RESONANCE and MAGNETIC RESONANCE.) In this case transitions occur between energy levels created by unpaired electron spins in the presence of an external magnetic field. Absorptions of this type are observed in molecules, free atoms, radicals, and solids.

For a review of properties of high-temperature species as studied by microwave absorption spectroscopy see Ref. 18.

The role of transient effects in microwave spectroscopy is a new area of research. Transients may be achieved by switching the applied Stark field in a microwave spectrometer. The main usefulness of the technique appears to be in the determination of the rates of energy transfer between gas molecules. For details on this subject and many references to other reviews and papers including the same when applied to infrared laser spectroscopy, see the review by R. H. Schwendeman.[19]

Microwave spectroscopy has been extended to the submillimeter infrared region; however, this extension has been limited by the ability to generate harmonics and mix signals in point contact devices. With the advent of the laser, coherent sources have become available in the infrared region. This related subject has been reviewed by V. J. Corcoran.[20]

Although less common than the Stark effect technique, the Zeeman effect, that is, exposure of the molecules to very high magnetic fields (up to 30 kg) may also be used to obtain molecular information. The molecules investigated by this technique are in a "nonmagnetic" ground state. The Zeeman effect then is due to the very small molecular rotational magnetic moment which results from the rotation of the unequally distributed positive and negative charge. The main effect is first order in the magnetic quantum number M, but the slight nonlinear compression of the splitting pattern yields magnetic susceptibility anisotropies that permit calculation of the molecular quadrupole moment tensor. For the effect on the Hamiltonian and reference to original papers see the review by H. D. Rudolph.[23]

For further details and discussion of topics omitted, the reader is referred to the book[13] by W. Gordy and R. L. Cook. For other books see Refs. 6 and 21. For a review of microwave spectroscopy see the article by D. R. Lide, Ref. 22; also the reviews by H. D. Rudolph (1970), Morino and Hirota (1969), and Flygare (1967).[23]

The Hamiltonian required to explain the results of molecular beam electric resonance (MBER) experiments involving radio frequency transitions contains the same kind of interaction terms listed above. Therefore the literature on MBER may be referred to for further theoretical discussion. See, for example, English and Zorn, Ref. 22.

For a review of beam maser spectroscopy see Ref. 24.

For a comprehensive computation of microwave spectra including measured frequencies, assigned molecular species, assigned quantum number, and molecular constants determined from such data, the reader is referred to the multivolume work "Microwave Spectral Tables" prepared by personnel of the National Bureau of Standards.[25]

MICROWAVE TRANSMISSION

That portion of the electromagnetic spectrum adjacent to the far-infrared region is commonly referred to as the microwave region. It is bounded by wavelengths in the vicinity of 10 centimeters (10 cm) and 1 millimeter (1 mm). The longest wavelength of 10 cm corresponds to a frequency of 3×10^9 cycles per second (abbreviated 3000 megahertz or 3 kilomegahertz or 3 gigahertz or 3 GHz). The shortest wavelength of 1 mm corresponds to a frequency of 3×10^{11} cycles per second (abbreviated 300,000 megahertz or 300,000 MHz or 300 kilomegahertz or 300 gigahertz or 300 GHz).

The development of microwave transmission on a major scale was initiated in 1940 with the advent of the magnetron, an electronic generator of high-power microwaves. The magnetron spearheaded wartime radar at approximately 3 GHz and led to the utilization of waveguides for the efficient transmission of microwaves from the generator of the transmitting antenna and from the receiving antenna to the detector.

In essence, a waveguide is a hollow metal tube capable of propagating electromagnetic waves within its interior from its sending end to its receiving end. Unlike waves in space which usually propagate outward in all directions, waves in waveguides are fully confined while they propagate.

An electromagnetic wave is comprised of an electric field and a magnetic field. In free space, these fields are always perpendicular to one another and to the direction of wave propagation at any instant in time. However, when a wave travels through a waveguide, the confinement forces one of the fields, but never both, to have a component that is parallel to the direction of wave propagation.

In a waveguide, there are a number of possible field configurations. Each configuration is known as an operating *mode* and is determined by the operating frequency or wavelength and the lateral dimensions of the waveguide. There are two fundamental classes of modes that may propagate in a waveguide. In one class, the electric field is everywhere perpendicular, or transverse, to the direction of propagation and the magnetic field has a longitudinal component. It is referred to as the *transverse electric mode* or TE mode. In the other class, the magnetic field is transverse and the electric field has a longitudinal component. This configuration leads to the *transverse magnetic mode* or TM mode.

Propagation of either the TE mode or the TM mode is limited by the cross-sectional dimensions of the guide. For example, in a rectangular waveguide, the longest wavelength that can be propagated is equivalent to twice its width. Therefore, to transmit a 3 GHz signal in a rectangular waveguide, the width of the guide must be at least 5 cm. At 300 MHz, this width becomes 50 cm. Thus, waveguides are reasonable in size for the transmission of microwaves. Furthermore, when used with ferrites, thin metallic films and magnets, waveguide components can be designed to function as isolators, circulators, modulators, discriminators, or attenuators.

The propagation of electromagnetic waves in free space between transmitting and receiving antennas can be characterized in terms of ground waves, sky waves, and space waves. At microwave frequencies, ground waves attenuate completely within a few feet of travel, sky waves are influenced by the ionosphere and can penetrate through into outer space, and space waves travel through the atmosphere immediately above the surface of the earth. At microwave frequencies, space waves behave like light waves and travel in a direct line of sight. They follow many of the rules of optics. They can be reflected from smooth conducting surfaces and can be focused by reflectors or lenses.

If a space wave is radiated from a point antenna, the radiated energy spreads out like an ever-expanding sphere, and the amount of energy per square foot of wave front decreases inversely with the square of the distance from the antenna. The power that can be extracted from a wave front by a similar point antenna varies inversely with the square of the frequency. Thus, a point antenna receives power which is inversely proportional to both the square of the distance from the source and the square of the frequency. The ratio of the power received to the total power radiated is known as path attenuation.

When the receiving antenna is a parabola-shaped dish, power extracted from the wave front is greatly increased. The ratio of the power received by such an antenna to the power received by a theoretical point antenna is defined as *antenna gain*. The gain of a parabolic antenna increases with the antenna area and the operating frequency. Thus, for a given microwave transmission with fixed-sized antennas, the path attenuation increases with frequency, the antenna gain increases with frequency, and the overall result is that one tends to offset the other.

In radio broadcasting, the signal power radiates equally in all directions, and a receiving antenna picks up only a tiny fraction of the signal power. To overcome this low efficiency, the broadcast station must transmit a large amount of power. By contrast, a point-to-point microwave system radiates only a small amount of power, but it uses a directional transmitting antenna to concentrate power into a narrow beam directed toward the receiving antenna. Consequently, such systems are characterized by high efficiencies.

Because microwave transmission in free space follows essentially a straight line, reflectors are utilized to redirect a beam over or around an obstruction. The simplest and most common reflector system consists of a parabolic antenna mounted at ground level which focuses a beam on a reflector mounted at the top of a tower. This reflector inclined at 45° redirects the beam horizontally to a distint site where a similar "periscope" reflector system may be used to reflect the beam down to another ground level. If two sites are separated by a mountain, it may be necessary to use a large, flat surface reflector referred to as a "billboard" reflector. In a typical system, a billboard reflector might be located at a turn in a valley, effectively bending the beam to follow the valley. Many arrangements are possible which, in effect, resemble huge mirror systems.

Microwaves are ideally suited for communication systems where a broad frequency bandwidth of the order of several megacycles is required for the rapid transmission of signals which contain a large amount of information, such as, in television signals. Most of the major cities of the United States are serviced by microwave television links so that they can receive television programs which originate from other cities. These systems can also accommodate thousands of telephone channels.

In 1960, experiments were initiated aiming toward communicating over transoceanic distances via microwaves by utilizing balloons as reflectors. Echo I and Echo II were attempts in this direction as passive satellites. The first active repeater satellite (Telstar I) was launched in 1962 and resulted in live telecasts between Europe and the United States in addition to teleprint and other signals. Telstar II added more data to accent the value of satellite communications.

In 1962, Congress authorized the formation of Communications Satellite Corporation (Comsat). In 1964, Comsat took the lead in forming the International Telecommunications Satellite Organization (Intelsat) to coordinate international developments in the use of satellites. Over 100 nations are now members of this extraordinary effort. Today, all transoceanic "live" TV broadcasts and two-thirds of all transoceanic telephone and telegraph communications are via Intelsat satellites. They operate in the 12/14 GHz band in addition to the 4/6 GHz band.

Microwaves are broadly used for radar, navigation, and for the launching, guidance, and fusing of missiles. A typical defense project which uses microwave techniques is the DEW radar line which protects the United States from external enemy attacks.

The HAYSTACK facility which has been in operation since 1966 at Millstone Hill in Massachusetts is the first Western radar built for spacecraft tracking, space communications, and radar astronomy. Through radar astronomical techniques, the multipurpose HAYSTACK 120-foot paraboloid antenna reflector has greatly enhanced our knowledge of the galaxy and solar system. Another famous facility is the 210-foot GOLDSTONE antenna at the NASA Deep Space Institute (California).

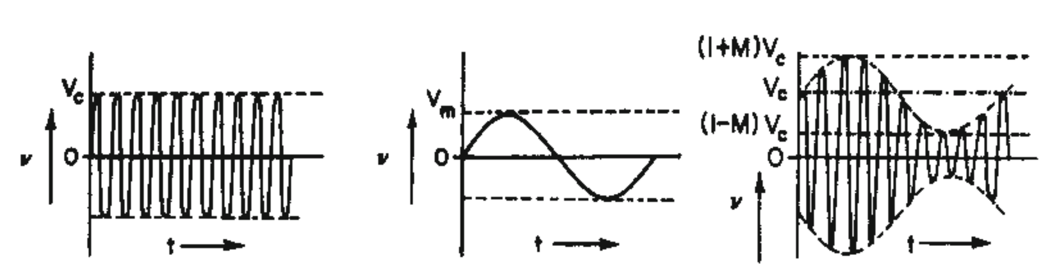
MODULATION

Modulation is defined as the process, or the result of the process, whereby some characteristic of one wave is varied in accordance with some characteristic of another wave (ASA). Usually one of these waves is considered to be a carrier wave while the other is a modulating signal. The various types of modulation, such as amplitude, frequency, phase, pulse width, pulse time, and so on are designated in accordance with the parameter of the carrier which is being varied.

Amplitude modulation (AM) is easily accomplished and widely used. Inspection of Fig. 1 shows that the voltage of the amplitude modulated wave may be expressed by the following equation

$$v = V_c(1 + M \sin \omega_m t) \sin \omega_c t,$$

where V_c is the peak carrier voltage, ω_c and ω_m are the radian frequencies of the carrier and modulating signals, respectively, and t is time in seconds. The modulation index M may have values from zero to one. When the trigonometric identity $\sin a \sin b = \frac{1}{2} \cos (a - b) - \frac{1}{2} \cos (a + b)$ is used in the equation above, this equation



(a) Carrier (b) Modulating signal (c) Amplitude-modulated Carrier

FIG. 1. Amplitude modulation.

becomes

$$v = V_c \sin \omega_c t + \frac{MV_c}{2} \cos (\omega_c - \omega_m)t$$
$$- \frac{MV_c}{2} \cos (\omega_c + \omega_m)t$$

This equation shows that new frequencies, called side frequencies or side bands, are generated by the amplitude modulation process. These new frequencies are the sum and difference of the carrier and modulating frequencies.

Amplitude modulation is accomplished by mixing the carrier and modulating signals in a nonlinear device such as a vacuum tube or transistor amplifier operated in a nonlinear region of its characteristics. The nonlinear characteristic produces the new side-band frequencies. Frequency converters or translators and AM detectors are basically modulators. The various types of pulse modulation are actually special types of amplitude modulation.

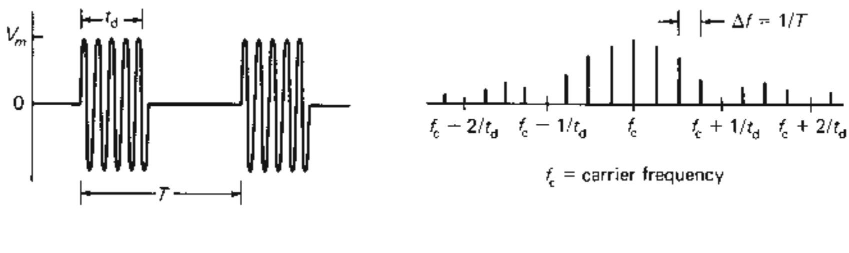
A special type of amplitude modulation known as *pulse modulation* is commonly used in digital communication and other applications. In pulse modulation, the modulating signal abruptly changes the carrier amplitude from zero to some maximum amplitude V_m (or vice versa) as shown in Fig. 2(a).

Therefore, the modulation index is 1, or 100%, at all times. The side frequencies produced in the modulation process are determined by first using Fourier analysis to find the frequency components of the rectangular modulating signal and then adding to the carrier frequency a pair of side frequencies for each of those components. The spacing of these components is $1/T$, which is the fundamental frequency, and the amplitude of these components vary as shown in Fig. 2(b). The envelope of this amplitude variation follows the familiar pattern of a $(\sin x)/x$ function. An infinite bandwidth would be required to either produce or reproduce a perfectly rectangular pulse, which of course is impossible to obtain. Bandwidths in the neighborhood of $2/t_d$, where t_d is the pulse duration in seconds, are commonly used to transmit a double-sideband pulse-modulated signal.

Frequency modulation (FM) is illustrated by Fig. 3. The frequency variation, or deviation, is proportional to the amplitude of the modulating signal. The voltage equation for a frequency modulated wave follows.

$$v = V_c \sin (\omega_c t + M_f \sin \omega_m t)$$

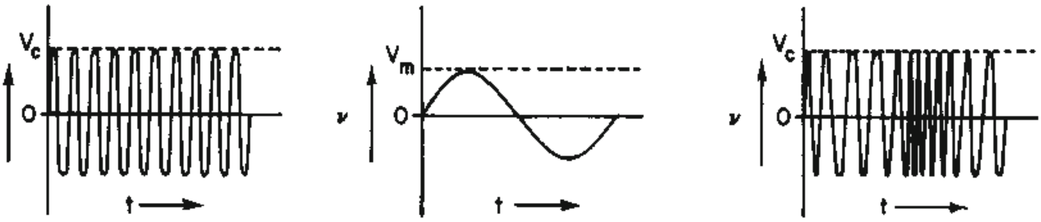
The modulation index M_f is the ratio of maximum carrier frequency deviation to the modulating frequency. This ratio is known as the deviation ratio and may vary from zero to values of the order of 1000. FM requires a broader transmission bandwidth than AM but may have superior noise and interference rejection capabilities. A large value of modulation index provides excellent interference rejection capability but requires a comparatively large bandwidth. The approximate bandwidth requirement for a fre-



f_c = carrier frequency

(a) Pulse-modulated carrier (b) side frequencies generated.

FIG. 2. Pulse (amplitude) modulation.



(a) Carrier (b) Modulating signal (c) Frequency-modulated Carrier

FIG. 3. Frequency modulation.

quency modulated wave may be obtained from the following relationship

$$\text{Bandwidth} = 2\,(\text{Modulating frequency})\,(M_f + 1)$$

The noise and interference characteristics of FM transmission are normally considered satisfactory when the modulation index or deviation ratio is five or greater.

Phase modulation is accomplished when the relative phase of the carrier is varied in accordance with the amplitude of the modulating signal. Since frequency is the time rate of change of phase, frequency modulation occurs when the phase modulating technique is used and vice versa. In fact, the equation given for a frequency-modulated wave is equally applicable for a phase-modulated wave. However, the phase-modulating technique results in a deviation ratio, or modulation index, which is independent of the modulating frequency, while the frequency modulating technique results in a deviation ratio which is inversely proportional to the modulating frequency, assuming invarient modulating voltage amplitude in each case.

The phase-modulating techniques can be used to produce frequency-modulated waves, providing the amplitude of the modulating voltage is inversely proportional to the modulating frequency. This inverse relationship can be obtained by including, in the modulator, a circuit which has a voltage transfer ratio inversely proportional to the frequency.

MOLE CONCEPT

The mole (derived from the Latin *moles* = heap or pile) is the chemist's measure of amount of pure substance. It is relevant to recognize that the familiar *molecule* is a diminutive (little mole). Formerly, the connotation of *mole* was a "gram molecular weight." Current usage tends more to use the term *mole* to mean an amount containing Avogadro's number of whatever units are being considered. Thus, we can have a mole of atoms, ions, radicals, electrons or quanta. This usage makes unnecessary such terms as "gram-atom," "gram-formula weight," etc.

A definition of the term is: *The mole is the amount of (pure) substance containing the same number of chemical units as there are atoms in exactly twelve grams of* ^{12}C. This definition involves the acceptance of two dictates—the scale of atomic masses and the magnitude of the gram. Both have been established by international agreement. Usage sometimes indicates a different mass unit, e.g., a "pound mole" or even a "ton mole"; substitution of "pound" or "ton" for "gram" in the above definition is implied.

All stoichiometry essentially is based on the evaluation of the number of moles of substance. The most common involves the measurement of mass. Thus 25.000 grams of H_2O will contain 25.000/18.015 moles of H_2O; 25.000 grams of sodium will contain 25.000/22.990 moles of Na (atomic and formula masses used to five significant figures). The convenient measurements on gases are pressure, volume and temperature. Use of the ideal gas law constant R allows direct calculation of the number of moles $n = (P \times V)/(R \times T)$. T is the absolute temperature; R must be chosen in units appropriate for P, V and T (e.g., $R = 0.0820$ liter atm mole^{-1} deg K^{-1}). It may be noted that acceptance of Avogadro's principle (equal volumes of gases under identical conditions contain equal numbers of molecules) is inherent in this calculation. So too are the approximations of the ideal gas law. Refined calculations can be made by using more correct equations of state.

Many chemical reactions are most conveniently carried out or measured in solution (e.g., by titration). The usual concentration convention is the *molar* solution. (Some chemists prefer to use the equivalent term *formal*). A 1.0 molar solution is one which contains one mole of solute per liter of solution. Thus the number of moles of solute in a sample will be

$$n = \text{Volume (liters)} \times \text{Molarity (moles/liter)}$$

The amount of chemical reaction occurring at an electrode during an electrolysis can be expressed in moles simply as $n = q\ (\text{coulombs})/z\,\mathcal{F}$ where z is the oxidation number (charge) of the ion and $\mathcal{F}$ is the faraday constant, 96 487.0 coulombs/mole. Thus the *faraday* can be considered to be the charge on a mole of electrons. This affords one of the most accurate methods of evaluating the Avogadro number (6.0220×10^{23}), since the value of the elementary charge is known with high precision.

Modern chemistry increasingly uses data at the atomic level for calculation at the molar level. Since the former often are expressed as quanta, appropriate conversion factors must involve the Avogadro number. Thus the *einstein* of energy is that associated with a mole of photons, or $E = Nh\nu$. Thus light of 2537Å wavelength will represent energy of

$$E = \frac{6.02 \times 10^{23}(\text{photons/mole}) \times 6.62 \times 10^{-27}(\text{erg-sec}) \times 3.000 \times 10^{10}(\text{cm/sec})}{2.537 \times 10^{-5}(\text{cm}) \times 4.184 \times 10^{7}(\text{erg/cal}) \times 10^{3}(\text{cal/kcal})}$$

$$E = 113 \text{ kcal/mole}$$

If the SI system of units is used

$$E = \frac{6.022 \times 10^{23}(\text{mol}^{-1}) \times 6.626 \times 10^{-34}(\text{J} \cdot \text{s}) \times 3.000 \times 10^{8}(\text{ms}^{-1})}{2.537 \times 10^{-7}(\text{m})}$$

$$= 4.740 \times 10^{5}(\text{J mol}^{-1})$$

Another convenient conversion factor is 1 eV/particle = 23.05 kcal/mole.

The chemist's use of formulas and equations always implies reactions of moles of material, thus HCl(g) stands for one mole of hydrogen chloride in the gaseous state. Thermodynamic quantities are symbolized by capital letters standing for molar quantities, e.g., C_v (heat capacity at constant volume in cal mole^{-1} deg^{-1}), G (Gibbs function in cal/mole), etc. At times it is more convenient to convert an extensive property into an intensive expression. This is especially true in dealing with multicomponent systems. These are referred to as "partial molal quantities" and are given a symbol employing a bar over the letter. Thus the partial molal volume, $\overline{V}_1 = (\partial V/\partial n_1)$ is the rate of change of the total volume of a solution with the amount (number of moles) of component 1.

MOLECULAR BIOLOGY

Molecular biology, the study of biologically important molecules and their interactions, is the result of the progression of biology from the classical study of whole organisms to the more recent study of individual cells and their components. Its beginnings are usually dated from the announcement of the double-helical structure of DNA molecules made by Watson and Crick in 1953. During the early years of molecular biology, most attention was focused on bacteria and their viruses, since they were the most easily studied systems. For example, under appropriately controlled conditions, hundreds or thousands of liters of bacteria can be prepared in which every cell is essentially identical. Most of our fundamental knowledge about the ways in which cells synthesize and use their macromolecules was originally derived from the study of bacterial systems.

At the present time, however, the trend is in the opposite direction. A concerted effort is underway to apply the models developed for molecular biologic processes to multicellular organisms. Such organisms present a real challenge to biologists, since most complex organisms contain more than one kind of cell (the cells have "differentiated"), and the interactions between these groups of cells within an organism are carefully controlled. Moreover cells from multicellular organisms differ in fundamental ways from those of bacteria.

Examples of these differences can be seen by referring to Figs. 1A and 1B, which show transmission electron micrographs taken of thin sections of the two types of cells. Figure 1A is a bacterial cell which exhibits typical features such as a central cluster of DNA; basically featureless cytoplasm (the liquid portion of the cell) surrounded by a lipid bilayer (cell or unit membrane); and a rigid cell wall around the entire organism. This type of cell is considered

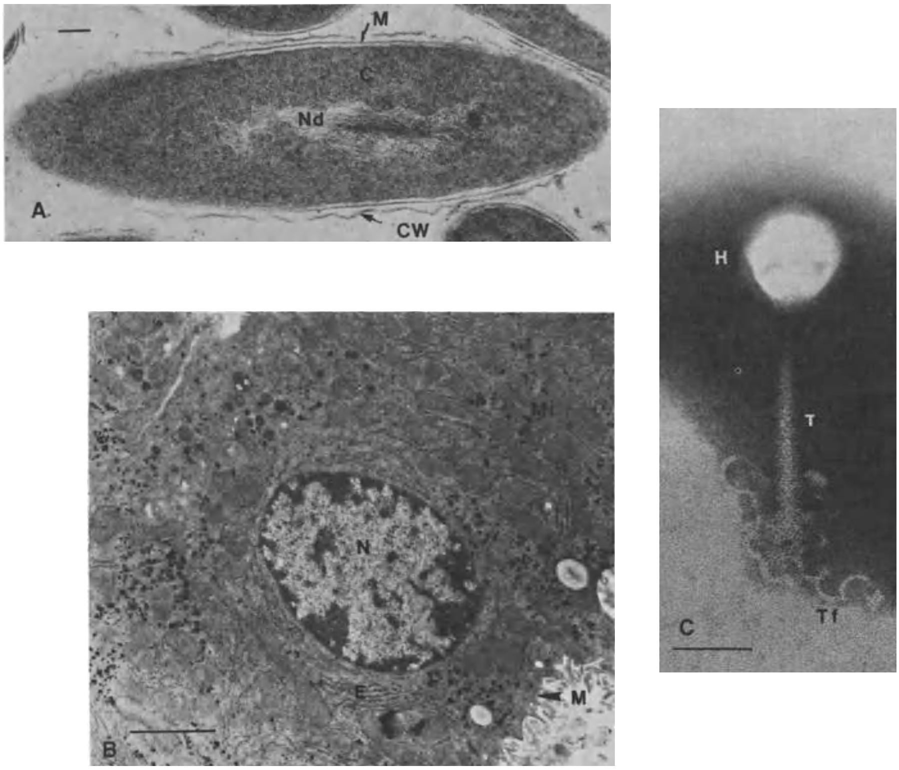

FIG. 1. Examples of biologic organization as seen in the transmission electron microscope. (A) A thin section of the prokaryote *Bacillus sphaericus* prepared by Dr. Elizabeth W. Davidson, Arizona State University. The length of the bar is 0.1 micrometer. (B) A thin section of a eukaryotic cell (from rat liver) prepared by Dr. Candice J. Coffin, Arizona State University. The length of the bar is 1.0 micrometer. (C) An intact bacterial virus, PBS1, negatively stained with potassium phosphotungstate by E. A. Birge. The length of the bar is 0.1 micrometer.

The labeled structures are: C, cytoplasm; CW, cell wall; E, endoplasmic reticulum; H, head; M, cell membrane; Mi, mitochrondria; N, nucleus; Nd, nucleoid; T, tail; Tf, tail fiber.

ancestral, in an evolutionary sense, to the type of cell shown in Fig. 1B, and is designated as prokaryotic. Figure 1B shows a eukaryotic cell with its typical nucleus surrounded by a unit membrane; cytoplasm containing energy-producing mitochondria and the membranous structures known as endoplasmic reticulum; and a unit membrane surrounding the entire cell. Animal cells do not have cell walls, although plant cells do. This type of cellular organization is typical not only of plants and animals but also the unicellular protozoa, fungi, and true algae.

Despite the differences noted above, there are basic similarities between prokaryotic and eukaryotic cells. The basic materials from which the cells are made are identical, as are many of the macromolecules within the cells. In both cases, the genetic material is deoxyribonucleic acid (DNA), which must be synthesized in a semiconservative manner (replicated) prior to each cell division. This process is facilitated by the double-stranded nature of the DNA molecule itself.

Both DNA and the related molecule ribonucleic acid (RNA) are polymers of nucleotide bases composed of certain nitrogenous bases (adenine, cytosine, guanine, thymine and uracil; abbreviated A, C, G, T, and U, respectively) coupled to a pentose (either deoxyribose or ribose) and then to phosphate, as shown in Fig. 2. The polymeric chain is formed by alternating pentoses and phosphates with the nitrogenous bases projecting to one side. RNA is generally single-stranded, incorporating the bases ACGU, while DNA is generally a double-stranded molecule incorporating the bases ACGT. The structure of DNA molecules is somewhat variable and dependent upon such factors as the temperature, salt concentration, and base composition, but a typical helical structure for DNA is shown in Fig. 3. The structure is formed by pairing bases from the parallel strands according to the following rule: A pairs with T and G pairs with C. When RNA is involved, U is substituted for T. During the replication process mentioned above, this base pairing is utilized to spontaneously line up the

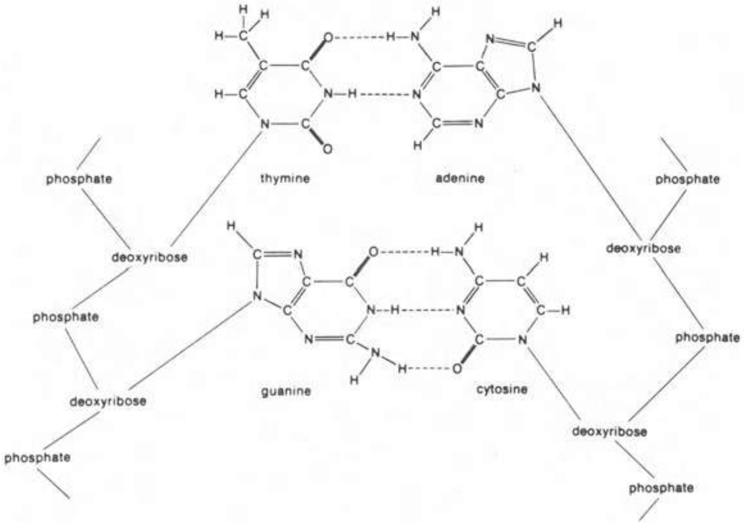

FIG. 2. Pairing of DNA strands to make a helix. In the diagram the backbones of the two DNA strands are shown along the right and left margins. The bases project into the space between and are held together by hydrogen bonds (dotted line). (Reproduced from Walter, W. G., McBee, R. H., and Temple, K. L., "Introduction to Microbiology," New York, D. Van Nostrand Company, 1973.)

precursor nucleotides so that a polymerase enzyme can join them together. Polymerases are extremely fast acting and may join as many as 250–1000 nucleotides per second under the appropriate conditions.

The genetic information for any cell is encoded in redundant form within its DNA base sequence due to the specificity of base pairing. This information is not, however, directly available for use. Instead an RNA copy of one of the two DNA strands (the "sense" strand) is made by an RNA polymerase following the usual base pairing rules in a process called transcription. Each coding region of the DNA is capable of producing specific RNA molecules whose functions are predetermined. Some are used as part of the subcellular structures called ribosomes and are designated rRNA. Others are used as highly specific carriers of the amino acids, the subunits of the polymers called proteins, and are designated transfer or tRNA. Still other molecules, the rarest class, contain the actual code which determines the sequence of amino acids used to construct a protein. These molecules are designated as messenger or mRNA molecules and tend to be unstable. They code for only one protein if isolated from a eukaryotic cell but may code linearly for as many as ten discrete proteins if isolated from a prokaryotic cell. To a first approximation, each region of the DNA coding for an rRNA, tRNA, or individual protein molecule represents a gene. Overlapping genes are rare but not unknown.

The next step in utilization of genetic infor-

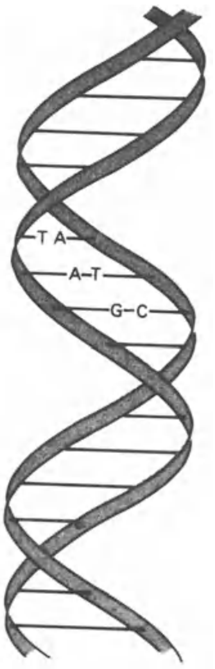

FIG. 3. The winding of a DNA double helix. A less magnified view of a DNA molecule than shown in Fig. 2, this diagram shows the B form structure. There are ten base pairs per turn of the helix, and each pair is rotated 36° with respect to the preceding pair. Reproduced from Walter et al.

mation is the translation of the genetic code into the appropriate sequence of amino acids. Each triplet of bases (codon) codes for a specific amino acid or punctuation signal, and all possible triplets are meaningful. Therefore ribosomes must always attach to mRNA at specific sites to ensure the proper "reading frame." During translation, codons on the mRNA are matched to corresponding anticodons on the tRNA by the usual base pairing rules to assure delivery of the correct amino acid.

In prokaryotes, which have no compartmentalization within their cytoplasm, translation occurs as soon as the mRNA is formed. In eukaryotes, however, the DNA and initial RNA transcripts are found in the nucleus, while the translation machinery is found in the cytoplasm. As a result the RNA must be exported from the nucleus. Before this can happen, the RNA must be processed to remove certain noncoding or intervening sequences which are present in most eukaryotic genes. The processed mRNA is passed through pores in the nuclear membrane into the cytoplasm. In either type of cell, translation occurs in a processive fashion on a complex of a single mRNA molecule and multiple ribosomes called a polysome. Although prokaryotic and eukaryotic ribosomes are similar in function, they are somewhat different in structure, with the prokaryotic ribosomes being smaller than their eukaryotic counterparts.

Interestingly certain organelles within eukaryotic cells, the chloroplasts (sites of photosynthesis) and the mitochondria, contain small DNA molecules coding for ribosomes of the prokaryotic type. It is now considered likely that at least chloroplasts are descended from primordial prokaryotic cells which colonized eukaroytic cells.

As protein molecules are produced, they fold spontaneously into three-dimensional configurations appropriate to their function. In the case of proteins intended for use outside the producing cell, they are generally produced in an inactive configuration which is altered by removal of a portion of the amino acid chain during transport through the cell membrane. As is true for most substances, movement of proteins across the cell membrane is an energy-requiring process.

All of the normal cellular processes mentioned above can be subverted by small obligate intracellular parasites called viruses. These entities represent the boundary between living and nonliving matter. When not in a cell, they have the appearance of complex crystals of protein and nucleic acid, as shown in Figure 1C. Viruses are generally rod-shaped or polyhedral structures consisting of a protein "coat" and a highly condensed nucleic acid molecule which may be RNA or DNA. Infection of a cell consists of movement of the nucleic acid across the cell membrane. In the case of prokaryotic cells, only the nucleic acid enters the cell. For eukaryotic cells the entire virus enters, and then the protein coat is removed.

Once inside the cell, viruses follow one of two patterns. In a "lytic" infection, the viral nucleic acid immediately uses the host cell enzymes to produce more viral nucleic acid and the proteins necessary to encase it. Other viral specific enzymes may be produced to facilitate this process by disrupting host cell functions not necessary for the production of viruses. New virus particles are produced not by division of a preexisting entity, as is the case with cells, but rather by a sequential assembly process which shows remarkable similarities to formation of chemical crystals from a supersaturated solution. In most cases, the host cell is destroyed or "lysed" during release of the viral particles. This observation has given rise to an alternative name for bacterial viruses—bacteriophages or simply phages.

The second mode of viral infection is called a "temperate" infection. In this case the viral nucleic acid establishes a semipermanent relationship with the cell which preserves both virus and host cell. If the viral nucleic acid is RNA, it is converted to DNA. The DNA then sets up a stable association with the host DNA such that the host cell replicates the viral DNA at the same time as it replicates its own DNA. The viral DNA, instead of producing coat proteins and lytic factors, produces a protein repressor which acts to prevent the synthesis of mRNA molecules coding for the lytic functions. The quiescent viral DNA is now designated as a provirus or prophage, since the appropriate stimulus will cause it to revert to the lytic form and destroy its host cell. Not all viruses are capable of the temperate response, and those which are capable of the temperate response do not necessarily use it.

Proviral DNA has been observed to exist in two forms. It may integrate itself into the host cell DNA and become an actual physical part of the cell's genetic material. Alternatively it may exist as a small independent circular DNA molecule which replicates side-by-side with the host DNA. The latter form of DNA is called a plasmid and is more commonly found in prokaryotes.

The term plasmid actually encompasses a much larger group of DNA molecules than just viruses. Nonviral plasmids have been observed in most bacteria and many of the simpler eukaryotes such as yeast. These extra pieces of DNA are considered dispensable to the host cell even though they may, under the appropriate conditions, increase the cell's chances for survival. Examples of this include plasmids which make bacterial cells resistant to certain antibiotics or which allow them to break down certain complex molecules such as xylene for food.

Recent discoveries in molecular biology are having a profound effect on our understanding of molecular genetics and on the way in which

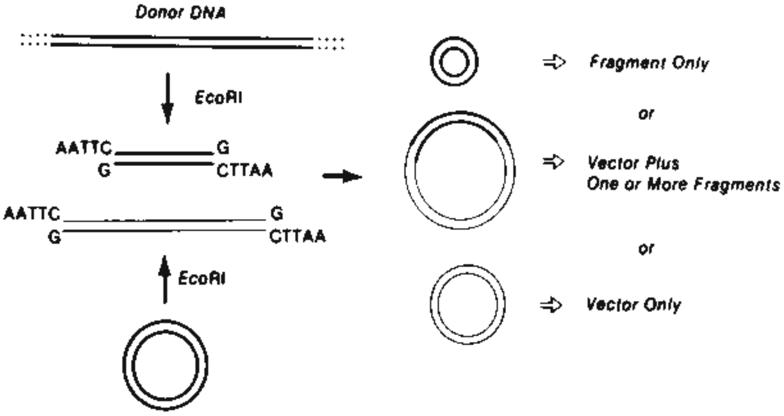

FIG. 4. A diagrammatic representation of gene splicing. The double circle at the bottom left of the diagram represents a double-stranded plasmid DNA molecule, while the double-stranded donor DNA at the top may be from any source. The *Eco*RI enzyme is the prototypical restriction endonuclease which always leaves identical single-stranded ends on the cut DNA. As shown on the right-hand side of the diagram, the single-stranded regions may pair so as to reform the original molecules or to form new constructs. (Adapted from Birge, E. A., "Bacterial and Bacteriophage Genetics: An Introduction," New York, Springer-Verlag, 1981.)

biologic problems can be solved. It is now known that while most portions of DNA molecules are stable over long periods of time, in both prokaryotes and eukaryotes certain small regions within the DNA molecules are naturally highly unstable. These unstable regions, called transposons, consist of special terminal elements with a wide variety of coding elements such as antibiotic resistance located between them. The terminal elements have the ability to cause the entire transposon to simultaneously replicate itself and insert itself into a new position on the same or a different DNA molecule. Transposons thus represent "jumping genes" and provide a way to move bits of DNA around in the cell in a more or less random fashion.

The greatest impact on modern biology has been made by combining the information presented above with the new techniques which have been developed for producing artificial rearrangement of DNA molecules—techniques known as gene splicing. The procedures all depend upon the action of certain restriction endonucleases produced by various bacteria. These enzymes attack all "foreign" DNA, molecules which have not been suitably modified by the addition of small substituents such as methyl groups at specific sites. They cleave the unmodified DNA at base sequence-specific sites to produce variably sized fragments. Since all DNA fragments produced by a given enzyme will have identical ends, it is a comparatively easy job to rejoin the fragments in new combinations and permutations in a manner such as shown in Fig. 4. When the spliced DNA is inserted into a cell and the cell is allowed to grow, the result is a clone of cells all of which carry the particular DNA segment of interest.

Application of these techniques has led to a true biologic revolution. It is now possible to splice purified DNA into the middle of plasmids or transposons and to insert the spliced DNA into living cells. This is genetic engineering in the fullest sense of the term. The results that have been obtained from the process have included such oddities as bacteria which produce human insulin or growth hormone or animal cells which carry bacteriophage DNA. Constructs like these may some day permit us to understand precisely how cells regulate their internal processes as well as their interactions with neighboring cells. They certainly promise to revolutionize the study of biology.

As the preceding discussion indicates, it is apparent that a cell is constantly involved in many activities which require the movement of molecules. The extent of this feat becomes more apparent when a few size comparisons are made. A typical bacterial cell may be a rod approximately one micrometer in diameter and several micrometers in length. The DNA molecule of the same cell is a circular structure approximately one millimeter in length. In the case of a human cell, the diameter of the nucleus is about 10 micrometers and the 46 linear DNA molecules represent a length of about one meter. Clearly the DNA cannot exist as a random coil within the cell and still allow space for other activities.

Prokaryotic and eukaryotic cells have solved this problem in different ways. In prokaryotic cells the circular DNA molecule is formed into

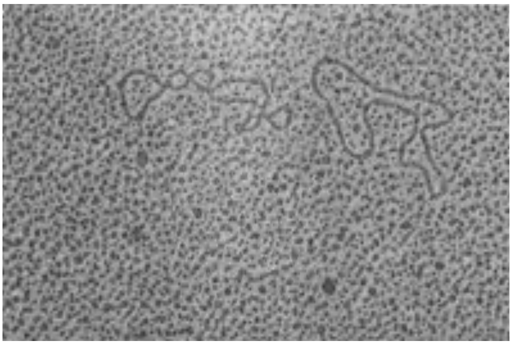

FIG. 5. Supercoiling of DNA. The two DNA molecules have been spread onto a thin plastic film; stained with uranyl acetate; and then shadowed with platinum and palladium. The molecule on the left has retained its supercoils, while the one on the right has one or more broken phosphodiester bonds and has therefore lost all of its superhelicity. (Electron micrograph by E. A. Birge.)

a series of loops, each of which is supercoiled by a family of enzymes called topoisomerases. These enzymes break either one or two strands of the DNA helix and can pass other strands of DNA through the nicked region. Therefore they also have the interesting property of being able to tie and untie knots within the DNA molecule. An example of the difference between supercoiled and "relaxed" DNA molecules can be seen in Fig. 5. The highly supercoiled DNA molecule comprises the nucleoid seen in Fig. 1A.

Eukaryotic cells literally coil their linear DNA around cylinders of protein called histones. There are four histone proteins, three of which are used to make cylinders and one of which covers the DNA which connects adjacent cylinders. The net effect is to take a single DNA molecule and coil it into a sort of "beads on a string" structure. Such a structure is called a chromosome and may exist in an extended state or in an even more condensed form during cell division.

Further information on packaging problems and many other topics discussed in this article can be obtained from the references.

MOLECULAR SPECTROSCOPY

Molecular spectroscopy encompasses the broad range of efforts to understand and utilize the interaction of gas-phase molecules with electromagnetic radiation. Spectroscopy is the basic tool for exploring the internal structure of molecules, and spectroscopic studies are of fundamental importance for understanding the microscopic properties of matter. Molecular spectroscopy is also of considerable practical value, since the spectrum of a molecule provides a characteristic "fingerprint" by which that molecule may be identified.

The spectrum of a molecule may be measured either by determining the wavelengths absorbed by the molecule (absorption spectroscopy) or by observing the wavelengths emitted by a sample of excited molecules (emission spectroscopy). In either case, the spectrum is far more complex than an atomic spectrum. Emission and absorption are found to occur from radiofrequency wavelengths through the infrared and visible regions of the spectrum and far into the ultraviolet. Under conditions of low resolution, the visible spectrum is observed to consist of numerous *bands*, hence the designation *band spectra*. Higher resolution demonstrates that each band is composed of numerous closely spaced lines. The microwave and infrared portions of the spectrum are much less congested and easier to analyze. Herzberg's three-volume work[1] on molecular spectroscopy is the major reference. The fact that Volumes I and II have been in print for over 30 years testifies to their enormous success. A more modern presentation is given by Steinfeld.[2]

Those wavelengths which are present in a molecular spectrum are governed by the law of quantum physics which states that a photon of frequency $f = (E_2 - E_1)/h$ is emitted or absorbed whenever the molecule undergoes a transition between energy levels E_1 and E_2. Here h is Planck's constant. Understanding the spectrum, then, is equivalent to understanding the energy levels of a molecule. All of the essential features of molecular spectra are present in diatomic molecules, to which the discussion below is restricted. The energy level structure of polyatomic molecules can be explained by extending the concepts developed for diatomic molecules. A recent compilation of data for diatomic molecules is given by Huber and Herzberg.[3]

It is customary in molecular spectroscopy to express frequencies in units of *wave numbers* (cm^{-1}). The wave number of a photon of frequency f is f/c, where c is the speed of light in vacuum. Since the frequency f and wavelength λ of an electromagnetic wave are related by $\lambda f = c$, it is seen that the wave number is the reciprocal of the wavelength. Using $f = (E_2 - E_1)/h$, the photon's wavenumber is $(E_2 - E_1)/hc$. The values E_1/hc and E_2/hc, which also have units of cm^{-1}, are known as the *term values* of the energy levels E_1 and E_2. Spectroscopists find it convenient to refer to energy levels by their term values, since a transition between two levels involves a photon whose wave number is given simply by the difference in the term values of the levels.

The electrons in a molecule are much lighter and move much more rapidly than do the nuclei. Consequently, it is possible, to a high level of accuracy, to separate the problems of electronic motion and nuclear motion. This procedure is called the Born-Oppenheimer approximation. Each electronic state is characterized by the value of its electronic angular momentum projected onto the internuclear axis. This component of the electronic angular momentum is conserved by virtue of the fact that a diatomic molecule is symmetric for rotations about the internuclear axis. In analogy with the atomic physics notation of $S, P, D, F, \ldots$, an electronic state is labeled Σ, Π, Δ, $\Phi, \ldots$ if its projected angular momentum, in units of $h/2\pi$, is $0, 1, 2, 3, \ldots$. The energy of an electronic state depends not only upon the electron configuration but also upon the internuclear separation R. Theorists are still challenged by the difficult problem of calculating accurate electronic energies. The transitions between different electronic states are responsible for visible and ultraviolet molecular spectra since, as in atoms, energy differences between the states are generally several electron volts. The appearance of bands rather than distinct lines is a consequence of the nuclear motion.

A physical model for the nuclear motion is obtained by considering the molecule to be a dumbbell which can vibrate along the internuclear axis as well as rotate end-over-end. The vibrational energy G and the rotational energy F must be added to the electronic energy T_e to give the total molecular energy: $T = T_e + G + F$. Nuclear vibration occurs in the potential well formed by the negative electronic binding energy, which is a function of R, and the positive energy due to Coulomb repulsion of the nuclear cores. The potential reaches a minimum at a particular value r_e of the internuclear separation. This is the equilibrium internuclear distance, and the nuclear separation oscillates about this equilibrium value. For small displacements from equilibrium, the vibrational motion can be approximated by that of a simple harmonic oscillator. The classical oscillation frequency for nuclei of mass M_1 and M_2 is given by

$$f_{\mathrm{osc}} = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}}$$

where k is the force constant and $\mu = M_1 M_2/(M_1 + M_2)$ is the reduced mass. Solution of the Schrödinger wave equation for the quantum harmonic oscillator leads to energy levels given by

$$E_{\mathrm{vib}}(v) = hf_{\mathrm{osc}}(v + \tfrac{1}{2})$$

where $v = 0, 1, 2, 3, \ldots$ is the vibrational quantum number. Transforming to term values, by dividing by hc, the vibrational energy levels of a harmonic oscillator molecule are

$$G(v) = \omega(v + \tfrac{1}{2})$$

where ω is the vibrational frequency expressed in cm^{-1}.

Although the harmonic oscillator approximation displays the essential features of the vibrational motion, the actual potential in which the nuclei vibrate deviates rather sharply from a harmonic potential. A more complete expression for the vibrational energy can be developed as a power series in $(v + \frac{1}{2})$ and is given by

$$G(v) = \omega_e(v + \tfrac{1}{2}) - \omega_e x_e(v + \tfrac{1}{2})^2 + \omega_e y_e(v + \tfrac{1}{2})^3 + \ldots.$$

Here the subscript e refers to the equilibrium position, and the coefficients for each higher-order term ($\omega_e x_e$, $\omega_e y_e$, . . .) become successively smaller. It is rarely necessary to go beyond the cubic term when analyzing experimental data. The energy difference between adjacent vibrational states is typically 0.1 electron volt, a factor of 100 less than the energy difference between electronic states.

A first approximation for the end-over-end rotational motion is to consider the molecule to be a rigid rotor. Quantizing the angular momentum leads to energy levels which are given by

$$E_{\mathrm{rot}}(J) = \frac{h^2 J(J+1)}{8\pi^2 I}$$

where I is the molecule's moment of inertia and $J = 0, 1, 2, 3, \ldots$ is the rotational angular momentum quantum number. Expressing these as term values, the rotational energy levels of a molecule are

$$F(J) = BJ(J+1)$$

where

$$B = \frac{h}{8\pi^2 cI}$$

is called the rotational constant.

Again, the actual nuclear motion is more complex than this simple model. Centrifugal distortion of the molecule has the effect of introducing a term proportional to $J^2(J+1)^2$. In addition, the rotational constant depends slightly upon the vibrational quantum number, since vibration changes the average moment of inertia. These considerations lead to a more general formula for the rotational energy, namely,

$$F(J) = B_v J(J+1) - D_v J^2(J+1)^2 + \ldots$$

where the subscript v indicates a dependence upon the vibrational quantum number. The separation between adjacent rotational energy levels is typically 0.001 electron volt.

Division of the molecular energy into electronic, vibrational, and rotational energies has been quite successful for understanding the primary features of molecular spectra. At the very highest levels of resolution, however, it is observed that each line in a band splits into several very closely spaced lines. This *fine structure* is a result of interactions, or couplings, between the various types of motion which, until now, have been considered separately. A typical example, known as Λ-doubling, is a coupling between the molecule's electronic and rotational motions. The existence of fine structure emphasizes the limitations of the Born-Oppenheimer approximation. After the various couplings are included, all known aspects of molecular spectra can be understood.

Each spectral line is a consequence of the absorption or emission of photons which occurs when molecules undergo transitions between two energy levels. Comparison of an observed spectrum with theoretical energy levels requires knowing which transitions are allowed and which are forbidden. Information of this sort is codified into *selection rules.* Most selection rules can be understood by considering the possible symmetries of a molecule.

Visible and ultraviolet spectra result from transitions between two different electronic states. The primary selection rule specifies that the molecule's angular momentum quantum number J can change only by $\Delta J = \pm 1$ or 0. Three groups of lines appear, each associated with a particular value of ΔJ, which are called P, Q, and R branches. Changes in the vibrational quantum number are not restricted by any selection rules. However, the Franck-Condon principle, which states that the internuclear separation cannot change during the emission or absorption of a photon, makes transitions between some pairs of vibrational levels far more likely than between other pairs. A band is formed from the combined P, Q, and R branches associated with a transition between a particular vibrational level of the upper electronic state and a particular vibrational level of the lower electronic state. Thirty or more rotational levels in the initial state of a room temperature gas can be populated, and each is allowed by the ΔJ selection rule to undergo a transition to three levels in the final state. Hence each band in a spectrum is comprised of 100 or more distinct lines. It is not surprising, then, that the analysis of molecular spectra made little progress before the advent of quantum physics.

Spectral lines in the infrared occur when a molecule undergoes a transition between two different vibrational levels within the same electronic state. The $\Delta J = \pm 1$ or 0 selection rule still holds, so P, Q, and R branches can again be identified (although the $\Delta J = 0$ Q-branch transitions are forbidden in Σ electronic states). If the vibrational motion were exactly that of a harmonic oscillator, a selection rule $\Delta v = \pm 1$ would apply to the vibrational quantum number. This rule is not rigorous since, as was noted, the harmonic oscillator model is not perfect. Nevertheless, $\Delta v = \pm 1$ transitions are usually the strongest.

Transitions between the rotational levels of a given vibrational level are characterized by frequencies in the far infrared and microwave regions of the spectrum. Only $\Delta J = \pm 1$ are possible for this case, so only a P and an R branch appear. Rotational spectra appear very simple and regular when compared to visible band spectra. Transitions between two rotational levels can often be detected by the absorption of microwaves. The high accuracy with which microwave frequencies can be measured allows rigorous tests of the theory of molecular structure. This aspect of molecular spectroscopy is discussed in a well-known text by Townes and Schawlow.[4]

Another important feature of a molecular spectrum is the intensities of the lines. Even casual observation of a spectrum reveals that some lines are quite intense while others are barely perceptible. This can be understood by noting that not all of the possible transitions from a particular initial state are equally probable. Each molecular transition is characterized, then, not only by a wavelength but also by a *transition probability.* The larger the transition probability, the more intense the spectral line. In emission spectroscopy, where the initial state is an excited state, the transition probabilities determine the average amount of time that a molecule spends in the excited state before emitting a photon. This quantity, known as the *lifetime* of the excited state, is typically 1×10^{-7} second. The measurement of excited state lifetimes is an important part of molecular spectroscopy.

Energy levels in polyatomic molecules may also be understood by a consideration of electronic, vibrational, and rotational motions. Instead of a single mode of vibration, an N-atom polyatomic molecule will have $3N - 6$ possible modes of vibration; $3N - 5$ for a linear molecule. Rotation in a polyatomic molecule is possible about three separate axes, although a useful simplification occurs for symmetric-top molecules, where two of the axes become equivalent. As a consequence of the additional vibrational and rotational motions, polyatomic molecules have many more energy levels than diatomic molecules. The spectrum which is actually observed is again dependent upon selection rules which govern the allowed transitions between energy levels. Even moderate-size molecules (3 or 4 atoms) exhibit spectra which are exceedingly complex, and full rotational resolution is, in general, obtainable only at the highest possible resolution. Spectra of larger molecules are usually analyzed only in terms of electronic and vibrational motions, rotational analysis not being possible. The study of polyatomic molecular spectra is aided considerably by the use of group theory.

Experimental molecular spectroscopy historically has been pursued with the use of grating spectrometers. While other techniques are now available, grating spectrometers continue to play a major role in contemporary research, especially for investigations of ultraviolet spectra. The wide spectral range of spectrometers, from the far infrared into the vacuum ultraviolet, makes them exceptionally versatile tools. Instruments range in size from portable tabletop models, with resolution of 1 part in 10^3, to room-size giants, with resolution of 1 part in 10^6. Spectrometers designed for use in the ultraviolet or far infrared are evacuated, to prevent atmospheric absorption, and utilize special optical materials.

Both absorption and emission spectra can be measured with a grating instrument. For absorption, light from a continuum source is passed through an absorption cell (sometimes the spectrometer itself) and then dispersed. Excitation spectra are obtained by dispersing the light from a discharge which contains the molecule of interest.

Photographic plates have long been the traditional means of detecting the dispersed light, but they are rapidly being replaced by photoelectric detectors, which are more sensitive as well as more compatible with computers.

Fourier transform spectroscopy[5] represents an alternative to grating spectroscopy. The basis for this technique extends back to Michelson, who noted that the output of an interferometer, as a function of time, is the Fourier transform of the light source spectrum, as a function of frequency. Practical realization, however, has awaited the appearance of high-speed, inexpensive computers. In a typical experiment, light from a continuum source passes through an absorption cell, containing the molecule of interest, and then through a Michelson interferometer. The interferometer's output intensity, as measured by an appropriate detector, is digitized as the mirror moves and then transferred to a computer, which calculates the Fourier transform of the data to produce the spectrum. Resolution with a Fourier transform spectrometer can exceed that with a large grating spectrometer. Infrared spectroscopy has made the most use of this technique, with high resolution studies of, among many other molecules, H_2O, CO_2, CH_4, and C_2H_4. Fourier transform spectroscopy has been valuable as well for visible spectra, especially for mapping the complex spectrum of I_2, which extends throughout much of the visible region of the spectrum.[6] Because of the high absolute precision with which they were measured, I_2 wavelengths are now routinely used as standards in many spectroscopy experiments.

The recent development of lasers, especially tunable lasers, has awakened a new interest in molecular spectroscopy and motivated a rapid proliferation of new experimental techniques.[7] Although absorption spectroscopy with laser sources has been highly successful, particularly in the infrared, the most innovative techniques have utilized laser-induced fluorescence. Spectra are obtained in these experiments by detecting photons which are emitted from excited states (fluorescence) as the laser wavelength is varied. Excitation to the higher energy level occurs whenever the laser's wavelength coincides with a spectral line, enabling those molecules in the proper lower energy level to absorb laser photons and thus undergo the upward transition. Significant advantages of laser spectroscopy include high resolution, low background and noise, and exceptionally high sensitivity. Laser-induced fluorescence experiments have obtained spectra from molecules at densities as low as 10^4 cm^{-3}. This has been especially valuable for the study of free radicals (chemically unstable molecules) and molecular ions.

Laser spectroscopy techniques have been developed for both the near-infrared and far-infrared spectral regions. Tunable diode lasers and color center lasers now cover the entire near-infrared region from 1 to 30 μm. Wavelengths for transitions between different vibrational energy levels of a single electronic state typically fall within this range, and laser absorption spectroscopy, because of the narrow laser linewidths, provides good resolution of the rotational structure even for quite large molecules. Extensive investigations have been made for molecules such as NH_3, C_2H_2, CF_4, and SF_6.

Far-infrared lasers have wavelengths which are well-matched to rotational transitions in many molecules. These lasers, however, operate at fixed frequencies. Spectroscopy can nonetheless be performed by "tuning" the molecule. This is accomplished by applying a strong magnetic field which shifts the molecule's energy levels (Zeeman effect) until the transition frequency between the two levels matches the laser frequency. Laser magnetic resonance, as this procedure is called, is rapidly increasing in usage as more and more far-infrared laser lines are discovered.

Tunable laser radiation from dye lasers is available throughout the visible region of the spectrum. Nonlinear optical techniques, such as frequency doubling, extend the range of tunability to wavelengths as short as 200 nm. This is the wavelength region for band spectra associated with transitions between different electronic states, and both laser absorption and laser-induced fluorescence, as well as more exotic laser techniques, have been used to study a large number of molecules. In most laser spectroscopy experiments, the resolution is limited not by the laser's linewidth but rather by the Doppler width of the transition, a consequence of molecular motion. The limiting resolution of around 1 part in 10^6, often inadequate to resolve rotational details in polyatomic molecules, is poor when compared with the limit of 1 part in 10^9 or better which is set by the laser's linewidth. This has spurred considerable interest in techniques of Doppler-free spectroscopy. One such technique, which has been especially fruitful for ultra-high resolution spectroscopy, is optical-optical double resonance. It has been used for studies of molecules such as BaF_2, CaF_2, and NO_2. Other Doppler-free techniques have been applied to a variety of molecules.

Ultrahigh resolution alone is often inadequate for analysis of the highly complex spectra of polyatomic molecules. A new experimental technique, introduced to grapple with this problem, is laser spectroscopy of supersonic molecular beams.[8] Molecules of interest, often seeded into a rare gas, are forced at high pressure through an expansion nozzle into vacuum. The expansion process cools the molecules' vibrational and rotational motions down to temperatures of only a few degrees Kelvin, leaving the molecules in only a handful of the lowest energy levels. This greatly simplifies the spectrum and facilitates analysis. The small molecule NO_2 has a remarkably complex visible spectrum which for many years had stubbornly resisted attempts at analysis. New efforts with supersonic beams and Doppler-free laser spectroscopy have, however, finally succeeded in establishing a basis for understanding this molecule.

Recent advances in the spectroscopy of free radicals and molecular ions,[9] difficult to produce in large quantities, stem from the development of such high-sensitivity techniques as laser spectroscopy. The unpaired electron found in most of these species adds complexity as well as interest to their spectra. The number of radicals and ions studied, however, remains quite small in comparison with stable, neutral molecules. High resolution studies of several molecular ions have been performed by laser spectroscopy of ion beams. The infrared spectrum of the one-electron molecule HD^+ was measured with sufficient accuracy to test rigorously the foundations of molecular theory. Another promising technique, which avoids problems due to the rapid recombination of molecular ions, is the use of laser spectroscopy to study ions which are stored in an ion trap.

Spectroscopic data for molecules are valuable far beyond the walls of the laboratory. Spectra are used in a wide range of applications, from the routine industrial analysis of chemicals to the identification of atmospheric pollutants. Perhaps the most important application in recent years of molecular spectroscopy has been in the field of interstellar chemistry.[10] Nearly 60 molecules in interstellar molecular clouds have been identified on the basis of their molecular spectrum, and the number continues to grow. While astronomers have observed and identified some visible spectral lines, most of the molecules have been detected by radio astronomers on the basis of microwave-emitting rotational transitions. Identification of these interstellar molecules has been possible only because of the extensive collection and tabulation of molecular spectroscopy data which has been going on for many years. In a few cases, suggestions by astronomers that some of the observed features were due to "exotic" molecules have prompted laboratory workers to produce and measure the spectra of these species. The interchange between astronomy and molecular spectroscopy has been beneficial for both sides, but with over 200 interstellar microwave lines still unidentified, much work remains to be done.

Both fundamental and applied spectroscopy have witnessed remarkable growth in the last decade. Increasing demand for spectroscopic data and continuing advances in technology will undoubtedly keep molecular spectroscopy vigorous for many years to come.

MOLECULAR WEIGHT

The molecular weight of a chemical compound is the sum of the atomic weights of its constituent atoms. The molecule is the smallest weight of a substance which still retains all of its chemical properties. By convention, each atomic weight, and therefore molecular weights, are expressed relative to an arbitrary standard (see below). For example, the molecule of acetic acid, CH_3COOH, contains two atoms of carbon, four of hydrogen, and two of oxygen, so that its molecular weight is the sum of 2(12.01) + 4(1.01) + 2(16.00), which totals 60.06. This molecular weight value is clearly in arbitrary units, but a related quantity, the gram-molecular weight or mole, is the molecular weight expressed in grams. One mole of any compound has been found to contain 6.022×10^{23} molecules, and this number is called the Avogadro constant.

For many years, the standard used for atomic weights was the exact value 16 for the naturally occurring mixture of isotopes of oxygen. Another system of atomic weights, based on the value of 16 for the most abundant (99.8 per cent) oxygen isotope, came into use for comparisons involving single atoms or molecules where isotopic differences were important. A conference of the International Commission on Atomic Weights in 1961 adopted as the standard a value of exactly 12 for the carbon-12 isotope, and since then all atomic weights in use have been based on this standard.

The weights of molecules range from a value of about two for the hydrogen molecule to several millions for some virus molecules and certain polymeric compounds. Molecular dimensions accordingly range from a diameter of about 4Å for the hydrogen molecule to several thousand angstroms—which has permitted viewing single large molecules in the electron microscope. Molecular sizes are generally much smaller and are not measured directly, but are deduced from x-ray diffraction studies of ordered groups of molecules in the crystalline state or from the physical properties such as hydrodynamic behavior of molecules in the gaseous or liquid state.

Many methods for determining molecular weights which are described below depend fundamentally on counting the number of molecules present in a given weight of sample. However, any usable sample contains a very large number of molecules: at least ten trillion of the largest known molecules are present in the smallest weight measurable on a sensitive balance. Therefore, an indirect count is made by measuring physical properties which are proportional to the large number of molecules present. A consequence of the large number of molecules sampled is the averaging of any variations in content of atomic isotopes in individual molecules, so that normal isotopic fluctuations lead to no measurable deviation of molecular weight values. Abnormally high concentrations of isotopes in radiation products may, however, produce altered molecular weights.

The term molecular weight is properly applied to compounds in which chemical bonding of all atoms holds the molecule together under normal conditions (see BOND, CHEMICAL). Thus, covalent compounds, as represented by many organic substances, usually are found to have the same molecular weight in the solid, liquid, and gaseous states. However, substances in which some bonds are highly polar may exist as un-ionized or even associated molecules in the gaseous state and in nonpolar solvents, but they may be ionized when dissolved in polar solvents. For example, ferric chloride exists in the gaseous state as $FeCl_3$ at high temperatures, as Fe_2Cl_6 at lower temperatures as well as in nonpolar solvents, but reverts to $FeCl_3$ in solvents of moderate polarity, and becomes ionic in water solutions—as chloride ions and hydrated ferric ions. Similarly, acetic acid and some other carboxylic acids associate as dimers in the vapor state and in solvents of low polarity, but exist as monomers with progressive ionization as the solvent polarity increases.

Truly ionic compounds, such as most salts, exist only as ions in the solid and dissolved states, so that the term molecule is not applicable and is not commonly used. Instead, the term, formula weight, is used; this denotes the sum of the atomic weights in the simplest formula representation of the compound. If a broad definition of a molecule as an aggregate of atoms held together by primary valence bonds is adopted, then salts in the crystalline state would appear to have a molecular weight which is essentially infinite and limited only by the size of the crystal, since each ion is surrounded by several ions of opposite polarity to which it is attached by ionic bonds of equal magnitude.

A further complication in the definition of molecular weights occurs with inorganic polymers, such as the polyphosphates and polysilicates, whose polymeric nature is clearly evident in both their crystal structure and their highly viscous behavior in the molten state. However, the magnitude of their molecular weights often cannot be found by conventional methods because they are either insoluble or react with solvents, with consequent degradation. These examples indicate that the molecular weight often depends on the conditions used for measurement and must be specified where compounds subject to association, dissociation or reaction are studied.

The history of the clarification of molecular weight concepts is of considerable interest, since this was so intimately related to other developments in chemical knowledge. Although Dalton had published a table of atomic weights in 1808, and by 1825 molecular formulas, derived from combining weights, were in use, many misconceptions of these formulas remained until about 1860. Then evidence from chemical reactions and from measurements of vapor densities firmly established the formulas of many inorganic and simple organic compounds as they are represented today. The vapor density method, based on Avogadro's hypothesis, was thus the first molecular weight method and continues to be useful for compounds that can be easily volatilized. It was not until 1881 that Raoult showed that the depression of freezing points was proportional to the molar concentration of solute. In 1884, van't Hoff related the osmotic pressure of solutions to the vapor pressure, boiling point, and freezing point behavior, and these methods were quickly put into use for determining molecular weights. The abnormal physical properties of salt solutions were explained in 1887 by the ionization theory of Arrhenius, and the very careful measurements of many of these properties furnished the strongest confirmation of the theory. While these measurements provided the most precise determinations of the extent of dissociation of weak electrolytes, they also contributed to the development of the Debye-Hückel theory for strong electrolytes.

Molecular Weight Distributions Most synthetic and many natural polymeric substances are mixtures of molecules having various chain lengths, and thus of different molecular weights—so-called polydisperse systems. In such cases, molecular weight values have an ambiguous meaning, and no single such value will completely represent a sample. Various techniques for measuring molecular weights, when applied to one of these materials, will produce values which often disagree by a factor of two or more. This disagreement arises from the different bases of the methods—for example, some methods yield so-called number-average molecular weights by determining the number-concentration of molecules in a sample, while other methods produce weight-average molecular weights which are related to the weight-concentrations of each species. Another common value is the viscosity-average molecular weight, which is related to the viscosity contribution of each species. Other bases are of importance for certain methods of study, and some of these are complex functions involving several averages. For some purposes, the determination of a single average molecular weight is sufficient for establishing relations between molecular weight and the behavior of polymers, but the type of molecular weight average must be so chosen as to have a close relation to the behavior property of interest. A more detailed knowledge of the constitution of a sample is sometimes required, particularly if several properties are to be considered, or if unusual forms of molecular weight distribution curve are present.

The problem of completely defining the molecular weight nature of polydisperse materials is most accurately solved by determining the frequency of occurrence of each molecular species and representing the results as a frequency distribution curve. Such a study is generally quite tedious, though there are a few methods which provide much of the required information in one experiment. The method currently most used for determining molecular weight distributions of polymers is size exclusion chromatography, which includes gel permeation chromatography and gel filtration. This involves measurement of the differences in extent of permeation of molecules of different sizes into pores of a solid or gel matrix. The distribution of molecular sizes found is converted into a distribution of molecular weights by calibration with standard polymer samples. The method is rapid and applicable to many polymer types. Alternatively, polymers can be separated by fractional precipitation or fractional solution into a series of fractions each of which contains a fairly narrow distribution of molecular weights. Each fraction can then be characterized by one of the methods described below to yield an average molecular weight. Finally, the molecular weight distribution curve can be constructed by summation of these results. While the curve derived is somewhat inexact, it is the best approach to samples which are not susceptible to analysis by the chromatographic methods. The ultracentrifuge is less commonly used for determining molecular weight distributions in a single experiment, partly because of high instrumentation costs and partly because of the complexity of methods needed to analyze the data.

Uses. Molecular weight measurements, in conjunction with the law of combining proportions, have enabled the atomic weights of elements in compounds to be determined. When the atomic weights are known, molecular weight measurements permit the assignment of molecular formulas. Other applications to compounds of low molecular weight allow determination of the extent of ionization of weak electrolytes, and the extent of association of some uncharged compounds which aggregate. The study of molecular weights is becoming increasingly valuable in assessing the effects which various molecular species of a polymer sample have on the physical properties of the product. Through such knowledge, the synthetic process may be modified to improve the properties of polymers.

Methods of Measurement Many physical and certain chemical properties vary substantially with the molecular weight of compounds, and these properties are the bases of all molecular weight methods. The summary given in this section includes principally the methods which are most frequently used or have general applicability. The choice of the most suitable method for a given sample depends on its state (gas, liquid, or solid), the magnitude of the molecular weight and the accuracy required in its determination, as well as on the stability of the compound to physical or chemical treatment. Some mention of the applicability of the methods in these regards is given wherever possible.

Gases and Liquids Avogadro's hypothesis (1811) that equal volumes of different gases contain the same number of molecules under the same conditions made it possible to find how many times heavier a single molecule of one gas is than that of another. Thus, relative molecular weights of all gases could be established by comparing the weights of equal volumes of gases. The significance of the idea and utilization of this method were first clearly demonstrated by Dumas in 1827, but it was not until 1860 that the results were accepted by most scientists when Cannizzaro showed that a consistent system of atomic weights resulted. With the additional information from chemical experiments on the number of atoms of each kind present in each molecule, the relative weights of each atom were obtained. The assumption of the integral value, 16, for the atomic weight of oxygen (to give a value close to unity for the lightest element, hydrogen) then enabled molecular weights of all gaseous compounds to be determined. The method obviously can be applied to other molecules which normally occur in the liquid state but can be volatilized by heating. The Dumas and Victor Meyer methods are most used for molecular weight determinations with liquids in this way. These methods have been refined so that gas densities can now be determined with an accuracy of 0.02 per cent, and extremely small weights of material (about 1 μg) can be similarly studied with somewhat less accuracy. High temperatures up to 2000°C have been used to study substances which are volatilized only with difficulty, provided decomposition can be avoided.

Solids Measured by Colligative Methods It has been shown that nonvolatile molecules dissolved in a solvent affect several physical properties of the solvent in proportion to the number of solute molecules present per unit volume. Among these properties are a decrease of the vapor pressure of the solvent, a rise in its boiling point, a decrease in its freezing point, and the development of osmotic pressure when the solution is separated from the solvent by a semipermeable membrane. Properties such as these which are related to the number of molecules in a sample rather than to the type of molecule are called colligative properties. They are the basis for some of the most useful techniques for molecular weight determination. The magnitude of the effects and the ease of measurement differ greatly, so that certain of the colligative properties are preferred for this purpose. For example, an aqueous solution containing 0.2 gram of sucrose (molecular weight 342) in 100 ml has a vapor pressure 0.01 per cent less than that of the solvent, a boiling point 0.003°C greater, and a freezing point 0.011°C lower than the solvent, but will develop an osmotic pressure of 150 cm of water. Since the effects are related to the number-concentration of solute molecules, each method leads to a number average molecular weight if the sample consists of a mixture of molecules of different sizes. Accurate results with any of the techniques are obtained only when measurements at a series of concentrations are extrapolated to infinite dilution where the system becomes ideal, i.e. is not affected by interactions between molecules.

Direct vapor pressure measurements with a differential manometer are generally limited to the larger depressions produced by low molecular weight solutes, while refined techniques such as isothermal distillation require the most exact control of conditions. Isopiestic methods allow the comparison of the vapor pressure of solutions of an unknown with those containing a known substance, and several modifications have been used more than other vapor pressure methods. Ebulliometric techniques which depend on the elevation of the boiling point of a solvent are often used for solutes of low molecular weight and find some use for large molecules. Since boiling points are highly sensitive to the atmospheric pressure, it is either necessary to control pressure very precisely, or more commonly to measure the boiling points of both the solvent and solution simultaneously. Often a differential thermometer is employed to determine only the difference of the two temperatures, and these devices have been made so sensitive that molecular weights as large as 30 000 have sometimes been studied. Techniques involving the lowering of the freezing point of a solvent (cryoscopic methods) are much used for rapid approximate determinations of molecular weights in the identification of organic compounds. For this purpose a substance such as camphor, which is a good solvent for many organic compounds and has a large molar depression constant, is often chosen to magnify the difference in freezing point of the solvent and the solution of the unknown. Since freezing-point depressions are not sensitive to atmospheric pressure, they are easier to measure accurately than the methods described above, and much use has been made of them for precise studies of solutes having low molecular weights. The possibility of association or ionization of the solute must be considered with any of these methods, since these effects will greatly influence the result.

Osmotic pressures are so much larger than any other colligative property that they are most widely used for molecular weight measurements, particularly for long-chain polymers where the high sensitivity of the method is required. For accurate measurements, a membrane is required which permits the flow of solvent through its pores but completely holds back solute molecules. This condition is best satisfied where there are large differences in size of the solute and solvent molecules or of their affinity for the membrane. Membranes made from cellulose compounds are often successfully used for polymers which contain little material with molecular weights below about 10 000. Below this molecular weight the pore size of the satisfactory membranes is so small that solvent flow is very slow, and thus a very long time is required to reach constant osmotic pressure. In spite of this handicap, some of the most precise osmotic pressure measurements have been obtained with aqueous solutions of sucrose and similar small solutes by the use of membranes prepared by precipitating such materials as copper ferrocyanide in the pores of a solid support. The upper limit of molecular weights satisfactorily meaured by osmometry is usually about 500 000, which is fixed by the lowest pressures that can be measured precisely and by the maximum concentrations of material which still give satisfactory extrapolations to infinite dilution. In comparing various colligative properties for the characterization of polymers, osmometry has the advantage that it is unaffected by the presence of impurities of very low molecular weight which will diffuse through membranes able to retain the polymer, whereas the other properties are greatly affected by the same impurities.

Modern instrumentation has provided commercial instruments utilizing several of these colligative properties for routine, accurate measurements in very short time and with small samples. This is true for boiling point, vapor pressure, and freezing point measurements of molecular weights up to several thousand, and for membrane osmotic pressure measurements of high molecular weight samples.

X-ray Diffraction X-ray diffraction analysis is a powerful method for determining exact molecular weight and structural characteristics of compounds in their crystalline state. However the method is complicated and slower than many techniques which provide molecular weights of accuracy sufficient for many purposes and so is usually employed only when the additional structural information is needed. The sample to be examined must have a high degree of crystalline order and is preferably a single crystal at least 0.1 mm in size; such samples are prepared fairly readily from many inorganic and nonpolymeric organic compounds. Alternatively, crystalline powders of certain crystal types may provide suitable results. Diffraction patterns are then obtained by one of several methods, and the angular positions of the reflections are used to calculate the lattice spacings, and thus the size of the unit cell. This unit cell is the smallest volume unit which retains all geometrical features of the crystalline class, and it contains a small integral number of molecules. A rough estimate of the molecular weight of the compound is needed from a determination by an independent method in order to obtain this integral number. Finally, the resultant molecular volume is multiplied by the exact bulk density of the crystal and by the Avogadro number to yield the molecular weight (see X-RAY DIFFRACTION).

Light Scattering Measurements of the intensity of light scattered by dissolved molecules allow the determination of molecular weights. Most commonly the method is used for polymers above 10 000 units, though under optimum conditions molecular weights as low as 1000 have been determined. Since the intensity scattered by a given weight of dissolved material is directly proportional to the mass of each molecule, a weight-average value of the molecular weight is obtained for a polydisperse system. An average dimension of the molecule can also be obtained by a study of the angular variation of scattered light intensity, provided some dimension of the molecules exceeds a few hundred angstroms. The interaction between dissolved molecules substantially affects the intensity of scattered light so that extrapolation to infinite dilution of data collected at several polymer concentrations is required. The method has been so well developed in the last decade that it is now probably the most used method for determining absolute molecular weights of polymers. In addition, it provides information on sizes which is furnished by few other methods. The greatest problem encountered is in the removal of suspended large particles which otherwise would distort the angular scattering pattern of the solutions. This is rather easily accomplished by filtration in some cases, but it may be a formidable difficulty for particles which are highly solvated or are peptized by the molecules to be studied. Auxiliary information is required on the refractive index increment of the sample, i.e., the change in refractive index of the solvent produced by unit concentration of the sample. This information is supplied by a differential refractometer using the same wavelength of light as that employed in measurements of the intensity of scatter.

The Ultracentrifuge. The sedimentation of large molecules in a strong centrifugal field enables the determination of both average molecular weights and the distribution of molecular weights in certain systems. When a solution containing polymer or other large molecules is centrifuged at forces up to 250 000 times gravity, the molecules begin to settle, leaving pure solvent above a boundary which progressively moves toward the bottom of the cell. This boundary is a rather sharp gradient of concentrations for molecules of uniform size, such as globular proteins, but for polydisperse systems, the boundary is diffuse, the lowest molecular weights lagging behind the larger molecules. An optical system is provided for viewing this boundary, and a study as a function of the time of centrifuging yields the rate of sedimentation for the single component or for each of many components of a polydisperse system. These sedimentation rates may then be related to the corresponding molecular weights of the species present after the diffusion coefficients for each species are determined by independent experiments. Both the sedimentation and the diffusion rates are affected by interactions between molecules, so that each must be studied as a function of concentration and extrapolated to infinite dilution as is done for the colligative properties. The result of this detailed work is the distribution of molecular weights in the sample which is available by few other methods. At present, this method is only partly satisfactory for molecular weight determinations with linear polymers because of the large concentration dependence of the diffusion coefficients. Difficulties have been found in reliably extrapolating diffusion coefficients beyond the lowest polymer concentrations which are experimentally attainable at present.

A modification of the sedimentation method which avoids the study of diffusion constants is the sedimentation equilibrium method in which molecules are allowed to sediment in a much weaker field. Under these conditions, the sedimenting force is balanced by the force of diffusion, so that after times from a day to two weeks molecules of each size reach different equilibrium positions, and the optical measurement of the concentration of polymer at each point gives the molecular weight distribution directly. However, again extrapolation to infinite dilution must be used to overcome interaction effects. The chief difficulty here is the long time of centrifuging required, and the necessary stability of the apparatus during the period. A newer and somewhat faster technique, the Archibald method, permits the determination of weight-average molecular weights of polymers by analysis of the concentration gradient near boundaries soon after sedimentation begins.

Chemical Analysis When reactive groups in a compound may be determined exactly and easily, this analysis may be used to determine the gram equivalent weight of the substance. This is the weight in grams which combines with or is equivalent to one gram-atomic weight of hydrogen. This equivalent weight may then be converted to the molecular weight by multiplying by the number of groups per molecule which reacted (provided they each are also equivalent to one hydrogen). If the number of reactive groups in the molecule is not known, then one of the physical methods for determining molecular weight must be used instead. The chemical method is convenient and often used for the identification of organic substances containing free carboxyl or amino groups which can readily be titrated, and for esters which can be saponified and determinations made of the amount of alkali consumed in this process. The equivalent weights of ionic substances containing, for example, halide or sulfate groups may also be determined by titration or by gravimetric analysis of insoluble compounds formed with reagents which act in a stoichiometric fashion. In the titration of acids, the "neutral equivalent" is the weight of material which combines with one equivalent of alkali, and a similar definition applies to the "saponification equivalent" of esters. If only one carboxyl or ester group is present in the molecule, these values equal the molecular weight of the compound.

In a similar way, if the terminal groups on polymer chains can be determined by a chemical reaction without affecting other groups in the molecule, the equivalent weight or molecular weight of the polymer may be obtained in certain cases. For polydisperse systems, a number-average value of the molecular weight is obtained because the process essentially counts the total number of groups per unit weight of sample. Since the method depends on the effect of a single group in a long chain, its sensitivity decreases as the molecular weight rises, and so is seldom applicable above molecular weights of 20 000. Particularly at high molecular weights, the method is very sensitive to small amounts of impurities which can react with the testing reagent, so that careful purification of samples is desired.

It is also important to know that impurities or competing mechanisms of polymerization do not lead to branching or other processes which may provide greater or fewer reactive groups per molecule. The analysis for end groups must be carried out under mild conditions which do not degrade the polymer, since this would also lead to lower molecular weight values than expected. Labeling of end groups either with radioactive isotopes or with heavy isotopes which can be analyzed with the mass spectrometer provides a rapid and convenient analysis for end groups. This labeling can be accomplished with a labeled initiator if this remains at the chain ends, or after polymerization is complete, by exchange of weakly bonded groups with similar groups in a labeled compound. Molecular weight determinations by end group analysis are often used for condensation polymers of lower molecular weights and are especially valuable in studying degradation processes in polymers.

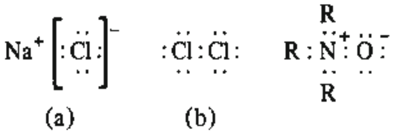
MOLECULES AND MOLECULAR STRUCTURE

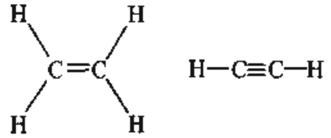
A molecule is a local assembly of atomic nuclei and electrons in a state of dynamic stability. The cohesive forces are electrostatic, but, in addition, relatively small electromagnetic interactions may occur between the spin and orbital motions of the electrons, especially in the neighborhood of heavy nuclei. The internuclear separations are of the order of 1 to 2 × 10^{-10} metres, and the energies required to dissociate a stable molecule into smaller fragments fall into the 1 to 5 eV range. The simplest diatomic species is the hydrogen molecule-ion H_2^+ with two nuclei and one electron. At the other extreme, the protein ribonuclease contains 1876 nuclei and 7396 electrons per molecule.

Historically, molecules were regarded as being formed by the association of individual atoms. This led to the concept of *valency*, i.e., the number of individual chemical bonds or linkages with which a particular atom can attach itself to other atoms. When the electronic theory of the atom was developed, these bonds were interpreted in terms of the behavior of the valence, or outer shell, electrons of the combining atoms. Each atom with a partly filled valence shell attempts to acquire a completed octet of outer electrons, either by electron transfer, as in (a), to give an electrovalent bond, resulting from Coulombic attraction between the oppositely charged ions



(a) (b) (c) ($R = CH_3$)

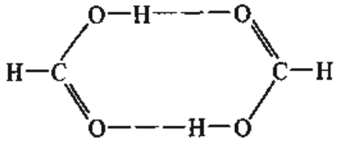
(W. Kossel, 1916); or by electron sharing, as in (b) and (c), to give a covalent bond (G. N. Lewis, 1916). In (b), each chlorine atom donates one electron to form a homopolar bond, which is written Cl—Cl where the bar denotes on this theory one single bond, or shared electron pair. In (c), the nitrogen-oxygen bond is formed by two electrons donated by only the nitrogen atom, giving a *semipolar*, or *coordinate-covalent* bond, which is written $R_3N \rightarrow O$, and which is electrically polarized. Double or triple bonds result from the sharing of four or six electrons between adjacent atoms, as in ethylene (d) and acetylene (e) respectively.



(d) (e)

However, difficulties arise in describing the structures of many molecules in this fashion. For example, in benzene (C_6H_6), a typical aromatic compound, the carbon nuclei form a plane regular hexagon, but the electrons can only be conventionally written as forming alternate single and double bonds between them. Furthermore, an electron cannot be identified as coming specifically from any of these bonds upon ionization. Such difficulties disappear in the quantum-mechanical theory of a polyatomic molecule, whose electronic wave function can be constructed from nonlocalized electron orbitals extending over all of the nuclei. The concept of valency is not basic to this theory, but is simply a convenient approximation by which the electron density distribution is partitioned in different regions in the molecule.

Molecular compounds consist of two or more stable species held together by weak forces. In *clathrates*, a gaseous substance such as SO_2, HCl, CO_2 or a rare gas is held in the crystal lattice of a solid, such as β-quinol, by van der Waals-London dispersion forces. The *gas hydrates*, e.g., $Cl_2 \cdot 6H_2O$, contain halogen molecules similarly trapped in ice-like structures. The hydrogen bond, with energy ~ 0.25 eV, is responsible not only for the high degree of molecular association in liquids such as water (O—H———O—H———) but also for such molecules as the formic acid dimer



which contains two hydrogen bonds indicated by dashed lines. *Molecular complexes* vary greatly in their stability; in donor-acceptor complexes, electronic charge is transferred from the donor (e.g., NH_3) to the acceptor (e.g., BF_3), as in a semipolar bond. The $BF_3 \cdot NH_3$ complex has a binding energy with respect to dissociation into NH_3 and BF_3 of 1.8 eV. The bond here is relatively strong; the electron transfer can occur between the components in their electronic ground states. On the other hand, in weaker complexes such as $C_6H_6-I_2$, with binding energy of about 0.06 eV, there is only a fractional transfer of charge from benzene to iodine. The actual ionic charge-transfer state lies at much higher energy than the ground state of the complex.

The discovery of $XePtF_6$ by Bartlett (1962) has been followed by the synthesis of many other rare gas compounds whose existence was not predicted by classical valency theories. Compounds such as XeF_2, XeF_4, XeF_6 and $XeOF_4$ are quite stable, the average Xe–F bond energy in the square planar molecule XeF_4 being 1.4 eV.

A molecule X is characterized by:

(1) A *stoichiometric formula* $A_aB_bC_c \cdots$ where $a,b,c, \cdots$ are the numbers of atoms of elements $A,B,C, \cdots$ that it contains. The ratio $a : b : c : \cdots$ is found by chemical analysis for these elements. The absolute values of a, b, c, $\cdots$ are then fixed by determination of the *molecular weight* of X. For a volatile substance, the gas density of X and of a gas of known molecular weight are compared at the same temperature and pressure. The molecular weights are in the ratio of the gas densities, since *Avogadro's principle* states that equal volumes of gases at the same temperature and pressure contain the same numbers of molecules. For a nonvolatile substance, a known weight can be dissolved in a solvent, and the resultant lowering of vapor pressure, elevation of the boiling point, or depression of the freezing point of the solvent can be measured. Each of these properties depends upon the number of molecules of solute present, so the number of molecules per unit weight of X is found and, hence, the molecular weight. For substances of high molecular weight such as proteins (molecular weight ~ 34 000–200-000) or polymers, the molecular weight is found from osmotic pressure measurements or the rate of sedimentation in a centrifuge. The molecular weight of a molecule in crystalline form is determined when the density of the crystal and the dimensions of the unit cell from x-ray analysis are both known. Finally, for stable volatile compounds, it is often possible to form the ion X^+ and pass this through a mass spectrograph to determine the molecular weight.

(2) The spatial distribution of the nuclei in their mean equilibrium or "rest" positions. At an elementary level, this is described in geometrical language. For example, in carbon tetrachloride, CCl_4, the four chlorine nuclei are disposed at the corners of a regular tetrahedron, and the carbon nucleus is at the center. In the $[CoCl_4]^{2-}$ ion, the arrangement of the chlorine nuclei about the central metal nucleus is also tetrahedral, whereas in $[PdCl_4]^{2-}$ it is planar.

At a more sophisticated level, each molecule is classified under a *symmetry point group*. Most nonlinear molecules possess only 1, 2, 3, 4 or 6-fold rotation axes, and belong to one of the 32 crystallographic point groups. For example, the pyramidal ammonia molecule NH_3 has a threefold rotation axis C_3 through the nitrogen nucleus and three reflection planes σ_v intersecting at this axis, and belongs to the $C_{3v}(3m)$ point group. Tetrahedral molecules CX_4 belong to the Td($\bar{4}3m$) point group. Linear diatomic and polyatomic molecules belong to either of the continuous point groups $D_{\infty h}$ or $C_{\infty v}$ according to whether a center of symmetry is present or not.

The symmetry classification does not define the geometry of a molecule completely. The values of certain *bond lengths or angles* must also be specified. In carbon tetrachloride, it is sufficient to give the C–Cl distance (1.77×10^{-10} meters) since classification under the T_d point group implies that all four of these bonds have equal length and the angle between them is 109° 28′. In ammonia, both the N–H distance (1.015×10^{-10} meters) and the angle HNH (107°) must be specified. In general, the lower the molecular symmetry, the greater is the number of such independent parameters required to characterize the geometry. Information about the symmetry and internal dimensions of a molecule is obtained experimentally by SPECTROSCOPY, ELECTRON DIFFRACTION, NEUTRON DIFFRACTION, X-RAY DIFFRACTION, and MAGNETIC RESONANCE. (See these topics for details.) Nuclear magnetic resonance (NMR) is widely used to study molecular structure since it gives information about both the chemical environment of a given nucleus in a molecule and also the disposition of neighboring nuclei. While commonly employed on protons, its use is increasing for other nuclei with nonzero spin angular momentum.

(3) The *dynamical state* is defined by the values of certain observables associated with orbital and spin motions of the electrons and with vibration and rotation of the nuclei, and also by symmetry properties of the corresponding stationary-state wave functions. Except for cases when heavy nuclei are present, the total electron spin angular momentum of a molecule is separately conserved with magnitude $S\hbar$, and molecular states are classified as singlet, doublet,

triplet, ··· according to the value of the multiplicity $(2S + 1)$. This is shown by a prefix superscript to the term symbol, as in atoms.

The Born-Oppenheimer approximation permits the molecular Hamiltonian H to be separated into a component H_e that depends only on the coordinates of the electrons relative to the nuclei plus a component depending upon the nuclear coordinates, which in turn can be written as a sum $H_v + H_r$ of terms for vibrational and rotational motion of the nuclei (we may ignore translation here). The eigenfunctions Ψ of H may correspondingly be factorized as the product $\Psi_e\Psi_v\Psi_r$ of eigenfunctions of these three operators, and the eigenvalues E decomposed as the sum $E_e + E_v + E_r$. In general, we find $E_e > E_v > E_r$.

Electronic states of molecules are classified according to the symmetry properties of Ψ_e (which forms a basis for an irreducible representation of the molecular point group). Thus $^3B_{1u}$ is a term symbol for benzene (D_{6h} point group) that denotes a triplet electronic state whose wave function transforms like the B_{1u} representation of the group. In the case of diatomic and linear polyatomic molecules, the term symbol shows the magnitude of the conserved component of orbital electronic angular momentum $\Lambda\hbar$ about the axis, states being classified as Σ, Π, Δ, ··· according to $\Lambda = 0, 1, 2, \cdots$. The superscript + or − shows the behavior of Ψ_e for a linear molecule upon reflection in a plane containing the molecular axis; for centrosymmetric linear molecules ($D_{\infty h}$ point group) the subscript g or u shows the parity +1 or −1 respectively for Ψ_e with respect to inversion at the center.

The vibrational wavefunction Ψ_v can be approximated by a product of $3N - 6$ harmonic oscillator wave functions ψ_i, each a function of a normal displacement coordinate Q_i,

$$\Psi_v = \prod_{i=1}^{3N-6} \psi_i(Q_i)$$

The product is $(3N - 5)$, for a linear molecule; N is the number of nuclei. Each oscillatory mode can be excited with quanta $v_i = 0, 1, 2, \cdots$. When $v_i = 0$, ψ_i transforms like the totally symmetrical representation of the molecular point group; when $v_i = 1$, ψ_i transforms like Q_i. The symmetry of Ψ_v under the molecular point group is found from the direct product for all the ψ_i. The vibrationless ground state with $v_1 = v_2 = \cdots = 0$ is always totally symmetrical.

Each rotational state is characterized by a value for the quantum number J, where $J(J + 1)\hbar^2$ is the squared angular momentum for rotation of the nuclei (apart from spin). If I_a, I_b and I_c denote the moments about the principal axes of inertia of the molecule, then a spherical top has $I_a = I_b = I_c$; a molecule with two principal moments equal is either a prolate ($I_c = I_b > I_a$) or an oblate ($I_c > I_b = I_a$) symmetric top; if $I_c > I_b > I_a$, the top is asymmetric. Symmetric top molecules have C_n symmetry axes with $n \geqslant 3$ and belong to point groups with degenerate representations. The component $K\hbar$ of rotational angular momentum about the top axis is conserved and the rotational levels are also characterized by the value of the quantum number $K = 0, 1, 2, \cdots J$. A symmetry classification is made for Ψ_r under the rotational subgroup of the molecular point group. Finally, each eigenstate is described as + or − according to the parity of Ψ under inversion in a space-fixed coordinate system.

(4) In order to distinguish between different electronic states Ψ_e of the same symmetry and spin multiplicity, a further classification is obtained by expanding Ψ_e as a product of n single-electron wave functions ϕ_i, each a function of the coordinates of one of the n electrons in the molecule.

$$\Psi_e = (n!)^{-1/2} \det|\phi_1(1)\phi_2(2)\phi_3(3) \cdots \phi_n(n)|$$

where $(n!)^{-1/2}$ is a normalization factor. Each of the molecular orbitals (MO's) ϕ_i is constructed to transform like an irreducible representation of the molecular point group and is usually formed by linear combination of atomic orbitals (LCAO) χ_i centered upon the individual nuclei

$$\phi_i = \sum_p C_{ip}\chi_p$$

The MO's are written in order of decreasing energy necessary to ionize the electrons which occupy them, and electrons are assigned to the MO's in accordance with the Pauli principle. For example, the electronic ground state of ammonia (C_{3v} point group) is written

$$(1a_1)^2(2a_1)^2(1e)^4(3a_1)^2 \qquad {}^1A_1$$

where the superscripts show the distribution of the ten electrons among three MO's of a_1 symmetry and one of e symmetry, the electrons in the $(3a_1)$ orbital being most readily ionized. The symmetry of the resultant molecular wavefunction Ψ_e is found by taking direct products for each orbital occupied by an electron. Here Ψ_e belongs to the totally symmetrical representation (and is also singlet). Excited electronic states are obtained by promoting electrons into orbitals with higher energies, but the molecular symmetry in such states often differs from that in the ground state, as a result of changes in geometry.

In calculations of molecular properties, the MO's ϕ_i can be improved by variational methods which make them satisfy the *Hartree-Fock* equations. This gives *self-consistent field* (SCF) MO's, yielding a better wavefunction Ψ_e. However the latter is still, in practice, constructed from an incomplete set of basic functions. Further improvement is achieved by *configuration interaction* (CI), in which Ψ_e's of the same symmetry are allowed to mix in linear combination.

MÖSSBAUER EFFECT

The Mössbauer effect is the phenomenon of recoilless resonance fluorescence of gamma rays from nuclei bound in solids. It was first discovered in 1958 and brought its discoverer, Rudolf L. Mössbauer, the Nobel prize for physics in 1961. The extreme sharpness of the recoilless gamma transitions and the relative ease and accuracy in observing small energy differences make the Mössbauer effect an important tool in chemistry, solid-state physics, nuclear physics, biophysics, metallurgy, and mineralogy.

Resonance fluorescence involves the excitation of a quantized system (the absorber) from its ground state (0) to an excited state (1) by absorption of a photon emitted from an identical system (the source) decaying from state (1) to (0). Not every nucleus has a suitable gamma transition; however, the Mössbauer effect has been observed in more than 60 different isotopes. The parameters characterizing the nuclear resonance process for some typical isotopes are illustrated in Fig. 1.

To conserve energy and momentum in the emission and absorption processes, each system, the source and absorber, must acquire a recoil energy R equal to $E^2/2Mc^2$, where E is the photon energy, M is the mass of the recoiling system and c is the speed of light. The energy available for the excitation of the absorber is thus reduced by $2R$, and resonance fluorescence can be achieved only if the missing energy $2R$ is not larger than the widths of the levels involved. Before 1958, it was thought that for all gamma transitions the width required to get overlap between the emission and the absorption line was much larger than the natural width Γ, where Γ is related to the half-life $T_{1/2}$ of the excited nuclear level by the expression $\Gamma T_{1/2} = 4.55 \times 10^{-16}$ eV sec. In fact, techniques had been developed to compensate for the recoil energy loss by applying large Doppler shifts with an ultracentrifuge or through thermal motion. These methods necessarily broaden the intrinsically narrow lines thereby reducing the absorption cross section.

Mössbauer discovered that in some cases these difficulties may be removed by embedding the source and absorber nuclei in a crystal. Being part of a quantized vibrational system, these nuclei interact with the lattice by exchange of vibrational quanta or phonons only. If the characteristic phonon energy is large compared to the recoil energy R for a free nucleus, the probability for the emission of a gamma ray without a change in the vibrational state of the lattice is large. For such a zero phonon transition, the lattice as a whole adsorbs the recoil momentum and the recoil energy is negligibly small. At the same time, the emission and absorption lines achieve the natural width Γ.

For an atom bound by harmonic forces, the fraction f of events without recoil energy loss is given by $f = \exp(-4\pi^2\langle x^2\rangle/\lambda^2)$. Here $\langle x^2\rangle$ is the mean square displacement of the radiating atom taken along the direction of the photon with wavelength λ. In an environment of lower than cubic symmetry, $\langle x^2\rangle$, and therefore f, may be anisotropic. A large recoilless fraction may be obtained when $\langle x^2\rangle$ is small and λ large. The former condition implies small vibrational amplitude and thus low temperature, high vibrational frequency and large mass M, while the latter implies low photon energy, E. Both conditions imply small recoil energy R.

Recoilless transitions can also occur in amorphous substances like glasses and high-viscosity liquids. For the latter, the diffusive motion superimposed on the thermal vibration results in a broadening of the Mössbauer line.

For all Mössbauer isotopes, the nuclear half-life $T_{1/2}$, typically 10^{-8} second, is very long compared to the period of the lattice vibrations, typically 10^{-13} second. A conceivable first-order Doppler shift of the Mössbauer line due to the thermal motion will therefore average out to zero. The second-order Doppler effect, however, leads to an observable shift, sometimes called the temperature shift. The photons emitted by a source nucleus moving with a mean square velocity $\langle v_s^2\rangle$ are lower in energy by a fraction $\langle v_s^2\rangle/2c^2$ as compared to the photons emitted at rest. Similarly the transition energy of a vibrating absorber nucleus appears lower to the incident photon by a fraction $\langle v_a^2\rangle/2c^2$. In principle, the two shifts may be different whenever the source and absorber are of different composition and/or temperature.

Mössbauer performed his original experiment with ^{191}Ir at 88 K, obtaining a recoilless frac-

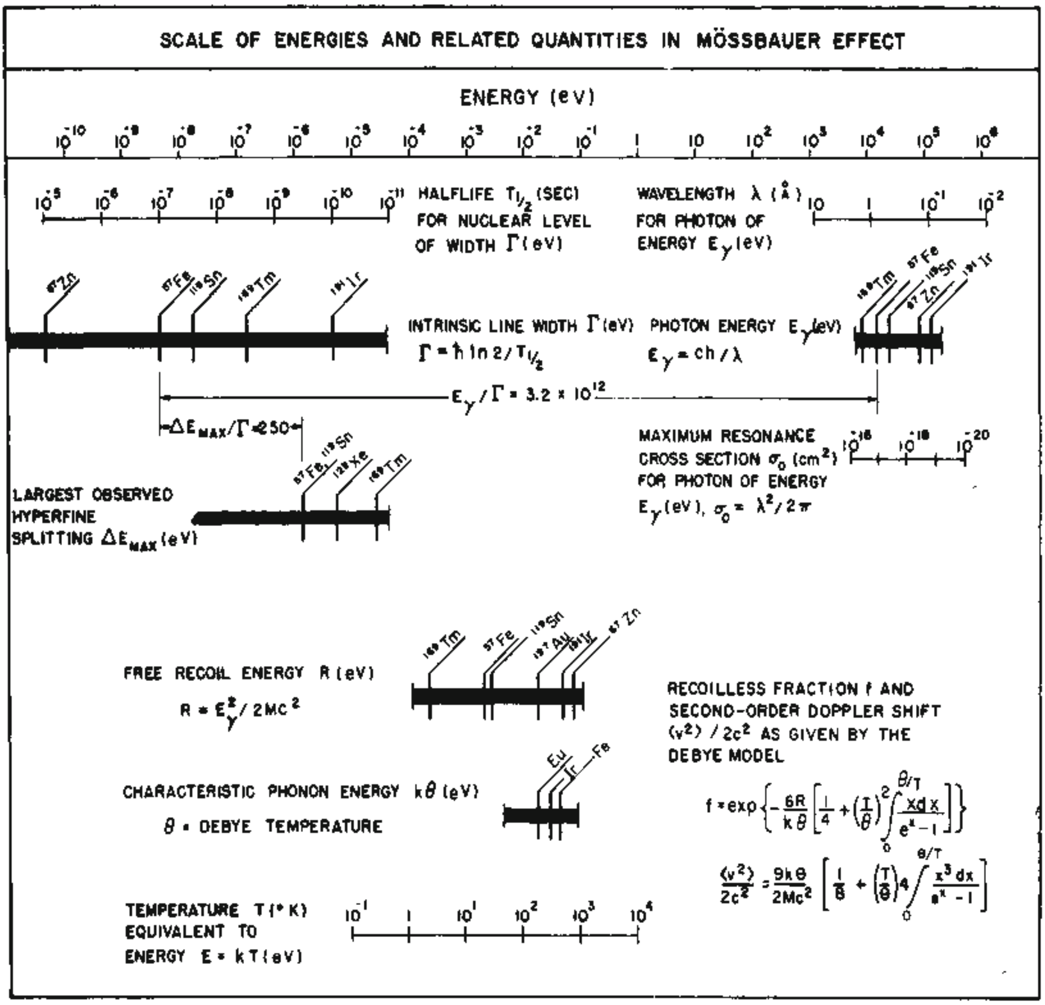

FIG. 1

tion of 1 per cent. Since the natural line width in ^{191}Ir, as in most other Mössbauer nuclides, is extremely narrow, Mössbauer was able to alter the degree of overlap between the emission and absorption lines by simply moving the source relative to the absorber at speeds v of the order of 1 mm/sec. Thus the gamma rays were slightly shifted in energy via the first-order Doppler effect by an amount $\Delta E = Ev/c$. By plotting the transmission through the absorber as a function of the relative source-absorber velocity, one thus obtains the characteristic Mössbauer velocity spectrum which exhibits the shape of the resonance curve. From such a plot, one can determine the recoilless fraction, the lifetime of the excited state and any possible energy differences between the emission and the absorption line.

With extreme care, it is possible to determine energy differences of the order of 1/1000 of the line width Γ. The latter typically varies with isotope from 10^{-10} to 10^{-15} times the actual gamma ray energy E. The Mössbauer effect therefore enables one to detect extremely small changes in this energy. One of the earliest applications of this great precision was the laboratory verification of the gravitational red shift by Pound and Rebka. According to Einstein's theory, photons have an apparent mass $m = E/c^2$. Thus if they fall toward the earth through a distance H, their energy increases by $\Delta E = mgH$, so that $\Delta E/E = gH/c^2 \cong 10^{-16}$ per meter. Using ^{57}Fe, which has a large recoilless fraction, and for which $\Gamma/E = 3 \times 10^{-13}$, the desired effect was observed when the photons were sent down the 22-meter tower at Harvard University.

It is well known from optical and high-frequency spectroscopy that a nucleus interacting with its environment through its charge distribution and magnetic moment can give rise to hyperfine shifts and splittings of the order of 10^{-9}eV to 10^{-5}eV. In Mössbauer experiments, such energy differences can readily be measured

NUCLEAR HYPERFINE INTERACTION FOR ^{57}Fe

FIG. 2

since the line width of the recoilless transitions is of the same order of magnitude. Perhaps, therefore, the most useful feature of the Mössbauer effect is that it may be used to obtain nuclear properties if the fields acting on the nucleus are known, and conversely, it is a powerful tool for probing solids once the various interactions are calibrated, i.e., the nuclear properties have been determined. Some representative results obtained with ^{57}Fe are illustrated in Fig. 2.

The most basic of these interactions is the effect of the finite nuclear size which, in general, is different for the ground state and the excited state. The electrostatic interaction of the nuclear charge with the s-electrons overlapping it raises the nuclear energy levels by an amount depending on the charge radii and s-electron density at the nucleus. Therefore under proper conditions, there appears a shift in the Mössbauer resonance, the isomer shift, which is proportional to $(\delta R/R)$ $\delta|\psi(0)|^2$, where $\delta R/R$ is the fractional change in the nuclear radius during the decay and $\delta|\psi(0)|^2$ is the difference in s-electron density between source and absorber. To determine the quantity $\delta R/R$, one compares the isomer shifts of two chemically simple absorbers, for which the s-electron density can be calculated. In the case of ^{57}Fe an isomer shift exists between compounds containing ferric ions, $Fe^{3+}(3d^5)$, and ferrous ions, $Fe^{2+}(3d^6)$. Although the number of s-electrons is the same for both ions, a detailed calculation shows that the shielding through the additional $3d$ electron changes the $3s$ density at the nucleus. For ^{129}I, the isomer shifts observed among different alkali iodides can be related quantitatively to the known transfer of $5p$ electrons to the ligands which affects the $5s$ density at the nucleus. Once calibrated, the isomer shift is a tool for measuring s-electron densities and is therefore of use in studying chemical bonding, energy bands in solids, and also in identifying charge states of a given atom.

One of the early successes of the Mössbauer effect was the observation of the completely resolved nuclear Zeeman splitting arising from the magnetic hyperfine interaction of ^{57}Fe in ferromagnetic iron. For this isotope, as well as for most other Mössbauer isotopes, the magnetic moment of the nuclear ground state is known from magnetic resonance experiments, and the calibration is therefore straightforward. Careful analysis of the velocity spectrum for magnetic samples is sufficient in general to reveal both the desired magnetic moment and internal magnetic field. The latter yields important information about the unpaired spin density at the nucleus, which in turn is related to the exchange interaction in crystals, molecular complexes, metals and alloys. For single crystals or magnetized samples, the intensities of the individual lines of the Mössbauer spectrum depend on the angle between the direction of the internal field and the emitted photon. From a measurement of the intensity distribution, one therefore obtains the orientation of the internal magnetic field. The temperature dependence of the splitting can yield Néel and Curie temperatures and also relaxation times.

Whenever one of the nuclear levels possesses a quadrupole moment and an electric field gradient exists at the position of the nucleus, quadrupole splitting of the Mössbauer spectrum may be observed. If the quadrupole moment is known either for the ground state or for the excited state, then a Mössbauer measurement will readily yield the parameters of the field gradient tensor. Usually, however, the quadrupole moment is not known, and the field gradient tensor must be determined from other work or else calculated from first principles. This tensor exists whenever the symmetry of the surrounding charge distribution is lower than cubic, and it is generally specified by two independent parameters. This tensor is easiest to calculate for cases of axial symmetry, in which it is characterized by one parameter, the field gradient, q. For simple ionic systems, it is possible to estimate q with some degree of certainty, and thereby determine the quadrupole moment. Once this is done, the Mössbauer effect may be used to measure field gradient tensors in more complicated systems. Such measurements yield information about crystalline symmetries, crystalline field splittings, shielding due to closed shell electrons, relaxation phenomena and chemical bonding. In addition, with single crystals, a study of the relative intensity of the various lines of the resonance spectrum as a function of angle can yield information about the orientation of the crystalline field axes and, thus, the orientation of complexes in solids.

In cases where both magnetic and quadrupole splittings are present the spectrum depends markedly upon the relative orientation between the hyperfine magnetic field and the axes of the electric field gradient tensor. Paramagnetic complexes of lower than cubic symmetry and many magnetically ordered compounds are of this type. Careful quantitative analysis can then yield the magnitude as well as the relative orientation of the hyperfine interactions. There are also disordered systems such as alloys, amorphous solids, and especially spin-glasses, in which each atom has a slighty different environment. In such cases ^{57}Fe or other Mössbauer nuclides have been used to probe the distribution of isomer shifts, local magnetic fields, and/or electric field gradients. Moreover, the hyperfine interactions may be nonstationary, for instance as a result of spin fluctuations, diffusion, or other time dependent processes. Such systems have been successfully treated using dynamical models of the Mössbauer line shape.

This article has only covered the basic features of the Mössbauer effect and the phenomena which affect the Mössbauer velocity spectrum in a general way. The actual application of the effect is extremely far reaching, embracing not only almost all areas of physics but also the fields of chemistry, biology, geology, metallurgy, and engineering. The reader is advised to consult the references for more information.

MOTORS, ELECTRIC

History Power conversion was discovered by M. Faraday in 1831; the commutator, by J. Henry, Pixii, and C. Wheatstone (1841); the electromagnetic field, by J. Brett (1840), Wheatstone and Cooke (1845), and W. von Siemens (1867); drum armatures, by Siemens, Pacinotti, and von Alteneck; ring armatures, by Gramme (1870); and disc armatures, by Desroziers (1885) and Fritsche (1890). Ring and disk types are now seldom used. Revolving magnetic fields (1885) and ac theory were discovered by G. Ferraris; polyphase motors and systems, by N. Tesla (1888); the squirrel-cage rotor, by C. S. Bradley (1889); and ac commutator motors, by R. Eickmeyer, E. Thomson, L. Atkinson, and others.

Principles These are explained by the laws of Ohm, Kirchoff, Lenz and Maxwell; specifically:

(1) Moving a conductor of length l across a magnetic flux field of density B with a velocity v generates in the conductor an electromotive force (emf) $e = vBl$ volts. In motors, e opposes the current i and decreases as load increases.

(2) The force on such a conductor equals $F = Bil$ newtons. Fig. 1 shows the directions of current and force.

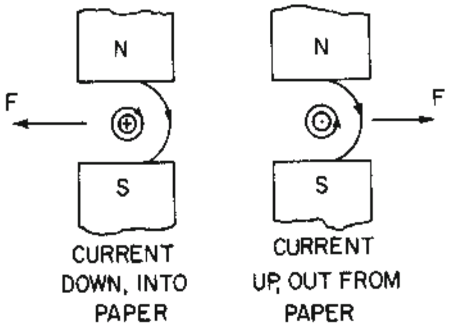

FIG. 1. Direction of force due to current in a magnetic field.

(3) Magnetic structures tend to move to the position of minimum reluctance (maximum inductance) with force $F = dw/dx$, where w is stored magnetic energy and x is distance.

(4) The force between two coupled circuits is

$$F = \frac{i_1{}^2}{2}\frac{dL_1}{dx} + i_1 i_2 \frac{dM}{dx} + \frac{i_2{}^2}{2}\frac{dL_2}{dx}.$$

Frequently L_1 and/or L_2 are constant and they make no contribution to the force. Here i_1 and i_2 are currents, L_1 and L_2 are total self-inductances, and M is mutual inductance.

Symbols

B = flux density in Tesla
F = force in direction x in newtons
i, i_1, i_2 = instantaneous currents in amperes
I_a, I_2 = dc and effective currents in amperes
L_1, L_2, M = inductances in henrys
s = slip = (Syn. rpm – rpm)/Syn. rpm
v = velocity in meters per second
w = energy in joules
l, x = length, distance, in meters
ϕ_a = useful flux per pole in webers
ϕ_m = maximum flux per pole in webers

Motor Types Of many hundreds, the most used are:

(1) *Direct Current* (a) Series. The field coils are of heavy wire in series with the armature. The torque and current are high at low speeds, and low at high speeds. Torque and speed vary inversely as a square-law function. These motors will run away at light loads unless a speed-limiting device is used.

(b) Shunt. The field coils are of fine wire in parallel with the armature. The speed drops slightly, and the current and torque increase with load. Many small motors (up to 15 hp) use permanent magnets for the field, particularly where high acceleration rates are necessary.

(c) Compound. Both shunt and series fields are used in the same motor. Behavior is intermediate between (a) and (b). The armature current in all dc motors is described as $I_a = (V_T - E_a)/R_a$, where $E_a = p\phi_a Z_a S/(m_a \times 60)$; V_T = terminal voltage, E_a = counter electromotive force (cemf), R_a = armature resistance, m_a = number of paths, and Z_a = number of conductors, all for the armature. In addition, p = number of poles, S = rpm, ϕ_a = useful flux per pole. ϕ_a may be nearly constant or it may be a function of I_a.

Speed control is achieved by adjusting field current and/or armature terminal voltage, tapped series coils, or (more rarely) field reluctance or double commutator. To avoid damage from excessive currents during starting, either starting resistances or voltage controls are needed, except for very small motors.

(2) *Alternating Current* (a) Polyphase induction: These are usually three-phase, with phase windings distributed equally in slots around the periphery of the stator to produce alternate N and S poles. When fed with polyphase current a revolving field is set up which turns at $S = 120f/p$ rpm. This revolving field induces a counter emf $E = 2.22f\phi_m Zk_w$ volts per phase, where ϕ is flux per pole, k_w is the winding factor, and Z is the number of series turns.

The rotor is made of a number of short circuited conductors. If these conductors are open, or the rotor is running at synchronous speed S, each rotor phase behaves as an inductance and draws an exciting current lagging nearly ¼ cycle behind the emf. Shaft load reduces the speed from S to $S(1 - s)$, where s is slip. When referred to the stator mounted armature (primary), s causes the emf in each rotor phase to be sE (in volts). Each rotor phase sees current (in amperes):

$$I_2 = \frac{sE}{\sqrt{r_2{}^2 + (sx_2)^2}} = \frac{E}{\sqrt{\left(\frac{r_2}{s}\right)^2 + x_2{}^2}}$$

where r_2 is the resistance and x_2 is the rotor leakage reactance in ohms per phase.

The current I_2 produces the needed torque. It creates a new magnetomotive force (mmf) which turns at synchronous speed S in the same direction as the revolving stator field, and lags the stator field in space by the electrical angle $90° + \tan^{-1}(x_2/r_2)$. To balance this mmf the stator draws additional current sufficient to produce the load torque. Performance can be calculated (as for a transformer) if r_2/s is taken as the independent variable. Three-phase motors require less material than one- or two-phase motors.

(b) Single-phase induction. With the motor at rest there is no revolving field; the motor will start in either direction only if given a push. Rotation sets up an elliptical revolving field which turns synchronously at nonuniform velocity in the same direction as the rotor and pulsates between the limits ϕ_m and $\phi_m(1 - s)$. The stator current is the resultant of (stator + cross axis) magnetizing + load + loss currents. Analysis of this type of motor is less simple than that for a polyphase motor.

Starting is with a line switch, reduced voltage (auto-transformer or "compensator," wye-delta, series resistors, or chokes), wound rotors and resistors, part-windings, or more elaborate schemes. For single-phase motors, auxiliary start windings (split-phase or capacitor), or repulsion-start are used and are removed at approximately 65% of full speed. For very small, low-torque motors, shaded poles are used.

Speed control has historically been by reduced voltage, wound rotor, or elaborate degenerative feedback schemes. State-of-the-art is variable-voltage, variable-frequency electronic inverters. The motor speed tracks the applied frequency.

(c) Synchronous. Commonly these have a stationary phase-wound armature and revolving dc or permanent magnet field structure. When at full speed and synchronized, the revolving armature mmf stands still relative to the dc field. When the angle $(I_a, E_a) = 0$, the armature mmf poles stand midway between the field poles. When I_a lags E_a, the armature mmf assists the field; it opposes the field when I_a leads E_a. Armature current I_a adjusts to a value and time phase position such that the counter emf E_a and current I_a are correct to meet the existing load. Important modeling relations are $I_a = (V - E_a)/Z_a$; power converted $= mI_a E_a \cdot \cos(I_a, E_a)$; input $= mI_a V \cos(I_a, V)$; and armature copper loss $= mI_a{}^2 r_a$. Where E_a is a function of (I_a, I_f); angle (I_a, E_a) and E_a are in opposition; I_a increases with load; and m = number of phases.

When connected directly to the utility power system, synchronous motors are used where the rpm must be fixed, for power factor correction, regulating transmission line voltages, or speeds too low for good induction motor performance. They are not self starting unless special means are provided, usually squirrel-cage or phase windings in the pole faces. Precautions against high ac voltages in the dc field coils are needed when starting. The motors will carry some load with the dc field winding open. Small sizes (reluctance types) operate without field windings. Single-phase motors are less satisfactory because of lower efficiency, tendency to severe hunting, and problems in starting.

(d) ac Commutator. These are mostly single-phase series, repulsion, or combination of these types. Single-phase series motors are used in large quantities for portable tools, vacuum sweepers, garbage disposals, household appliances, etc. The ac series motor is similar to the dc motor except for a laminated field and precautions against low power factor and poor commutation. The runaway speed is high.

(e) *Brushless dc.* These are ac synchronous and induction motors which receive their power from electronic inverters. The inverters are fed from a dc source. By proper inverter control, the entire system responds the same as a dc motor. Uses include industrial drives, electric cars, railways, and aircraft control actuators.

(f) *Stepper Motors.* ac and dc motors specially designed for high torque and low inertia. Normally electronically controlled to discrete positions, or steps. These are used extensively for industrial positioners, computer line printers, robots, etc.

Probable Future Trends These include less expensive, higher energy product permanent magnets; electrical insulators with better heat conduction properties; and superconductors. Superconducting windings will require motors to be built of nonmagnetic materials, since the magnetic fields will exceed the saturation levels of magnetic materials. Rapid advances in power electronics will influence motor designs.

MUSICAL SOUND

Musical sound may be characterized as an aural sensation caused by the rapid periodic motion of a sonorous body, while noise is due to nonperiodic motions. The above statement, originally made by Helmholtz, may be modified slightly so that the frequencies of vibration of the body fall into the limits of hearing: 20 to 20,000 Hz. This definition is not clear cut; there are some noises in the note of a harp (the twang) as well as a recognizable note in the sqeak of a shoe. In other cases it is even more difficult to make a distinction between music and noise. In some modern "electronic music" hisses and thumps are considered a part of the music. White noise is a complex sound whose frequency components are so closely spaced and so numerous that the sound ceases to have pitch. The average power per frequency of these components is approximately the same over the whole audible range, and the noise has a hissing sound similar to that one gets from FM radio that is tuned between stations. Pink noise has its lower frequency components relatively louder than the high frequency components and this is accomplished by keeping the average power the same in each octave (or in each $\frac{1}{3}$ octave) band from 20 to 20,000 Hz.

The attributes of musical sound and their subjective correlates are described briefly. The number of cycles per second, *frequency*, is a physical entity and may be measured objectively. *Pitch*, however, is a psychological phenomenon and needs a human subject to perceive it. In general, as the frequency of a single sinusoidal vibration of a sonorous body (pure tone) is raised, the pitch is higher. However, pitch and frequency do not bear a simple linear relationship. To define the relationship human subjects are used to construct a pitch scale so that one note can be judged to be two times the pitch of another and so on. The unit of pitch on this scale is called the *mel*, and a pitch of 1000 mels is arbitrarily assigned to a frequency of 1000 Hz. In general, it is observed that the pitch is slightly less than the frequency when the frequencies are higher than 1000 Hz, and slightly more than the frequency at frequencies less than 1000 Hz. Pitch also depends on loudness; for a 200 Hz tone if the loudness is increased, the pitch decreases, and the same happens for frequencies up to 1000 Hz. Between 1000 and 3000 Hz pitch is relatively independent of loudness, while above 4000 Hz, increasing the loudness raises the pitch. Small pitch changes with loudness do occur with complex tones and whether the pitch goes up or down with loudness seems to depend on the harmonic structure of the complex sound. A rapid variation in pitch when the variation occurs at the rate of from two to five times per second is called *vibrato*. The pitch variation in mels may be large or small but the rate at which the pitch is varied is rarely greater than five times per second. Violinists produce vibrato by sliding their fingers back and forth a minute distance on a stopped string. A variation in loudness occurring at the rate of two to five times a second is called *tremolo*. Singers often produce a combination of tremolo and vibrato to give added color to their renditions.

The ability to discriminate between pitches depends on other variables beside the acuity of the listener. The *just noticeable differences* (jnd's) also depend on the frequencies of the pure tones. Jnd's generally get larger as the frequency increases. Duration of a pure tone is also a requirement for recognition of pitch. Some pure tones of even 3 millisecond duration can still be recognized as having a definite pitch. The duration of time required to recognize pitch depends on the frequency and to some extent on the loudness of the tone. It takes longer to recognize the pitch of a low frequency pure tone than for one of a high frequency. In all cases if the time is too short one hears a click rather than a clear pitch. The pitch of a complex musical tone depends on the spectrum of the complex tone. If the complex tone is composed of the fundamental and exact overtones, the ear recognizes the pitch as that of the fundamental, even if the fundamental is weak or is *missing*. Manufacturers of small portable radios take advantage of this when they install small loudspeakers in these radios. These speakers are not capable of producing the fundamentals of certain low frequency musical sounds but the ear seems to fill in the "missing fundamental."

Like frequency, *intensity* is a physical entity defined as the amount of sound energy passing through unit area per second in a direction perpendicular to the area. It is proportional to the square of the sound pressure, the latter being the rms pressure over and above the constant mean atmospheric pressure. Since sound pressure is proportional to the amplitude of a longitudinal sound wave (see WAVE MOTION) and to the frequency of the wave, intensity since it depends on energy, is proportional to the square of the amplitude and to the square of the frequency. Sound intensity is measured in watts per second per square centimeter and, since the ear is so sensitive, a more usual unit is the microwatt per second per square centimeter. By way of example, a soft speaking voice produces an intensity of 0.1 micromicrowatt/cm^2 sec, while fifteen hundred bass voices singing fortissimo at a distance 1 cm away produce 40 watt/cm^2 sec. Because of such a large range of intensities, the *decibel scale* of intensity is normally used to designate intensity levels. An arbitrary level of 10^{-16} watts/cm^2 sec is taken as a standard for comparison at 1000 Hz. This level is very close to the threshold of audibility. At this frequency, other sound levels are compared by forming the logarithm of the ratio of the desired sound to this arbitrary one. Thus log $I/10^{-16}$ is the number of bels a sound of intensity I has, compared to this level. Since this unit is inconveniently large, it has been subdivided into the decibel, one-tenth its size. Thus 10 log $I/10^{-16}$ equals the number of decibels (dB) the sound has. A few intensity decibel levels are listed:

	db
Quiet whisper	10
Ordinary conversation	60
Noisy factory	90
Thunder (loud)	110
Pain threshold	120

While intensity levels can be measured physically, loudness levels are subjective and need human subjects for their evaluation. The unit of loudness is the *phon*, and an arbitrary level of zero phons is the loudness of a 1000 Hz note which has an intensity level of 0 dB. Sounds of equal loudness, however, do not have the same intensity levels for different frequencies. From a series of experiments involving human subjects, Fletcher and Munson in 1933 constructed a set of equal-loudness contours for different frequencies of pure tones. These show that for quiet sounds (a level of 5 phons) the intensity level at 1000 Hz is about 5 dB lower than an equally loud sound at 2000 Hz, for 30 Hz about 70 dB lower, and at 10,000 Hz about 20 dB lower. In general, as the intensity level increases, loudness levels tend to be more alike at all frequencies. This means that as a sound gets less intense at all frequencies, the ear tends to hear the higher and lower portions of sound less loudly than the middle positions. Some high fidelity systems incorporate circuitry that automatically boosts the high and low frequencies as the intensity level of the sound is decreased. This control is usually designated a *loudness control*.

At times it is necessary to have a scale of absolute perceived loudness. The unit of this perceived loudness is the *sone*. It is arrived at by a set of complicated procedures involving human subjects usually placed in a free field situation (e.g., anechoic chamber). One sone of loudness is defined as the sound pressure at the ear of 40 dB for a 1000 Hz pure tone. Two sones is perceived in these experiments as twice as loud, three sones three times, etc. In many situations, musical as well as noisy, the figures for sones of multiple sounds seem to add up in an arithmetical way; figures for db do not. Some consumer testing groups use the sone scale for evaluating the noise of various consumer products.

The entity which enables a person to recognize the difference between equally load tones of the same pitch coming from different musical instruments is called *timbre*, *quality*, or *tone color*. A simple fundamental law in acoustics states that the ear recognizes only those sounds due to simple harmonic motions (see VIBRATION) as pure tones. A tuning fork of frequency f, when struck, causes the air to vibrate in a manner which is very nearly simple harmonic. The sound that is heard does, in fact, give the impression that it is simple and produces a pure tone of a single pitch. If one now strikes simultaneously a series of tuning forks having frequencies f (the fundamental), $2f$, $3f$, $4f$, $5f$, etc. (overtones), the pitch heard is the same as that of the fork of frequency f except that the sound has a different timbre. The timbre of the sound of the series can be changed by altering the loudness of the individual forks from zero loudness to any given loudness. Another way to alter the timbre is to vary the time it takes for a composite sound to grow and to decay. A slow growth of an envelope, even though it contains the same frequencies, makes for a different timbre than one which has a rapid growth. The difference in timbre between a B-flat saxophone and an oboe is almost entirely due to the difference in growth or decay time.

A fundamental theorem discovered by the mathematician Fourier states that any complicated periodic vibration may be analyzed into a set of components which has simple harmonic vibrations of single frequencies. If this method of analysis is applied to the composite tones of musical instruments, it is seen that these tones consist of a fundamental plus a series of overtones, the intensity of overtones being different for instruments of differing timbre. Rise and decay times will also differ. The reverse of analysis is the synthesis of a musical sound. Helmholtz was able to synthesize sound by combining sets of oscillating tuning forks of various loudness to produce a single composite steady tone of a definite timbre. Modern synthesizers are more sophisticated. Electrical oscillators of the simple harmonic variety are combined electrically and then these electrical composite envelopes are electronically modified to produce differing rise and decay time. A transducer changes the electrical composite envelope into an acoustical one so that a sound of any desired timbre, rise and/or decay time can be produced. An alternative way to produce similar effects is to use an oscillation known as the *square wave*. When this oscillation is analyzed by the method of Fourier, it is shown to consist of a fundamental plus the odd harmonics or overtones. Another kind of oscillation, a *saw-tooth wave*, then analyzed, is shown to consist of the fundamental and all harmonics—even and odd. A square wave or a sawtooth wave produced by an appropriate electrical oscillator can be passed through an electrical filter which can attenuate any range of frequencies of the original wave. This altered wave can later be transformed into the corresponding sound wave. In this way sounds having desired rise and decay times, plus the required fundamental and overtone structure, can be made as desired.

N

NEUTRINO

The neutrino is an elementary particle postulated by W. Pauli[1] in 1930 to explain the apparent non-conservation of energy and momentum in that class of nuclear radioactivity known as beta decay. A quantitative theory of beta decay incorporating the neutrino hypothesis was formulated by E. Fermi[2] in 1933 in analogy with the quantum theory of radiation and served to predict the nature of the neutrino and its extremely weak interaction with matter. According to the Pauli-Fermi ideas, the neutrino (in Italian, "little neutral one") is a particle of vanishingly small and possibly zero rest mass, no electrical charge, with spin 1/2, and the ability to carry energy and linear and angular momentum. Its interaction with matter is so weak that a 3-MeV antineutrino is predicted to be capable of penetrating an astronomical thickness of matter, e.g., 100 light-years of liquid hydrogen. In 1956, a group of Los Alamos physicists[3] succeeded in making a direct observation of the neutrino, $\tilde{\nu}_e$, emitted from beta-decaying fission fragments produced in a powerful reactor at the Savannah River Plant operated by the du Pont Company for the U.S. Atomic Energy Commission. These investigators used giant liquid scintillation detectors to observe the inverse beta decay reaction

$$\tilde{\nu}_e + p \rightarrow e^+ + n$$

where p is the target proton and e^+ and n are the product positron and neutron. The experiment consisted of observing the distinctive delayed coincidence between the prompt annihilation of the positron and the capture of the neutron by a cadmium isotope dissolved in the scintillator. In 1957, following the "overthrow" of parity conservation in weak interactions as a result of the work of Lee and Yang[4], the character of the neutrino was further elucidated. Two kinds of neutrinos were accepted: the neutrino, ν_e, produced in beta decay in association with positrons, and the antineutrino, $\tilde{\nu}_e$, produced in beta decay in association with negative electrons. The neutrino emerged as completely polarized with the spin angular momentum parallel (antiparallel) to the linear momentum for the antineutrino (neutrino). A theory of weak interactions encompassing the neutrino, in which the relativistically invariant forms, vector and axial vector, were found to be sufficient to account for most of the known characteristics of the weak interactions, was then formulated by Marshak and Sudarshan[5], and Feynman and Gell-Mann[6].

In 1962, an experiment at the Brookhaven National Laboratory by a Columbia-Brookhaven group,[7] using a heavily shielded 10-ton spark chamber array, showed that the neutrino most frequently associated with the decay of the Π meson differed from the neutrino produced in nuclear beta decay, thus enlarging the class of neutrinos to four; ν_e, $\bar{\nu}_e$, $\bar{\nu}_\mu$, ν_μ. It now appears that any decay or inverse process involving an electron has associated with it an electron type neutrino while any such process involving a mu meson occurs in association with a mu-type neutrino. The discovery by Perl[8] (1975) of a heavy (1.9 times the proton mass) weakly interacting particle called a tau suggests that a third pair of neutrinos exists (ν_τ, $\bar{\nu}_\tau$).

An interaction of the neutrino which did not change the electrical charge of the target—a neutral current—was observed[9] at CERN (1973) in accordance with the theoretical prediction of Salam and Weinberg[10] (1967–72). The existence of the reactions $\nu_\mu + e^- \rightarrow \nu_\mu + e^-$ and $\nu_\mu + N \rightarrow \nu_\mu + N'$ supported the theoretical picture which resulted from unification of the weak and electromagnetic forces. More recent work[11] shows that, as expected, the neutral current reaction $\bar{\nu}_e + \mathrm{D} \rightarrow \bar{\nu}_e + n + p$ also occurs. A further prediction of the theory is the existence of carriers of the weak interaction called intermediate bosons $W^\pm$, Z^0 having masses in the range some 90 times that of a proton. The existence of these particles was demonstrated at the CERN $\bar{\mathrm{p}} > \mathrm{p}$ colliding beam accelerator (1983).[12]

Recent experiments suggest that the neutrino may be more complicated than hitherto believed—in particular it may not have a vanishingly small rest mass. Theoretical models for such a possibility[13] advanced by Nakagawa et al. (1963) and Pontecorvo (1969) assume that the observed neutrinos are linear combinations of massive base states. Such combinations would give rise to observed states, e.g., ν_e, ν_μ, ν_τ, which differ in an energy-dependent manner with distance from a neutrino source. Such variations, called oscillations by analogy with the composite motion of coupled pendula, have been sought using reactor neutrinos $\bar{\nu}_e$ (1980) and higher energy neutrinos from accelerators, and hints of an effect[14] are being subjected to further tests.[15]

The implications of finite neutrino mass range from a mixing of neutrino types to consequences of an equally profound character in the formation of galaxies and the universe itself. A neutrino mass ~20 eV would result in a closed universe.

A search for ν_e from the sun[16] using a 400-ton perchloroethylene (C_2Cl_4) target located ~1 mile below the earth's surface to diminish the background due to cosmic rays has, thus far, yielded unexpectedly negative results. In this experiment the ^{37}Ar produced by solar neutrinos via the reaction $\nu_e + {}^{37}\mathrm{Cl} \rightarrow {}^{37}\mathrm{Ar} + e^-$ was sought by collecting the ^{37}Ar from the C_2Cl_4 container and counting in a tiny low background proportional counter. The limits set, a factor of ~3 below expectation, are difficult to reconcile with the current solar model.[17]

Because of the threshold for ^{37}Cl reaction (0.8 MeV) the solar ν_e signal is dependent on the details of the solar model. An experiment which is insensitive to the solar model is in process of development by Davis et al.[16] (1980). The reaction $\nu_e + {}^{71}\mathrm{Ga} \rightarrow {}^{71}\mathrm{Ge} + e^-$ has a threshold of 0.24 MeV and hence can be caused by ν_e from the essentially model independent $p + p$ reaction which is responsible for the bulk of the sun's energy:

$$p + p \rightarrow d + e^+ + \nu_e \qquad \text{(0.42 MeV endpoint).}$$

At this stage the experiment appears to be feasible, assuming the availability of the required 25 tons of gallium.

Two groups, one 2 miles underground in a South African gold mine,[15] and the other in the Kolar gold fields[20] at a slightly lesser depth, have detected high-energy muon neutrinos produced in the atmosphere by the interaction of cosmic ray primaries. A measure of the meager flux and weakness of the interaction is indicated by the small number of neutrino-induced events collected: the Indian, Japanese, British Kolar group recorded ~17 in two years of operation; the American, South African group detected ~100 with somewhat larger equipment and four years of operation.

Ambitious proposals are being formulated to study these "natural" neutrinos by means of giant (10^6–10^9 tons) water Čerenkov detectors to be located deep (~5 kilometers) in the ocean. As in the case of the gold mine experiments the neutrinos would be detected via product muons. Of special interest is the sensitivity of such an imagined detector to very energetic neutrinos ($\gtrsim 10^{10}$ eV). If current conjectures regarding energetic extraterrestrial sources are correct such a deep underwater muon and neutrino detector (DUMAND)[21] shows promise of observing them.

It is seen that neutrino physics encompasses low-energy reactions using fission reactors, work in the structure of the weak interaction using giant electronuclear machines, and the beginnings of various studies of neutrino sources such as the sun and high-energy cosmic rays[22] as well as the nature of the neutrino itself.

NEUTRON

Significance The role of neutrons and their applications is of central importance to nuclear physics and, indeed, to science in general. Some indication of their wide-ranging significance in the current world is provided by the breadth of the topics covered in an International Conference on The Neutron and its Applications,[1] September 13–17, 1982, commemorating the fiftieth anniversary of the 1932 discovery of neutrons by (Sir) James Chadwick[2] in Cambridge (UK). The following sample of topics exemplifies the scope: Neutron sources; properties, lifetime, moments and structure of the neutron; ultracold neutrons; neutrons in astrophysics and neutron stars; nuclear interactions of the neutron; scattering, diffraction, and neutron optics; radiation; fission and fusion; reactor physics; transmutation, transfer, and transport theory; magnetism; molecular sciences, polymers, and materials sciences; molecular biology, biology, medical, and therapeutic applications; technological applications; theoretical and particle aspects; etc.

This recent overview follows surveys of neurton physics in previous international conferences that dealt with the interactions of neutrons with nuclei[3] and nuclear structure study with neutrons,[4,5] supplementing review articles,[6–8] and topical textbooks.[9–14]

The neutron is thus a fundamental particle of immense versatility, a constituent of all matter (except hydrogen, ^{1}H, whose nucleus consists solely of a proton) as one of the two principal particle species, collectively termed *nucleons*, that make up the nuclei of atoms. The protons that form the companion species have almost the same characteristic properties as the neutrons, with one important exception: they carry a positive electric charge, whereas neutrons are electrically neutral, i.e., uncharged, and therefore not susceptible to any electrostatic repulsive forces. Likewise, for this reason neutrons cannot attract (negatively charged) electrons to form neutronic "atoms," nor can they be deflected, focused, or detected directly through electric-field devices. But, being uncharged, they can and do approach, penetrate, and interact with nuclei much more readily than protons, since they have no Coulomb repulsion to overcome. Moreover, they can and do function as the "binding agents" within a nucleus to hold it relatively stably together despite the disruptive electrostatic forces that the constituent protons exert on each other. In this capacity they respond to the strong-interaction internucleon force (they are classified as *hadrons*, i.e., "the strong ones," from the Greek *hadrós*, "strong," a family of particles that includes not only the protons and other *baryons*, i.e., "the heavy ones," but also *mesons*, i.e., "the medium ones," when the latter are susceptible to strong interactions). This nuclear force is a powerful binding force that acts attractively between nucleons at short range, keeping them pinioned within the confines of a nucleus, whose diameter is on the order of 10^{-15} to 10^{-14} meters, about a million times smaller than the diameter of an atom.

The binding among neutrons and protons in a nucleus is mediated by the exchange of mesons: principally, pi(π)-mesons (or *pions*, the "primary" mesons), but also rho(ρ)-mesons, both of which species may carry a positive, negative, or zero electrical charge, and omega(ω)-mesons, which exist only in the uncharged state. This meson-exchange model of the forces inside a nucleus also provides an explanation (indicated below) for the otherwise puzzling fact that the mean lifetime of many varieties of nuclei containing bound neutrons can greatly exceed the mean free-neutron lifetime. From measurements performed on large statistical aggregates of neutrons in the free state, their mean lifetime has been determined as $\tau = 925 \pm 11$ sec, which corresponds to a "half-life" of $T_{1/2} = 641 \pm 8$ sec, after which time interval on an average one-half of the aggregate will have decayed into products indicated by the following symbolic decay scheme:

$$n \rightarrow p^+ + e^- + \bar{\nu}.$$

This expresses the decay of any given neutron into a triad of particles comprising a proton ($p^+ = {}^1$H, the positively charged nucleus of the hydrogen atom), an electron ($e^- = \beta^-$, the particle identified as the constituent of β-rays in radioactivity) and an antineutrino ($\bar{\nu}$). This particular decay transition, termed "β-decay" in allusion to the presence of the β (electron) among the decay products, is an instance of a *weak* interaction. Thus the neutron in its *free* state participates in a *weak*-interaction decay, whereas in its *bound* state in a nucleus, it participates in a *strong*-interaction binding among the other nucleons. The heavy particles (n, p) featured in above β-decay transition are members of the baryon family; the light particles (e, $\bar{\nu}$) are *leptons*, wherein the presence of the antineutrino is indicative of a *weak* interaction. Of the two nucleons, the neutron is very slightly the more massive: hence its decay into a proton and other products does not violate the principle of conservation of mass-energy. The neutron's intrinsic angular momentum, or *spin*, is (in units of $h/2\pi$, where h is Planck's constant, a fundamental physical constant in quantum theory that has the dimensions of energy times time) $s = \frac{1}{2}$; this "quantum number" is numerically the same for the other end-product particles of β-decay, which accordingly is consistent with the conservation of angular momentum, schematically expressed as $\frac{1}{2} \rightarrow \frac{1}{2} + \frac{1}{2} - \frac{1}{2}$. The most recent concensus for the mass of a neutron is

$$m_n = (1.6749542 \pm 0.0000048) \times 10^{-27}\ \text{kg}$$
$$= 1.0086650 \pm 0.0000028\ \text{u},$$

where the atomic mass unit (u) is defined as 1/12 of the mass of the neutral ^{12}C atom. When expressed in energy units (million electron-volts, or MeV), this is equivalent to a rest-mass-energy of 939.5731 ± 0.0027 MeV, as against the proton's rest-mass-energy of 938.2796 ± 0.0027 MeV, which corresponds to

$$m_p = (1.6726483 \pm 0.0000048) \times 10^{-27}\ \text{kg}$$
$$= 1.0072764 \pm 0.0000029\ \text{u}.$$

The neutron's mass m_n is about 1839 times that of the electron, and the proton's mass is about 1836 times that of the electron:

$$m_e = (9.1095339 \pm 0.0000250) \times 10^{-31}\ \text{kg}$$
$$= (5.4858027 \pm 0.0000015) \times 10^{-4}\ \text{u},$$

or, in energy units, 0.5110034 ± 0.0000014 MeV. The rest mass of the antineutrino is zero (or, at all events, vanishingly small relative to the above, bearing in mind that the most recent theories suggest that it may not necessarily be precisely zero). Thus, the mass excess of the neutron over the proton, as expressed in energy units, is

$$m_n - m_p = 1.29343 \pm 0.00004\ \text{MeV}.$$

The decay, after a mean half-life of roughly 10.7 min, of neutrons into protons (which are completely stable or, at any rate, have extremely long mean lifetimes, on the order of 10^{31} years if the latest unified theories of particles and their interactions prove to be valid) would seem to preclude the existence of neutrons within stable or long-lived nuclei. On the other hand, their presence in conjunction with protons as the ingredients that make up a nucleus successfully explains all the known properties of nuclei and, in particular, overcomes the numerous, otherwise insurmountable, difficulties posed by earlier, pre-1932, models of nuclear structure, such as the proton-electron model, in which the nucleus was visualized to be composed of protons (making up the mass) and electrons (serving to neutralise the excess electric charge). Not only can the presence of electrons within the confines of a nucleus be excluded by quantum-theoretical arguments, but simple reasoning based upon spin-conservation can rule out such a proton-electron configuration in the case of such nuclei as nitrogen-14, for which measurements indicate the positive nuclear charge to be 7 units ($^{14}{}_7$N, a designation in which the superscript on the left denotes the mass number A and the subscript on the left denotes the atomic number Z) and the ground state to have an *integer* spin (of value 1 in the conventional $h/2\pi$ units): no aggregate of 14 protons (each having *half*-integer spin, $s = \frac{1}{2}$) and 7 electrons (each having a single negative electric charge, and half-integer spin, $s = \frac{1}{2}$), making up a composite of an *odd* total number (21) of half-integer-spin particles, can yield a system having *integer* net spin, whereas of course a cluster of 7 protons with 7 neutrons constitutes an *even*-number aggregate that can give rise to an *integer* net spin.

In adopting the neutron-proton model of nuclear structure, with meson exchange to promote the binding, it is evident that the continual acquisition and loss of mesons by neutrons must be the factor responsible for inhibiting the neutrons' natural tendency to decay. By way of a somewhat oversimplified picture, one might conceive of the momentary combination of an uncharged neutron with a positively charged companion meson as akin to an overweight, but stable, proton: hence, whenever the bound neutron gains its accompanying π^+ (or ρ^+) exchange meson it assumes the character of a long-lived (pseudo-proton) particle and so enhances the nuclear lifetime beyond that of the normal free neutron. The mesic "clouds" in a nucleus thus participate in an ever-ongoing rapid exchange process, binding the nucleons and augmenting the stability of the nucleus.

As the number of neutrons (N, the *neutron number*) in a nucleus increases, up to and beyond the atomic number Z (equal to the number of protons in the nucleus, and hence to the number of counterbalancing electrons in the electrically neutral atom), the nucleus becomes more stable—up to a reasonable limit, beyond which, with a growing neutron excess ($N - Z$), the instability again progressively grows worse. For stable nuclei of odd mass number $A = N + Z$ it is found that to a good approximation the neutron number is

$$N_{(\text{most stable})} = \frac{490A + 7.75A^{5/3}}{990 + 7.75A^{2/3}}.$$

Whereas the number of nuclear protons (and thus of atomic electrons) determines the particular chemical element (e.g., $Z = 1$ for hydrogen, $Z = 2$ for helium, $Z = 27$ for cobalt, $Z = 92$ for uranium, etc.), it is the number of *neutrons* that determines the particular *isotope* (Greek, "same place") of that element. For example, the stable nuclide ^{59}Co has $N = A - Z = 59 -$

27 = 32, while the unstable isotopes on either side, ^{57}Co and ^{61}Co, respectively have $N = 30$ and 34; according to the above stability equation, one would expect ^{59}Co to be the most stable of these, since substitution of $A = 59$ yields the desired $N_{(\text{most stable})} = 32$, whereas with $A = 57$ one would obtain $N_{(\text{most stable})} = 31$, and with $A = 61$ one would find that $N_{(\text{most stable})} = 33$.

The transformation of nuclei by neutron capture to form new isotopes was first accomplished in Rome by Enrico Fermi in 1934 (the year in which he also put forward his detailed theory of β-decay). This opened up an altogether new branch of nuclear physics (proton-induced transmutation had been discovered by John Cockcroft and Ernest Walton in 1932, for which they were jointly awarded the Nobel Prize in physics in 1951; Chadwick had received the Nobel Prize in physics in 1935, and Fermi in 1938). The importance and breadth of the subsequent developments hardly need to be stressed; on the cosmic scale, neutron capture processes in stars have profound astrophysical significance, the discovery of fission in Berlin by Otto Hahn (recipient of the Nobel Prize in chemistry in 1944) and Fritz Strassmann in 1939 through the capture of slow neutrons by uranium literally had earth-shaking consequences, and the seemingly boundless range of neutron-induced nuclear transmutation reactions under widely differing conditions offered new vistas in the rapidly expanding field encompassed by neutron science.

The discovery of its conjugate antiparticle, the antineutron ($\bar{n}$, uncharged), by B. Cork, G. R. Lambertson, O. Piccioni, and W. A. Wenzel[15] in 1956 (one year after the 1955 identification of the antiproton by O. Chamberlain, E. Segrè, C. Wiegand, and T. Ypsilantis), the recognition of the neutron's having a complicated internal structure (since, as discussed below, it has a magnetic moment, and therefore acts like a magnet, there must be internal electric charges circulating within it, even though its net electric charge is found from external measurements to be zero), the interpretation of the make-up of the neutron as a baryon in terms of a triad of quarks (e.g., the *pnn* or, in more recent parlance, *udd* quark combination, comprising an "up" quark and two "down" quarks, the former of which carries a positive charge, $+\frac{2}{3}e$, and the latter of which each carry a negative charge, $-\frac{1}{3}e$, where e is the electronic charge), and other related particle aspects, have all collectively made this a particularly interesting, if difficult, particle to study in its own right. Lately,[1] increasing consideration is being given to the possible existence of "neutron oscillations," namely, the likelihood that free neutrons could be represented as a superposition of n and $\bar{n}$ states, with an interconversion (oscillation) period $\tau_{n\bar{n}}$ in excess of 10^5 sec. The understanding of neutron-neutron forces is still far from complete in its quantitative details; studies with polarized neutrons, the acquisition of explicit information on neutron matter and neutron stars, and application of neutrons for technological, biological, and medical purposes as well as for purely scientific ends, the development of more intense neutron sources and more efficient means of detection, the potentialities offered by, e.g., ultracold nuetrons, or at the other extreme, by ultrahigh-energy neutrons: all these have the ability to provide fruitful, valuable insights into the physical world that would otherwise remain unexplored and unexploited.

Discovery and Classification No finer "coming-of-age present" for nuclear physics could be imagined than the 1932 discovery of neutrons by Chadwick,[2] precisely twenty-one years after the birth of nuclear physics following the recognition by (Sir) Ernest Rutherford in 1911 that at the central core of atoms there lay a massive, dense "nucleus." To set this neutron discovery in perspective, it should be borne in mind that with the discovery of natural radioactivity by Henri Becquerel in 1896 and of electrons as the "β-ray" component of such radiation) by (Sir) Joseph Thomson in 1897, the groundwork was laid for the elucidation of the make-up of atoms. This received its major impetus in 1911 from Rutherford's interpretative studies and in 1913 from Niels Bohr's quantum-theoretical explanation, which rendered an admirable account of many observations of atomic phenomena. With the definite identification of the proton in 1919, it appeared reasonable to contend that nuclei consisted of protons and electrons in intimate combination. Upon further scrutiny, however, this model became increasingly difficult to reconcile with the findings, and by 1930 it was evident that it was untenable. Speculation was rife that the nucleus might possibly harbor a neutral ingredient, a suggestion that Rutherford espoused. With the finding of the neutron, having all the desired properties, the difficulties were solved in 1932.

Stemming from the 1930 observation by Walther Bothe and H. Becker in Berlin that a penetrating radiation resulted from the bombardment of various target elements by naturally produced α-particles (alpha-particles are helium-4 nuclei, emitted spontaneously by a radioactive polonium source and by some other radioactive sources), and that the reaction with beryllium was particularly intense, investigations were undertaken at various centers into the nature of this radiation, unusually rich in energy and of novel penetrative capability. Among these was the Cavendish Laboratory in Cambridge (UK) where, first, H. C. Webster and, subsequently, Chadwick pursued these studies to higher precision than had been attained previously, which ruled out the possibility of the radiation's being high-energy γ-rays (gamma-rays are the third component of the α, β, γ triad of radiations observed by Becquerel and separated by the Curies; they are identified as uncharged photons, i.e., electromagnetic radiation of short wavelength). Rather, Chadwick reached the conclusion that the uncharged radiation was composed of neutral massive particles, whose mass he showed to be comparable with, and slightly larger than, that of the proton. Following Rutherford's suggestion, he designated these particles as "neutrons" and concluded his exposition of their discovery with the following words: "The neutron hypothesis gives an immediate and simple explanation of the experimental facts; it is consistent in itself and it throws new light on the problem of nuclear structure."

Thus was the foundation laid for the neutron-proton model of the nucleus in 1932. That same year, Werner Heisenberg, drawing on an analogy with chemical bonding, put forward his theory of the exchange nature of binding forces; although his first (incorrect) surmise was that *neutrino* exchange was responsible for the strong internucleon forces, this was subsequently emended to *meson exchange*, putting the n-p-(π) model on a sound footing. Another contribution by Heisenberg, also in 1932, lay in the assignment of *isospin* $I = \frac{1}{2}$ to the n-p nucleon doublet, treating the neutron and the proton as merely different isospin states, with respective "projected third components of isospin" $I_3 = -\frac{1}{2}$ and $+\frac{1}{2}$, of the basic "nucleon." Thus were sown the seeds of particle classification schemes, brought to their full flower in more recent years.

Properties As well as having the mass stated above, the neutron has a spin $s = \frac{1}{2}$ (hence is subject to the Pauli exclusion principle in its quantum states, and is governed by Fermi-Dirac statistics, therefore being termed a *fermion*, as opposed to a particle that has *integer* spin and so obeys Bose-Einstein statistics, termed a *boson*). As a member of the nucleon family it has isospin $I = \frac{1}{2}$ (and, by convention, $I_3 = -\frac{1}{2}$), positive intrinsic parity ($\pi = +$), and baryon number $B = +1$ (the antineutron has $B = -1$). Its strangeness quantum number is zero ($S = 0$: it is not a so-called "strange" particle), as is also its lepton number ($L = 0$). Its hypercharge quantum number is $Y = +1$. Its net electric charge is zero ($Q = 0$, or at any rate, less than 10^{-21} of the magnitude of the electron's unit charge). As a baryon, it is composed of three quarks, arranged in the *udd* ("up-down-down") combination. Multineutron states or particles, such as ^{2}n, ^{3}n, or ^{4}n, do not exist. There is only one known decay mode of the neutron, namely the ($pe\bar{\nu}$) β-decay mode, with a mean half-life of $T_{1/2} = 10.7 \pm 0.1$ min and a maximum energy release per decay event of $E_{\beta\,\mathrm{max}} = 0.78245 \pm 0.00007$ MeV. The probability (branching fraction) for the charge-nonconserving, but baryon-conserving and lepton-conserving, decay mode ($p\nu\bar{\nu}$) has been found to be less than 9×10^{-24}.

A property of the neutron that has particular significance is its anomalous magnetic moment, first accurately measured by Luis Alvarez and Felix Bloch.[16] The presently accepted value of this quantity,[17] expressed in units of the nuclear magneton ($\mu_N \equiv eh/4\pi m_p c = 3.1524515 \times 10^{-18}$ MeV/gauss, where c is the vacuum velocity of light) is

$$\mu_n = -1.91304184 \pm 0.00000088.$$

The negative sign implies that the magnetic-moment vector points in a direction opposite to that of the spin (i.e., indicates the magnetic polarity), while the nonzero (anomalous) value implies the existence of inner circulating positive and negative, self-cancelling electric charges in the interior of the neutron. Also of significance is the electric dipole moment (also termed the E1 moment, or the EDM) of the neutron, which has to be zero if the time-reversal invariance is to hold. The experimentally determined value is consistent with zero; in the conventional units of $10^{-23}\,e \cdot$ cm, it is[18]

$$D_n = 0.04 \pm 0.15,$$

which implies that, within 90% confidence limits, $D_n/e < 0.3 \times 10^{-23}$ cm. An estimate[19] of this value in Steven Weinberg's model of "CP violation" (akin to time-reversal violation) invoking contributions from strange quarks yielded the result $D_n/e \simeq 0.07 \times 10^{-23}$ cm, which is very close to the current experimental limit (see under "Ultracold Neutrons" below).

An illustrative instance of its usefulness as a probe of interaction characteristics, apart from its strong binding interaction and weak β-decay interaction and, indeed, from its participation in the intermediate-strength electromagnetic interaction during neutron-induced radiative capture (n, γ) reactions, is exemplified by its having been chosen[20,21] as the first massive non-self-conjugate elementary particle to test gravitation at the fundamental microscopic level: a well-collimated beam of low-energy neutrons sent along a lengthy horizontal evacuated pipe was observed to evince the expected downward deflection as a function of horizontal distance. Here, neutrons were used in order to avoid electromagnetic complications and because their path could be well determined by Bragg reflection to high precision. The successful outcome prompted the proposal to undertake an analogous long-flight-path experiment with antineutrons[22,23] as a means of testing the effect of gravity on antimatter at very high sensitivity (a 1-MeV beam of antineutrons traversing a horizonal distance of 1 km would be expected to fall a vertical distance of only 2.5×10^{-8} m). More recently, however, an alternative arrangement using antiprotons (and, for comparison, protons) in a very long drift tube, avoiding some of the inherent difficulties of the antineutron experiment, has been suggested.[24]

Details of other neutron properties and numerical data have been given in handbooks,[25] reviews of particle properties,[26] and compilations of measured data.[27] For neutron-induced reaction data, especial attention is drawn to the Evaluated Nuclear Data Files, the ENDF bank, established and maintained by the National Neutron Cross Section Center at the Brookhaven National Laboratory, Upton, NY 11973.

Production Neither neutrons nor protons are emitted spontaneously in the course of nuclear radioactive decay, which is confined solely to α, β, or γ-emission. Free neutrons must therefore be produced artificially, through nuclear reaction processes which may be induced by charged particles (α, d, p principally), γ-rays ("photoneutron production"), or other neutrons (as in fission chain reactions). A useful more recent alternative is the spontaneous-fission source, containing a nuclide such as plutonium-240 (^{240}Pu) or californium-252 (^{252}Cf) which has a reasonably long half-life ($T_{1/2}$ = 6760 yr or 2.55 yr, respectively) and, in undergoing spontaneous fission produces fairly copious amounts of neutrons among the disintegration products (the more intense source, ^{252}Cf, produces 3 × 10^{12} neutrons/sec per gram). Other self-contained neutron sources employ natural α-emitting nuclei such as ^{226}Ra or ^{230}Pu mixed with ^{9}Be to bring about the neutron-producing reaction

$$^{9}\mathrm{Be} + \alpha \rightarrow n + {}^{12}\mathrm{C} + 5.7\ \mathrm{MeV}$$

within a sealed capsule. In polonium-beryllium (Po-Be) sources, the α particles emanate from ^{210}Po (which decays to stable lead, ^{206}Pb, with a half-life $T_{1/2}$ = 0.3789 yr, and hence has less durability). Photoneutron sources employ fairly energetic spontaneous γ-ray emitters such as sodium-24 (^{24}Na) to obtain neutrons from the

$$^{9}\mathrm{Be} + \gamma \rightarrow n + 2\alpha \quad \text{or} \quad {}^{2}\mathrm{H} + \gamma \rightarrow n + {}^{1}\mathrm{H}$$

reactions. In the former, the produced α-particles may initiate additional neutron production from the ^{9}Be content; in the latter, a deuterium target is disintegrated into neutrons and protons.

Nowadays, one of the most common means of producing neutrons is to direct accelerated charged particles, such as deuterons (d) or protons (p), from an accelerator onto a gaseous or solid target (of deuterium, tritium, helium-3, lithium-7, or beryllium-9) to bring about a neutron-producing reaction such as

$$^{2}\mathrm{H} + d \rightarrow n + {}^{3}\mathrm{He} + 3.269\ \mathrm{MeV},$$

"D-D reaction"

$$^{3}\mathrm{H} + d \rightarrow n + {}^{4}\mathrm{He} + 17.590\ \mathrm{MeV},$$

"D-T reaction"

$$^{3}\mathrm{H} + p \rightarrow n + {}^{3}\mathrm{He} - 0.764\ \mathrm{MeV},$$

"P-T reaction"

$$^{7}\mathrm{Li} + p \rightarrow n + {}^{7}\mathrm{Be} - 1.644\ \mathrm{MeV},$$

or

$$^{9}\mathrm{Be} + d \rightarrow n + {}^{10}\mathrm{B} + 4.362\ \mathrm{MeV}.$$

Neutrons from the D-D reaction typically have energies around 2–4 MeV; those from the D-T reaction have energies around 14 MeV (the residual nuclei take up some recoil energy), while neutrons having energies below 1 MeV can be produced from the endothermic reactions having a *negative* energy term on the right-hand side. The D-D and D-T reactions are instances of thermonuclear fusion processes, such as account for energy generation in stars, in the hydrogen bomb, and in controlled thermonuclear reaction (CTR) devices for power production. An overview of some accelerator-based neutron installations and facilities has been given by S. W. Cierjacks,[3] and a survey of the high-flux production of neutrons has been presented by Lawrence Cranberg.[3] Methods for producing intense sources of fast neutrons have been reviewed by Henry Barschall;[28] in particular, the generation of high-intensity ($\gtrsim 10^{13}$ neutron/sec) beams of 14-MeV neutrons for cancer therapy[29] has been the subject of increasing attention over the past decade.[3] Of course, intense neutron fluxes can also be produced in nuclear explosions underground. Neutrons are being constantly produced in the atmosphere as one of the secondary effects of cosmic rays; typically approximately 2 × 10^{-6} neutrons per m^{2} are so produced every second in the 1–2 MeV energy range. From pulsed accelerators, such as the Van de Graaff generator, pulsed neutron beams (which can be bunched, using the Mobley principle) can be produced; a text on pulsed-neutron scattering technology has recently been issued.[30] Reactors are, likewise, prolific (continuous) sources of neutrons. However, neutrons of different energies are produced at different locations within the assembly, from which they may be extracted via "canals" or beam tubes; the energy spread of the fission neutrons is considerable and although their actual energy can be reduced by the insertion of "moderator" materials such as graphite (which also acts as a blanketing shield), it is impossible without special ancillary methods to acquire monoenergetic neutron beams from a reactor.

To get well-defined beams of definite energy one may use velocity-selector devices,[8] such as filters (an Sc-Ti combination transmits only 0.002-MeV neutrons, while a ^{56}Fe-Ti combination passes 0.024-MeV beams, and a ^{28}Si filter passes only 0.144-MeV beams) or "choppers" (cadmium-steel cylinders, absorptive cylinders containing one or more nonabsorbing, transparent channels, set into rotation at such a speed as to allow only a preselected velocity to pass through). Alternatively, one may utilize the γ-ray flux of a reactor to produce monoenergetic photoneutrons resonantly by directing it onto a suitable nuclear target material. High-energy, relativistic, neutron beams would, of course, be produced from the bombardment of appropriate targets by high-energy charged-particle beams from a high-energy accelerator.

Detection The methods used for the detection of neutrons depend upon their energy, and in all instances require indirect means of detection, since the absence of an electric charge prevents the neutron from being detectable directly. Such secondary processes include the observation of charged particles or, e.g., radiation, emanating from neutron-induced reactions, the detection of recoil protons or recoil nuclei from collisions, the registration of fission fragments, or measurement of the heat produced in a given neutron-initiated reaction. The requisite instrumentation[31] that responds to these secondary charged particles includes ionization or fission chambers, Geiger or proportional counters, scintillators or solid-state surface-barrier detectors, photographic emulsions, cloud, bubble, or spark chambers, with appropriate shielding. The latter usually takes the form of copper shadow bars, borated paraffin wax (sometimes impregnated with lithium carbonate), lead, etc. Air scattering of neutrons is considerable; electronic means of discrimination and background correction have to be utilized. As an instance of energy-matching in the selection of a detector, fission chambers clad with ^{235}U are sensitive to slow neutrons; those clad with ^{238}U respond to fast neutrons. By modifying the design of a counter, its energy region of best response can be changed: for the detection of slow neutrons, boron counters are frequently employed; by surrounding these with a thick sheath of paraffin wax or other hydrogeneous material to slow down any fast primary neutrons they may, as so-called "long counters," be adapted to respond to fast neutrons. Their response is triggered by the α-particles that ensue from the $^{10}B + n \rightarrow \alpha + {}^7Li +$ 2.78 MeV reaction which takes place within the boron-filled counter (usually containing gaseous BF_3 enriched in the ^{10}B isotope). The neutron-activation technique also finds many applications. Since the total neutron energy cannot be directly registered it is customary to adopt time-of-flight spectrometry methods[32,33] in which subnanosecond time resolutions over protracted measuring runs are attainable. High-energy neutron detection methods, constantly being improved, have been discussed by R. T. Siegel.[34]

Categorization Just as it has become customary to distinguish between "hard" and "soft" X-rays on the basis of their energy (i.e., wavelength), so has a nomenclature for different neutron classes come into usage. The principal categories are:

(a) Ultracold neutrons, having energies around 10^{-7} eV, whose velocities are therefore but a few meters/sec, the corresponding temperature being only 10^{-3} K, i.e., one-thousandth of a degree above absolute zero (in Kelvin degrees);

(b) Cold neutrons, having kinetic energies $\lesssim 0.002$ eV;

(c) Thermal neutrons, an important class whose kinetic energy of about 0.025 eV corresponds to velocities that are compatible with tne velocity of molecules in thermal motion, i.e., at "room temperature" ($T \simeq 20°C \simeq 293$ K) $v \simeq 2.2$ km/sec;

(d) Epithermal neutrons, having somewhat higher energies, in the region $\gtrsim 0.5$ eV;

(e) Resonance neutrons, another especially important class, having energies in the range of 1-100 eV that correspond to the region of strong (resonant) absorption by nuclei.[35]

Neutrons within the categories (a)-(e) are all considered "slow neutrons." Others are

(f) Intermediate neutrons, having energies from 0.001 to 0.5 MeV;

(g) Fast neutrons, whose energies lie within the 0.5 to 15 MeV range;

(h) Very fast neutrons, from 15 to 50 MeV;

(i) Ultrafast neutrons, from 50 to 10,000 MeV;

(j) The rest, with energies above 10,000 MeV, constitute highly relativistic neutrons.

Ultracold Neutrons Interesting recent developments have opened up a new branch of knowledge and application in neutron physics.[1,3,8,12,36] Ultracold neutrons, whose motion is comparable with human running speed, have the remarkable property of being totally reflected from solid surfaces, which enables them to be isolated within suitable metal (usually, aluminum or copper) or glass containers, or trapped within magnetic storage rings (now constructed with superconducting windings), after traveling along a selective guide tube. Because of their low energy, they can rise only about a meter against the earth's gravity before falling back. A proposal to create and trap them from cold neutrons in refrigerated superfluid helium is currently being tried out.

The wavelength (in meters) of a neutron is related to its energy (in eV) as

$$\lambda = \frac{2.86 \times 10^{-11}}{\sqrt{E}}$$

and hence if E is equal to 10^{-7} eV, the wavelength is $\lambda = 9 \times 10^{-8}$ m (i.e., 900 Ångstrøm units), about two orders of magnitude larger than the spacing between the atoms in solids, which are thus impervious to a wave of ultracold neutrons. In effect, the wave is repelled by the solid, as predicted and demonstrated (for higher-energy neutrons) by Fermi in 1945. The reflection is total, provided the velocity is below a critical value which varies from one material to another, being roughly 6 m/sec for nickel, iron, beryllium, or copper. Ultracold neutrons are defined as those having a total velocity below this critical value for a given material. Thus, v = 6 m/sec corresponds to $E = 2 \times 10^{-7}$ eV, which in turn represents a temperature $T = 2 \times 10^{-3}$ K (two-thousandths of a degree above absolute zero). Though only sparsely available in the neutron flux from reactors, they have been successfully extracted and investigated. An obvious application is in the determination of the mean lifetime of free neutrons to a higher accuracy than has hitherto been feasible. However, unforeseen and as yet still not fully understood problems in maintaining the necessary long containment times have hampered these measurements, although refinement of the isolation and storage arrangements is leading[38] to the desired conditions for the experiment to be completed satisfactorily. Similarly, ultracold neutrons offer an ideal means of establishing finer limits to the value of the electric dipole moment (EDM) of the neutron. The accepted value[18] for D_n was determined at the ultracold-neutron facility situated in the Institut Laue-Langevin in Grenoble (France), while a result with even smaller error limits, namely $D_n/e = (4 \pm 7.5) \times 10^{-25}$ cm, has been obtained[39] at the B. P. Konstantinov Institute (USSR). This indicates that, at the 90% confidence level, $|D_n/e| < 0.16 \times 10^{-23}$ cm.

Because of their comparatively long wavelength (longer than that of electron beams, albeit shorter than that of visible light), ultracold neutrons lend themselves to use in a neutron microscope, complementing the familiar electron microscope, or to examination of interatomic forces and the motions of atoms in solids, through the use of a neutron spectrometer arrangement. Among other potentialities that they present is the possibility for the first time of obtaining a pure neutron target for atomic and nuclear experiments, without the need to employ subtraction procedures to correct for the presence of impurities or other nuclei.

Slow Neutrons In this category, the most important classes are the thermal neutrons (which initiate fission reactions in, e.g., ^{235}U or ^{239}Pu) and resonance neutrons (whose likelihood of being captured by a nucleus in, e.g., a radiative capture process, peaks sharply at certain resonance energies, rising dramatically to a very high, narrow, maximum). Slow-neutron capture in particular is a widely used process for the production of radioactive isotopes from stable nuclides. Whereas the probability for elastic scattering of low-energy neutrons does not change greatly with energy or emergence angle, that for neutron capture, in which radiation or particles are emitted, follows a characteristic diminishing trend that is inversely proportional to the incident neutron velocity: the "$1/v$ law" holds for such exothermic capture reactions, except at resonance energies, when the probability may increase a hundredfold or more over a narrow incident energy range. For example, radiative capture of neutrons on indium-115(^{115}In) occurs reasonantly at E_n = 1.457 eV; the capture probability at just this energy is about 180 times larger than when measured at about $\frac{1}{2}$ eV on either side of this resonance value. For thermal neutrons (E_n = 0.025 eV), cadmium has a high capture probability: natural cadmium is, to 12.3%, comprised of the isotope ^{113}Cd, which displays a broad, powerful resonance for the absorption of neutrons about the energy E_n = 0.176 eV, overlapping with the thermal region. For this reason, cadmium is used in the fabrication of choppers and in the safety control rods of nuclear reactors.

Neutrons in Fission and Parity Violation The general subject of fission is too broad for coverage here;[1,3,40–43] this Encyclopedia discusses it elsewhere (see FISSION). Most reactors operate through fission induced in a core containing an overcritical amount of ^{235}U or ^{239}Pu, whose break-up into fission fragments (medium-heavy nuclei, more neutrons, and radiation) when bombarded by thermal neutrons (i.e., neutrons slowed down by a graphite or deuterium "moderator" to "thermal" speeds) liberates about 200 MeV of energy per fission event. Because some 2.5 neutrons are released from each fission event initiated by a single thermal neutron, capable of bringing about further fission, a "chain reaction" can occur readily, triggered by this multiplication of neutrons. Through the use of absorptive cadmium control rods, the controlled operation of a fission reactor can be maintained. In so-called "breeder reactors," based upon a plutonium or thorium cycle, as much or more fissionable material is produced in the course of operation as is used up from the primary fuel; hence a self-sustaining power-producing plant, such as that in the Superphénix installation in France can be devised for the more conserving use of nuclear fuel resources.

Parity violation, i.e., the inequivalence of coordinate-system "handedness" in the description of nuclear processes, evoked much attention when first identified in weak interactions in 1956. Although the weak interactions were found to manifest maximal parity violation, it was not considered to play any role in strong interactions. Recently, however, some indications of its presence even in strong-interaction phenomena has come to light. A mechanism for parity violation in thermal-neutron-induced fission[44] has been worked out by O. P. Sushkov and V. V. Flambaum.[45] Similarly, an explanation for parity violation in the radiative capture of polarized neutrons has been provided by D. F. Zaretskii and V. K. Sirotkin,[46] while that for neutron scattering at threshold (e.g., on ^{124}Sn) has been discussed by G. Karl and D.

Tadic.[47] The first clear evidence for parity-nonconserving spin-rotation of neutrons passing through matter has been observed in tin isotopes (^{124}Sn, ^{117}Sn, and natural Sn) by M. Forte et al.[48]

Fast Neutrons Above the threshold energy, a wide variety of interaction processes is available for neutrons to undergo. These include elastic and inelastic (i.e., excitation) scattering from nuclei, from which the neutrons emerge with effectively unchanged, or diminished, energy, multineutron emission, in which more than one neutron is ejected by each incident projectile neutron, particle or multiparticle release from nuclei following neutron capture, radiative capture (whose likelihood diminishes with energy), even fast-neutron fission, induced, e.g., in ^{232}Th or ^{238}U. A major branch of nuclear-reaction studies deals with neutron-induced processes which play a vital role in nuclear physics and astrophysics.

Ultrafast Neutrons Already at E_n = 6.32 MeV the (classical) kinetic energy of a neutron differs by 1% from that calculated relativistically; above about 50 MeV the neutrons are distinctly relativistic. At these high energies, multiple particle emission is, with increasing frequency, found to occur when neutrons in the 50–500 MeV range are directed onto nuclear targets. The mechanism is in general complicated: in an initial step, knock-on nucleons are likely to be ejected directly, followed by the redistribution of the surplus excitation energy in the residual nucleus, which deexcites by the emission of γ-rays and one or more additional nuclear particles. Spallation is often caused by ultrafast neutrons.

Neutron Polarization As spin-$\frac{1}{2}$ particles with a nonzero spin magnetic moment, neutrons can be polarized,[16] i.e., oriented in the direction of an applied external magnetic field. This magnetic moment may, at least in part, account for the small attractive force that acts between a neutron and an electron, the first evidence of which Fermi discovered in 1947. Thus, polarized neutron beams can be produced, and used in the derivation of basic information on nuclear forces or other characteristics.[1,3–5,12,49–51] Several methods exist for the production of polarized neutron beams: partial polarization can be induced by the passage of a neutron beam through a slab of magnetized iron (the "Bloch effect," first established in 1936/37 by Felix Bloch). Neutrons can be partially polarized by scattering: the use of double-scattering experiments (in which the first scattering causes the polarization, and the second scattering analyzes it) is particularly noteworthy. The neutrons produced in reactions can also be partly or almost wholly polarized.[50] The β-decay of polarized neutrons has been used to test the time-reversal invariance of the weak interaction; polarized neutrons have also been employed in other investigations of time-reversal invariance in nuclear reactions. The values of the neutron's electric and magnetic polarizabilities have not yet been established definitively;[1] theoretical estimates of the electric polarizability indicate typically α_n = 8.5 × 10^{-49} m^3 but experimental values are inconclusive, whereas up to the present the magnetic polarizability has not been measured at all.

Condensed Matter (Neutron Stars) The extreme densities associated with nuclear matter, averaging about 10^{17} kg/m^3, are encountered in practice only in the highly compressed matter of neutron stars, in which the immense inward gravitational attractive force effectively "squeezes" atomic electrons onto nuclear protons to produce a highly condensed "neutron fluid" as the stellar material. Such neutron stars[52,53] constitute the end product of a stellar evolution sequence from protostar to main-sequence object, red giant and variable phase, thence to the white-dwarf stage and, via a supernova explosion if the mass transcends the Chandrasekhar limit of 1.44 solar masses, to the neutron-star condition, having a radius of but a few kilometers and rotating rapidly, as a "pulsar" emitting radio signals.

Neutron Diffraction and Interferometry Over the energy interval E_n = 0.001–10 eV, the wavelength of neutrons, according to the formula above, ranges from about λ = 0.1 to 10 Å. Such a wavelength is well suited to the examination of the structure of materials, akin to investigations pursued with X-ray (Bragg) diffraction. Neutron diffraction on the atomic lattice planes of a crystal can occur by way of reflection or transmission; many designs of neutron spectrometers have been employed in a wide variety of solid-state and material studies, making use of interferometry.[1,3,14,54,55]

Other Applications Neutron applications are too numerous to list exhaustively.[1,3,56] By way of example, one might make mention of neutron radiography in studies of paintings, in metal science and in medical investigations. Neutrons have been used extensively for other biomedical applications, including biotherapy, in the production of radioisotopes and infrared detectors or the enhancement of computer memory devices or food preservation, in many analytical applications, including activation analysis, and for such diverse purposes as assaying, moisture gauging and well-logging, forensic and archaeological investigations, solid-state research and chemical molecular studies. Their use to such ends in benefitting mankind "has been both beneficient and benevolent"[56] and has far outweighed the potential misuse in explosive fission devices.

NEUTRON ACTIVATION ANALYSIS

Neutron activation analysis (NAA) is a powerful and sensitive method of elemental analysis based upon the quantitative detection of radionuclides produced in samples via nuclear reactions resulting from the high-flux thermal-neutron bombardment of the samples. There are also other types of nuclear activation analysis in which the bombarding particles are energetic charged particles (e.g., protons from a cyclotron), energetic photons (e.g., bremsstrahlung photons from an electron linear accelerator), or fast neutrons (e.g, 14 MeV neutrons from a deuteron accelerator). However, activation with the high fluxes of thermal neutrons produced by a research-type nuclear reactor provides the best sensitivities of detection for most elements, and is the most fully developed and most widely used form of the nuclear activation analysis method—hence this discussion will be limited to NAA, particularly with reactor thermal neutrons.

Neutron Sources Lower fluxes of thermal neutrons (but still useful for teaching purposes, and for the determination of major, minor, and a few trace elements) can be produced with commercially available isotopic sources—(α, n) sources or ^{252}Cf spontaneous-fission neutron sources, or with modest-sized Cockcroft-Walton or Van de Graaff accelerators. Since all sources of neutrons produce neutrons of appreciable kinetic energies, they must be slowed down to thermal velocities (a mean kinetic energy of about 0.025 eV, at 20°C) by use of a suitable moderator—usually water or some other hydrogenous material. Where activation by fast neutrons is desired, no moderator is used.

Far higher fluxes of thermal neutrons are produced in typical research-type nuclear reactors. For reactors operating at steady power levels of 0.1, 1, or 10 megawatts, thermal-neutron fluxes of, respectively, about 10^{12}, 10^{13}, or 10^{14} n cm^{-2} s^{-1} are available for the activation of samples. Most such reactors are of the pool type, in which the reactor core is located at the bottom of a deep pool of circulating high-purity water. The water serves as a transparent coolant, neutron moderator, and biological shield. The neutrons produced by the thermal-neutron fission of ^{235}U have high initial energies (ranging from about 0.5 MeV up to many MeV), but collisions with water protons rapidly slow them down to thermal energies. Where irradiation with only epithermal plus fast neutrons is desired, samples are enclosed in a thin cadmium container—the Cd serving to remove almost quantitatively all neutrons with energies less than about 0.4 eV. Using a fast-transfer pneumatic tube (for production and detection of induced radionuclides with half lives in the range of seconds to minutes), samples and standards are activated and rapidly counted one at a time. Where the interest is in the production and detection of longer-lived induced activities (half lives of an hour or longer), longer irradiations of many samples and standards are carried out, simultaneously, followed by sequential counting of the activated specimens at selected longer decay times.

Types of Neutron Reactions With only a few exceptions, thermal neutrons interact with atomic nuclei by only the (n, γ) reaction, producing a nucleus of the same atomic number (Z) as the target nucleus, but now one unit larger in mass number (A). In most cases (those of use in the conventional radioactive-decay NAA method), such (n, γ) products are radionuclides. In most instances, being neutron-rich radionuclides, these decay by β^- emission, and in all but a few cases the β^- emission is accompanied by the emission of gamma-ray photons of one or more characteristic, sharply defined energies. In (n, γ) reactions, the γ refers to the prompt gamma rays emitted immediately after the neutron capture, as the highly excited product nucleus cascades down to its ground state. These prompt gammas are quite different in their energies from the subsequently emitted radioactive-decay gamma rays. Prompt gammas are also used, somewhat, in "prompt-gamma NAA," with a sample being concurrently bombarded with a much lower beam-tube flux of thermal neutrons and counted on a γ-ray spectrometer. For almost all elements prompt-gamma NAA is much less sensitive than radioactive-decay NAA, and hence this discussion will be limited to the latter.

With sample bombardment by fast neutrons (e.g., 1–15 MeV neutrons), the cross sections for (n, γ) reactions are very small, whereas the cross sections for many (n, n'), (n, p), (n, α), and $(n, 2n)$ reactions become appreciable—ranging from millibarns to about 1 barn (1 barn is a reaction cross section of 10^{-24} cm^2 per nucleus). For most target nuclei, fast-neutron reaction cross sections are 1, 2, or more orders of magnitude smaller than thermal-neutron (n, γ) cross sections.

Of these five main kinds of neutron reactions, the (n, γ) reaction is always exoergic (usually by 5–15 MeV), has no Coulomb barrier or threshold energy, and produces a neutron-rich product of the same element, one unit larger in mass number. The (n, n') neutron inelastic-scattering reaction is always somewhat endoergic and hence has a threshold energy, has no Coulomb barrier, and produces a metastable isomer of the target nucleus (same Z and A). Metastable isomers usually decay by isomeric transition, emitting characteristic gamma radiation. The $(n, 2n)$ reaction is always considerably endoergic, has no Coulomb barrier, and produces a neutron-deficient product of the same element (same Z) but one unit lower in mass number. Neutron-deficient radionuclides usually decay by orbital electron capture (EC), by β^+ emission (if energetically possible), or both. (n, p) and (n, α) reactions may be either endoergic or exoergic, but both exhibit effective threshold energies because of their Coulomb barriers. The (n, p) reaction forms a neutron-rich product nucleus of the element one unit lower in Z than the target nucleus, but of unchanged mass number. The (n, α) reaction generally produces a neutron-rich product nucleus—that of the element 2 units lower in Z than the target nucleus, and 3 units lower in mass number.

Theory of the NAA Method When a sample containing a particular kind of target nucleus (of a particular Z and A) is bombarded with a steady flux ϕ of thermal neutrons, the steady rate of formation of (n, γ) product nuclei from it is simply:

$$dN^*/dt = -dN/dt = N\phi\sigma, \qquad (1)$$

in which N is the number of such target nuclei in the sample, N^* is the number of (n, γ) product radionuclide nuclei it produces, and σ is the thermal-neutron (n, γ) cross section of the target nucleus. If the product nuclei are radioactive, they will be decaying, even during the irradiation, by the usual first-order radioactive decay process:

$$\frac{-dN^*}{dt} = \lambda N^* = \frac{\ln 2}{T} N^* = \frac{0.69315}{T} N^*, \qquad (2)$$

in which λ is the radioactive-decay rate constant of the product radionuclide, and T is the half-life of the radionuclide. The net rate of formation of the radionuclide during the irradiation is thus its steady rate of formation ($N\phi\sigma$) minus its ever-increasing rate of decay (λN^*):

$$\text{net } dN^*/dt = N\phi\sigma - \lambda N^*. \qquad (3)$$

This equation, when integrated by means of an integrating factor, yields the basic equation of NAA:

$$A_0 = (-dN^*/dt)_0 = N\phi\sigma(1 - e^{-0.69315 t_i/T}), \qquad (4)$$

in which A_0 represents the radionuclide disintegration rate (in disintegrations per second, dps) at the end of the irradiation (i.e., at zero decay time), and t_i is the duration of the irradiation period, expressed in the same units of time as the half-life, T.

The N term may be expressed in terms of the weight of that element present in the sample, w (the sought-for unknown in the analysis of a sample for that element):

$$N = \frac{waN_A}{AW}, \qquad (5)$$

in which w is the weight of the element present (in grams), a is the fractional isotopic abundance of the target stable nuclide (stable isotope) among the various stable isotopes of that element (i.e., a = exactly 1 for the 20 elements that are monoisotopic in nature), N_A is Avogadro's number (6.022×10^{23} atoms per gram atom), and AW is the regular chemical atomic weight of the element, in atomic mass units (i.e., the abundance-weighted mean of the atomic masses of its various stable isotopes).

The parenthetical term in Eq. (4),

$$1 - e^{-0.69315 t_i/T},$$

is called the saturation term S, the only time-dependent term in Eq. (4), other than A_0. It is a dimensionless term, ranging only from 0 (for $t_i/T = 0$) to 1 (for $t_i/T = \infty$). For t_i/T values of 0, 1, 2, 3, 4, 5, . . . , S acquires values of, respectively, 0, $\frac{1}{2}$, $\frac{3}{4}$, $\frac{7}{8}$, $\frac{15}{16}$, $\frac{31}{32}$, . . . , i.e., it asymptotically approaches the limiting value of 1 with increasing t_i/T (at $t_i/T = 10$, $S = 1023/1024$, or 0.999). The saturation term is very important in NAA work, since it enables one to accentuate the production and detection of short-lived species by employing very short irradiation periods, followed rapidly by a short counting period. To accentuate the production and detection of medium-lived species, one employs a longer irradiation period, followed by a decay period long enough for the shorter-lived species to decay out, prior to a somewhat longer counting period—and similarly even longer irradiation, decay, and counting periods to accentuate the production and detection of even longer-lived species.

All of the above equations apply to each radionuclide being produced in the thermal-neutron irradiation of a multi-element sample, independently of one another. Once the irradiation is ended, each radionuclide present decays away according to its particular half-life (Eq. (2)). When Eq. (2) is integrated, one obtains the equation for the number of radionuclei of a given type (N^*) present after a decay period t, compared with their number ($N_0{}^*$) present at the end of the irradiation:

$$N^* = N_0{}^* e^{-0.69315t/T}. \qquad (6)$$

Since $-dN^*/dt = \lambda N^*$, and $(-dN^*/dt)_0 = \lambda N_0{}^*$, this equation can also be expressed in terms of disintegration rates (A) instead of in terms of number of nuclei present:

$$A = A_0 e^{-0.69315t/T}. \qquad (7)$$

In practice, one does not measure absolute disintegration rates, but instead (usually) one measures the photopeak counting rate (PPcps) of the principal decay gamma-ray photon emitted by the radionuclide. For counting with a particular γ-ray detector, at a particular counting geometry, PPcps = ϵA, where ϵ is the overall photopeak detection efficiency of the detector, at that geometry, for gamma rays of that energy (also taking into account the fraction of the decays of that radionuclide that produce a gamma ray of that energy). Thus, Eq. (7) can also be expressed in terms of PPcps:

$$\text{PPcps} = (\text{PPcps})_0 e^{-0.69315t/T}, \qquad (8)$$

or, integrating over the counting period t_c, since the number of net photopeak counts NPPC accumulated during the counting period is NPPC = [(PPcps at SOC)T/0.69315] (1 − $e^{-0.69315t_c/T}$):

$$\text{NPPC} = (\text{NPPC})_0 e^{-0.69315t/T}, \qquad (9)$$

in which SOC refers to the PPcps at the start of the counting period.

In practice, one seldom uses an "absolute" method in NAA work, but instead employs a "comparator" method, in which samples and standards of the elements of interest are activated and counted identically. Then, if the basic equations above are written for a sample and for a standard of the element of interest, and one equation is divided by the other, all of the parameters that are common to both (i.e., ϕ, σ, t_i, T, S, a, N_A, AW, ϵ, and t_c) cancel out, leaving only the very simple comparator equation (for the same decay time and same counting period):

$$\frac{\text{NPPC of sample peak}}{\text{NPPC of standard peak}} = \frac{w \text{ in sample}}{w \text{ in standard}}. \qquad (10)$$

Since sample and standard are counted at somewhat different decay times (on the same detector), one must be corrected to the decay time of the other, via a slight modification of Eq. (7). The main advantages of the comparator method over the "absolute" method are (1) it is much simpler, and (2) it is more accurate, since it does not depend upon accurate knowledge of the parameters common to both sample and standard, many of which are not accurately known (e.g., σ values) or are difficult to measure accurately (e.g., ϕ and ϵ values).

Detection Sensitivities for Various Elements Because of the wide range of each of the variables involved in NAA, among the different elements and their various (n, γ) products, the lower limits of detection (LOD's) of the different elements cover a wide range, for any given set of conditions. The LOD's for 68 elements (in the absence of significant levels of other induced activities) are summarized in Table 1. These are LOD's calculated for a fairly typical set of conditions: $\phi = 10^{13}$ n cm^{-2} s^{-1} (thermal neutrons), $t_i \leqslant 5$ hours, $t_{\text{decay}} = 0$, $t_c \leqslant 100$ minutes with a 40 cm^3 Ge(Li) detector at a distance of 2 cm. In each case, the LOD is based upon the largest photopeak of the radionuclide formed to the largest extent by the element, and is based upon a defined minimum detectable (to a reasonable relative precision, i.e., about ±20% of the value) number of NPPC, 30.

Table 1 includes all the nonradioactive or nearly nonradioactive (i.e., K, Th, and U) elements for which the NAA method is highly or fairly sensitive, except the inert-gas elements (for which NAA is also very sensitive, except for He)—since the noble gases are not significantly present in most solid or liquid samples. Noticeably absent from the table are the lowest atomic number elements (H, Li, Be, B, C, N, and O), which are scarcely activated by thermal neutrons, and the elements P, Tl, Bi, which

TABLE 1.

LOD (μg)	Elements
10^{-7}-10^{-6}	In, Eu, Dy, Ho
10^{-6}-10^{-5}	Mn, Sm, Au, Rh, Lu, Re, Ir
10^{-5}-10^{-4}	Co, Cu, Ga, As, I, Cs, La, Er, W, Hg, U, Na, V, Br, Ru, Pd, Sb, Yb, Th
10^{-4}-10^{-3}	Sc, Ge, Sr, Te, Ba, Nd, Ta, Cl, Se, Cd, Gd, Tb, Tm, Hf, Pt
10^{-3}-10^{-2}	Al, Zn, Mo, Ag, Sn, Ce, Os, K, Ti, Cr, Ni, Rb, Y, Pr
10^{-2}-10^{-1}	Mg, Zr
10^{-1}-1	F, Ca, Nb
1-10	Fe, Si
10-100	S, Pb

form only pure β^- emitters, with no accompanying gamma radiation.

Forms of the Method There are two forms of the NAA method: (1) the purely instrumental, nondestructive form, based upon gamma-ray spectrometry only, and (2) the radiochemical separation, destructive, form which utilizes post-irradiation radiochemical separations with carriers, of the induced activities of interest. Nowadays, instrumental NAA usually involves the counting of activated samples and standards, at selected decay times, with a high-resolution Ge(Li) or intrinsic Ge γ-ray detector, coupled to a multichannel pulse-height analyzer (typically of 4096 analysis and storage channels). The instrumental form of the method has the advantages of detecting and measuring many elements simultaneously, of not destroying the sample, and of requiring a minimum of the analyst's time. However, in some kinds of samples high levels of other induced activities can raise the LOD for an element of interest by one or two orders of magnitude above its interference-free LOD (by producing a very high Compton continuum level in the pulse-height spectrum, superimposed upon which is the photopeak of interest). In such cases, one may have to resort to the more time-consuming, sample-destructive radiochemical-separation technique, prior to counting.

Sample Sizes, Precision, and Sources of Error In NAA work, samples (any kind of solid or liquid material) can be as small as micrograms to as large as grams, depending upon how much sample is available or the maximum amount that can be used without resulting in counting rates so high that the pulse-height spectrum is markedly distorted by pulse pileup. Since one part per million (ppm) by weight corresponds to 1 μg of element per gram of sample, it is evident that the μg LOD's tabulated above are numerically the same as the various ppm LOD's in a one-gram sample.

The precision of NAA measurement of an element in a sample can be estimated, if other sources of variance are carefully minimized, from the counting statistics. For N observed counts, the standard deviation (resulting from the random nature of radioactive decay) is simply $\pm N^{1/2}$. Thus, if a certain number of gross photopeak counts (GPPC) are measured, for a particular γ-ray peak, its standard deviation is $\pm(\text{GPPC})^{1/2}$. If the underlying Compton continuum baseline counts (BLC) are estimated by summing the counts in channels on either side of the photopeak (using as many baseline channels as the number of channels included in the peak), its subtraction from the GPPC gives the desired NPPC and its standard deviation: $\pm[\text{GPPC} + \text{BLC}]^{1/2}$.

As with any analytical method, errors are possible. Discussion of these is beyond the scope of this short summary, but a few such sources of error deserve mention. They include particularly thermal-neutron self shielding and sample γ-ray self-attenuation. The experienced activation analyst, however, recognizes situations in which such sources of error can be appreciable, and knows how to avoid them, minimize them, or correct for them.

Applications A summary of the extensive applications of the NAA method that have been made, and are being made, is also beyond the scope of this short summary. However, it should be noted that NAA has found extensive application in essentially every field of physical science, biological science, and industry—as well as in such diverse fields as art, archaeology, and crime investigation.

NEUTRON DIFFRACTION

An experiment by Laue, Friedrich, and Knipping in 1912 demonstrated that x-rays were a form of electromagnetic radiation, with a wavelength of the same order of magnitude as the distance apart (10^{-8} cm) of atoms in crystals. This meant that beams of x-rays could be diffracted by crystals in a rather similar way to that in which an optical diffraction grating, in which the elements are separated by about 10^{-5} cm, will produce a spectrum for visible light. As a result of Laue's discovery, a technique for studying the underlying structure of solids by "x-ray diffraction" has grown up. For any given solid, the end product of this technique is a specification of the shape and content of the building block, or "unit cell," out of which the solid is built. The content is specified in terms of "electron density," and it follows that the various atoms or ions which make up the molecule of the substance can be identified.

A rather similar, but in some respects a much more powerful, technique has grown up using beams of neutrons instead of x-rays. A neutron is often thought of simply as a particle, with a mass approximately equal to that of a hydrogen atom, but in terms of wave mechanics a beam of neutrons can be regarded as a wave motion. If the neutrons are moving with velocity v, then they can be considered to have a wavelength equal to h/mv, where m is the mass of the neutron and h is Planck's constant. If such a neutron beam is scattered by a solid, it will be distributed in space as if it were radiation of this wavelength. It so happens that for neutrons having energies equivalent to a temperature of a few hundred degrees centigrade, which are readily obtainable from nuclear reactors, the wavelength is about 10^{-8} cm, i.e., 1Å, which, as we have seen above, is about equal to the interatomic distance in solids. It was shown in 1936 that neutrons, then obtainable only from a radium-beryllium source, could indeed by diffracted by solids. However, it is only since nuclear reactors have produced *intense* beams of suitable neutrons that the application of diffraction techniques to the study of solids has proved worthwhile.

Since high-intensity neutron beams are only available at a limited number of research institutions throughout the world, we shall be concerned only with their application to problems which cannot be solved by any other method. In particular, we shall enquire what can be achieved with neutrons which cannot be found out by using a beam of x-rays, and we shall see the answers to this question by making a comparison of the ways in which atoms and solids scatter x-rays and neutrons. *X-rays* are scattered by the outer, extranuclear, electrons in an atom, and it is for this reason that x-ray diffraction studies produce a picture of electron density. It follows that heavy atoms, such as lead and uranium which contain many electrons, will predominate in these pictures and that a one-electron atom, i.e., hydrogen, can be located and detailed with much less accuracy. On the other hand, *neutrons* are scattered not by electrons but by the neucleus of an atom, and the way in which the scattering power increases with the mass of the atom is very far from being a steadily increasing function. The scattering power or, more precisely, what we call the "scattering length" arises from the summation of two quite separate effects. The first of these depends on the size of the nucleus, which has a radius proportional to the cube-root of the atomic weignt, so that this effect does indeed increase with atomic weight, but nevertheless fairly slowly. Superimposed on this scattering, however, is resonance scattering, which depends in a complicated way on the actual structure of the nucleus and on its energy levels. This additional scattering often varies quite considerably from atom to atom, and sometimes from isotope to isotope, as we advance up the periodic table. When we combine together the two effects, and thus assess the resultant scattering by a nucleus, we find that it varies quite irregularly from atom to atom and this is illustrated for elements at the lower end of the periodic system in Fig. 1. It will, however, be noted that there is a relatively small spread of values among these scattering lengths. The mean value for all the nuclei which have so far been measured is 0.62×10^{-12} cm, and practically all elements have values which lie between a half and twice this average. As a result of this we find that most elements are roughly equally "visible" to neutrons, though there are a few very interesting exceptions. The practical outcome of this is that hydrogen atoms can be located quite accurately in whatever environment they are found, and this has meant important advances in our knowledge of the role of hydrogen bonds and molecules of water of crystallization in building up the structures of both inorganic and organic crystals. At the same time, we have often been able to get much improved information on the thermal motion of molecules, particularly in those common cases where hydrogen atoms are found on the outside of molecules and which, therefore, provide a very good index of the molecular movement. The technique of detection becomes much more powerful if we can use *deuterated* material, instead of ordinary hydrogen. Deuterium has a neutron scattering length of 0.65×10^{-12} cm and is, therefore, a "good average" atom, whereas ordinary hydrogen, at 0.38×10^{-12} cm, is somewhat below average. This comparison provides a very good example of a difference between the scattering behavior of two different isotopes of an element, arising from differences in the nuclear structures.

Another important field of chemistry to which neutron diffraction has contributed some useful results is in the study of the compounds of ura-

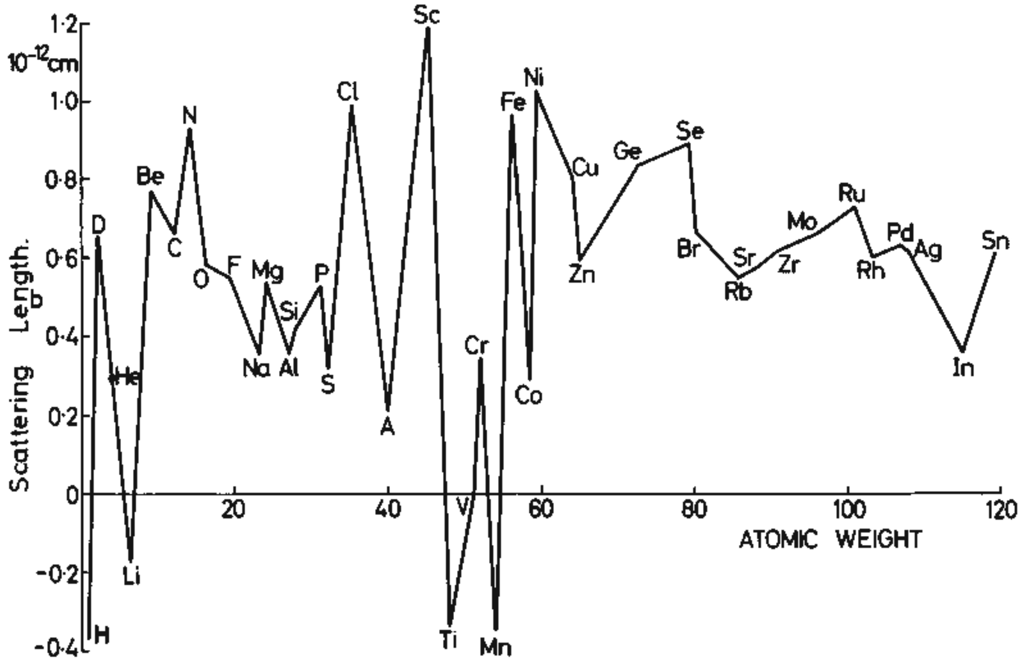

FIG. 1. The variation of the nuclear scattering amplitude of elements for neutrons, shown as a function of atomic weight, in units of 10^{-12} cm.

nium, and post-uranic elements, with nitrogen and oxygen. In the case of x-ray studies, the 92 electrons of a uranium atom completely overshadow the seven and eight of nitrogen and oxygen respectively. For neutrons, however, the value of the scattering length for uranium (0.85×10^{-12} cm) is actually less than the value for nitrogen (0.94×10^{-12} cm) and is only fractionally greater than that of oxygen (0.58×10^{-12} cm).

Of intrinsic interest, and having particular significance in the growing field of study of chemicals of biological importance is the so-called "anomalous scattering" of neutrons by a few elements, such as cadmium and samarium, for which the nuclear scattering amplitude is a complex quantity, with real and imaginary components. This can provide crucial information for determining the structure of large molecules such as insulin if one of these anomalous scatterers can be incorporated in the molecule.

So far we have been considering the process whereby the neutron is scattered by the atomic *nucleus*, and this is a process which occurs for all atoms. There is, however, an additional scattering which takes place for *magnetic* atoms, i.e., for atoms which have a resultant magnetic moment on account of the fact that the atoms contain unpaired electrons. Examples of this are an atom of iron in metallic iron, which appears to contain 2.2 unpaired electrons, and the doubly-charged manganese ion Mn^{++}, which contains 5 unpaired electrons, in manganese salts. Such atoms or ions scatter additional neutrons, making an additional contribution to the scattering length by an amount which is proportional to the magnetic moment. If the magnetic moments in such a material are not arranged in any regular single direction, but point haphazardly as in a *paramagnetic* material, then there will not be any well-defined diffracted beams but there will be a broadly distributed contribution to the scattered background. This contribution may be a little difficult to identify but, nevertheless, the identification can be achieved and the phenomenon can be confirmed. In other magnetic materials, however, all the magnetic moments in a single domain lie parallel to a single direction, and in the particular case of a *ferromagnetic* material they all point *algebraically* in the same sense. In this circumstance the magnetically scattered neutrons contribute specifically to the diffracted beams and the intensity of these is observed to vary with increase of temperature, falling to a minimum at the approach of the Curie temperature, above which no ferromagnetic alignment takes place. In the case of antiferromagnetic materials, in which the moments lie parallel to a single direction but alternately up and down with opposite algebraic sense, the neutron data are extremely informative. In such a material it will be appreciated that, from a *magnetic* point of view, the repeat distance (considering the alternate + and

– moments) is twice the repeat distance which is apparent when only the *chemical* nature of the atoms is considered. This means that extra diffraction spectra will be produced at smaller angles of scattering, corresponding to what would happen if the inter-line spacing of an optical diffraction grating were doubled. The existence of antiferromagnetism can, therefore, be detected very directly by noting the appearance of these extra spectra, particularly if the neutron diffraction pattern is compared either with an x-ray pattern or with a neutron pattern taken at a higher temperature at which the regular magnetic arrangement has broken down. Such a comparison of results obtained at two different temperatures is illustrated in Fig. 2. Results such as these have established the antiferromagnetic structures of a variety of materials and have demonstrated the true nature of ferrimagnetism, as for example in the ferrites in which moments are directed in both positive and negative directions but with a net balance in one direction. Moreover, with further research, it has been demonstrated that these structures are only the simplest examples of a wide range of "magnetic architecture" which it is now possible to draw in detail as a result of study with neutron beams. This later work, devoted to the iron group of transition elements and the elements of the rare earth group, has identified a variety of noncollinear arrangements of magnetic moments such as the spiral spins in MnAu$_2$, the umbrella structure in CrSe, composite structures in holmium and erbium and the complicated structures, not yet fully understood, which occur in metallic chromium.

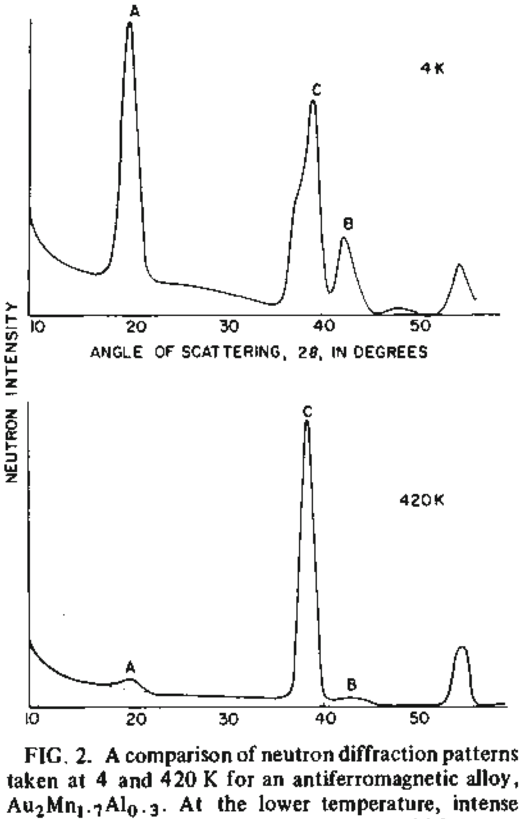

FIG. 2. A comparison of neutron diffraction patterns taken at 4 and 420 K for an antiferromagnetic alloy, Au$_2$Mn$_{1.7}$Al$_{0.3}$. At the lower temperature, intense magnetic lines A and B appear, but at the higher temperature, where very little magnetic order remains, these extra lines have practically disappeared. The patterns also show the composite nature of the nuclear scattering line C at low temperature, which occurs because the crystal symmetry changes from cubic to tetragonal when the magnetic order becomes established.

In our discussion so far, we have implicitly assumed that when a neutron is scattered by an atom it is scattered *elastically* and does not lose any of its energy. This is no more than a first approximation to the truth, because atoms are by no means rigidly fixed but are in vibration about their mean positions because of their possession of thermal energy. A neutron which makes collision with an atom may, therefore, lose or gain a quantity of energy. If we keep in mind the fact that atoms in a solid are not isolated, and that the movement of one atom will invariably affect to some degree the motion of its neighbors, it becomes fruitful to regard the interchange of energy as occurring between the neutron and the lattice vibrations of the solid. Indeed we speak of "phonons" which are the embodiment in *particle* form, from the point of view of wave mechanics, of the quanta of energy among the crystal vibrations. If we could measure accurately the interchanges of energy, then we could learn about, and indeed study in detail, the phonon spectra and the dispersion law for the solid. In fact, for *neutron* scattering, but not for x-rays, such a measurement can be made and this gives a quite unique value to the use of inelastic neutron scattering for studying solids. The particular supremacy of neutrons becomes clear if we consider the actual energies of a neutron and x-ray quantum which possess the same wavelength. We find in fact that the latter is roughly 10^5 times larger. Thus, whereas the energy of a neutron of wavelength 1Å is about equal to that of a quantum of crystal energy, yet the energy of 1Å x-ray is 10^5 times greater. It follows, therefore, that if a neutron gains or loses such a quantum, then its own energy will be greatly changed; for example, it could easily be roughly doubled or halved. On the other hand such an interchange for an x-ray would be quite insignificant and the resulting change of wavelength could not be detected. It is in fact possible, therefore, to measure both momentum and energy changes in neutron-phonon interchanges, and this information leads directly to the details of the dispersion law in the solid. The full power of these methods can be achieved only by detailed and extensive observations with single crystals. Nevertheless a relatively simple technique of neutron spectroscopy is available for powdered and polycrystalline samples, which has rather similar aims to conventional infrared and Raman spectroscopy, but with some distinctive advantages. In particular, any vibrations in which hydrogen atoms are involved are greatly enhanced, and moreover, the selection rules which limit the observation of transitions in optical spectra do not generally apply to the neutron spectra of inelastic scattering.

As the intensity of the beams of neutrons available from research reactors has steadily increased, with roughly a tenfold increase each ten years, these techniques have become progressively more powerful and determinative, leading to a steadily widening view of solids and liquids in the several unique respects which we have discussed. A neutron flux of 1.2×10^{15} cm^{-2} sec^{-1} is now available but it may be difficult to increase the flux beyond this. Further progress is being made using linear accelerators from which pulsed beams of protons generate neutrons by reactions with heavy-element targets. However, it is likely that the limitations in the use of neutron-diffraction techniques will continue to be set by the limited availability of adequate neutron sources. It may fairly be said that many promising applications have never been tested.

NOISE, ACOUSTICAL

Strictly defined, noise is any unwanted sound, whether pleasant or unpleasant. More commonly, however, sounds that are unpleasant and disturbing, or that mask desired sound, are termed noise. Thus, noise, in a general sense, may be thought of as any sonic disturbance. Depending upon the degree of pitch distribution, intensity, and persistance, noise can range from being merely annoying, to hazardous or injurious. In our highly industrialized society, with its rapid growth of energy-producing and converting systems, noise has become a major problem. Some of its harmful effects are interference with mental and skilled work, impairment of sleep, creation of emotional disturbances, damage to hearing and a deterioration of health and well-being. Consequently, the control and reduction of noise has become an important science.

Adequate measuring means are a prime requirement in the scientific control and reduction of noise. Even then, the problem of establishing a true relationship between the subjective and objective properties of noise is difficult because of the many different aspects of human reaction to noise. The first relationship between the subjective and objective measurement of sound is the simplified rule relating *loudness in sones* to the *loudness level in phons*. The loudness scale in sones is proportional to the average person's estimate of the loudness. Also, the loudness level, P, of a given sound, in phons, is numerically equal to the median sound pressure level, p_L, of a free progressive wave at a frequency of 1000 Hz presented to listeners facing the source, which is judged by the listeners to be equally loud. The sound pressure level, p_L, is defined as

$$p_L = 20 \log_{10} \frac{p}{p_0} \text{ (decibels)} \qquad (1)$$

where p is measured sound pressure, in microbars, and $p_0 = 2 \times 10^{-4}$ microbars.

The relation between sones, S, and phons, P, is given by

$$S = 2^{(P-40)/10} \qquad (2)$$

Referring to Eq. (2), a loudness level of 40 phons produces a loudness of one sone, and a loudness level of 80 phons produces a loudness level of sixteen sones, etc.

The simplest means for the measurement of noise is the sound level meter, an instrument comprising a microphone, an amplifier, frequency weighting networks, and an output meter. The characteristics of the frequency weighting networks in the meter are based upon the equal loudness contours of hearing for different levels.

More sophisticated means for measuring noise include octave band and one-third octave band sound analyzers that supply information on the sound level in various frequency ranges. These analyzers are used for research on the reduction of machine noise, transmission and other areas where information on the sound levels in specific frequency bands is required. Narrow-band analyzers may be used to obtain the spectrum of a noise. The sound-pressure spectrum level is that level within a frequency band of 1 Hz. This level is plotted against frequency to obtain the spectrum frequency characteristic of the noise. If the spectrum level of a noise is known, sophisticated means may be used to relate the objective to the subjective qualities of the noise.

As noted earlier, noise abatement has become an important science. For instance intensive research on the quieting of automobiles has been in progress for three decades, with outstanding results; some of the major problems remaining to be solved involve wind- and road-induced noise. Similarly, research has been carried out on the reduction of noise of all types of household appliances employing motors, fans, compressors, pumps, gears, and other moving parts. Another phase of acoustical engineering involves methods for reducing the transmission of sound through the walls, floors, ceiling and partitions in all manner of buildings or enclosure by the use of construction and materials based on fundamental acoustical principles.

The noise in typical environments and noise produced by various sources are given in Table 1.

The masking effect produced by noise reduces the intelligibility of speech. For example, if the speaker and listener are separated by 5 feet, the levels of noise that will barely permit reliable word intelligibility are 51 dB for normal conversation, 57 dB for raised speech, 63 dB for very loud speech, and 69 dB for shouting.

A person subjected to high noise levels for long periods of time may suffer considerable impairment of hearing. The use of ear protectors may provide sufficient insulation under such conditions.

There are now federal regulations on permissible noise in industry as given in the reference below. Examples of the permissible noise exposures are as follows: for 8 hours per day the permissible sound level is 90 dBA, for 4 hours per day 95 dBA, for 1 hour per day 105 dBA, etc.

HARRY F. OLSON

TABLE I. NOISE LEVELS FOR VARIOUS SOURCES AND LOCATIONS[a]

Source or Description of Noise		Noise Level (dB)
Threshold of pain		130
Hammer blows on steel plate	2 ft	114
Riveter	35 ft	97
Factory		78
Busy street traffic		68
Large office		65
Ordinary conversation	3 ft	65
Large store		63
Factory office		63
Medium store		62
Restaurant		60
Residential street		58
Medium office		58
Garage		55
Small store		52
Theatre		42
Hotel		42
Apartment		42
House, large city		40
House, country		30
Average whisper	4 ft	20
Quiet whisper	5 ft	10
Rustle of leaves in gentle breeze		10
Threshold of hearing		0

NUCLEAR INSTRUMENTS

Nuclear instruments are detectors of ionizing radiation and associated apparatus for amplification and analysis of the signals. Nuclear instruments are used in measuring the activity of a radioactive sample and identifying radioisotopes by their characteristic radiations, in nuclear physics experiments with particle accelerators, control of nuclear reactors, dosimetry for radiation safety and cancer radiotherapy, and for medical diagnosis in radiology and nuclear medicine.

Ionizing radiation includes energetic charged particles such as electrons, protons, alpha particles, and fission fragments; uncharged particles (neutrons); and short-wavelength electromagnetic radiation (x-rays and gamma rays). The charged particles ionize directly, while neutrons must first undergo a nuclear reaction that produces charged particles. X-rays and gamma rays interact primarily by the photoelectric effect, Compton scattering, or pair production, which generate secondary electrons. It is interesting that a single nuclear particle or quantum of electromagnetic radiation can be detected, and in many cases its energy and time-of-arrival measured.

Detection depends on interaction of the radiation with the detecting medium, and transfer of energy by ionization and excitation. The signal-generation process may involve generation of many electrons and ions (or holes in semiconductors) and the movement and collection of these charges; emission of light (luminescence); induction of chemical changes, or heating.

Gas ionization detectors include the ionization chamber, proportional counter, and Geiger-Müller (GM) counter. Fig. 1 illustrates some general features of these detectors. The detecting medium is a gas such as argon (or a special mixture for the GM counter), often at or below atmospheric pressure but sometimes at a few atmospheres pressure for increased interaction efficiency. The gas is contained in a vessel fitted with high-quality insulated electrodes in either parallel plate or coaxial cylinder geometry as shown. A grounded guard electrode may be added to intercept leakage current across the insulators. The applied dc potential V_0 may be a few hundred to a couple thousand volts. Normally the gas is an insulator, no current flows, and a steady electric field is established between anode and cathode. When ionizing radiation interacts in the gas or electrode, many low-energy ions and electrons are released in the gas. The energy required to generate an ion-electron pair, W, depends on the gas but is typically around 30 electron volts. Thus a 3-MeV alpha particle would release 100,000 ions and electrons. These charges drift to the oppositely charged electrode under the

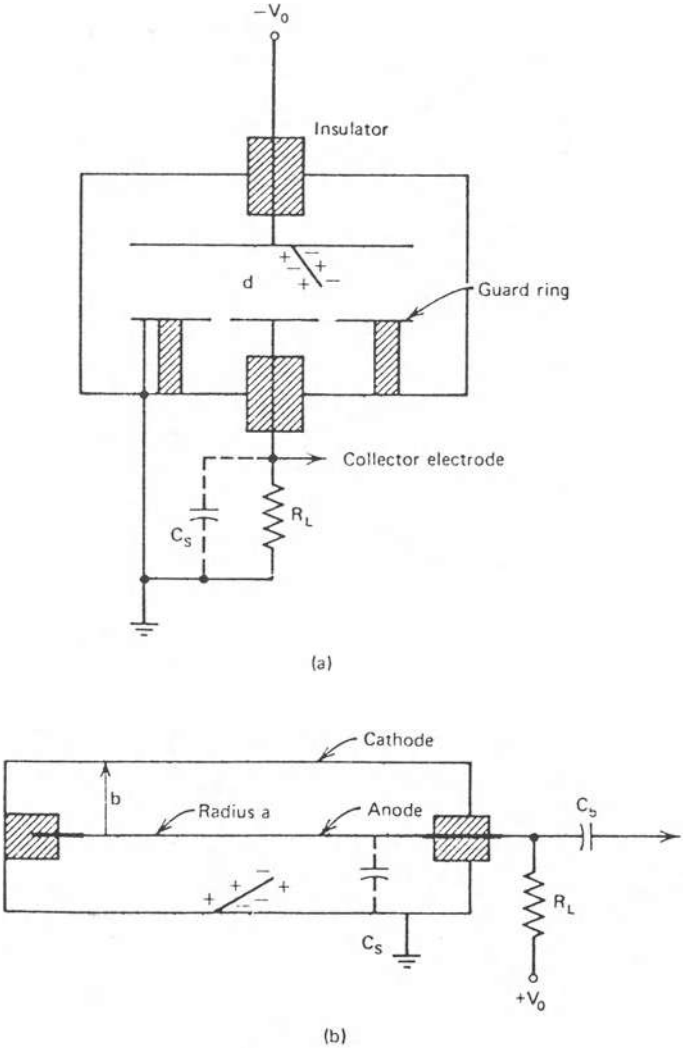

FIG. 1. General features of gas-ionization detectors: (a) parallel-plate ionization chamber with guard ring to define field and intercept leakage current; (b) cylindrical proportional or GM counter. (From Profio, A. Edward, "Experimental Reactor Physics," New York, Wiley, 1976, p. 244; reproduced in Profio, A. E., "Radiation Shielding and Dosimetry," New York, Wiley, 1979, p. 266.)

influence of the electric field. This motion constitutes a current which can be amplified, or the voltage drop across the load resistor R_L can be amplified and measured. Eventually (microseconds for electrons, milliseconds for ions) the charges are collected on the stray capacitance C_s, until drained off through R_L.

If the time constant R_LC_s is small compared to the drift time of the electron or ion, that component of the signal voltage will not reach full amplitude. Furthermore, a detailed analysis shows that the contribution of each component depends on the distance from ionization point to electrode. Only if both electrons and ions are collected does the charge and corresponding voltage reflect the energy deposited by ionization in the gas. For simple counting without energy analysis, only the fast (electron) component is needed. If the time constant is long compared to the mean interval between ionizing nuclear particles, the detector will not resolve individual pulses of charge, but the current will indicate the mean rate of detection of the nuclear radiation. If the time constant is very long, the charge is integrated and read out at the end of the irradiation. The pulse ionization chamber has been replaced by the semiconductor detector except where radiation damage is a consideration. The mean-level and integrating ionization chambers are commonly used for radiation monitoring and for reactor control. The detector is made sensitive to neutrons by coating the wall with boron or boron-10, or a fissionable material such as uranium-235, or by filling the chamber with boron trifluoride gas.

The proportional counter and GM counter differ from the ionization chamber in that the charge is increased by gas multiplication. The amount of gas multiplication is a function of $\mathcal{E}/p$, the ratio of the electric field strength to the gas pressure. The ionization chamber operates at low $\mathcal{E}/p$, where $\mathcal{E}$ is large enough to separate the ions and electrons before they can recombine, but there is no gas multiplication. Thus the ionization chamber operates in region 2 in Fig. 2, which plots the number of charges collected as a function of applied voltage, for

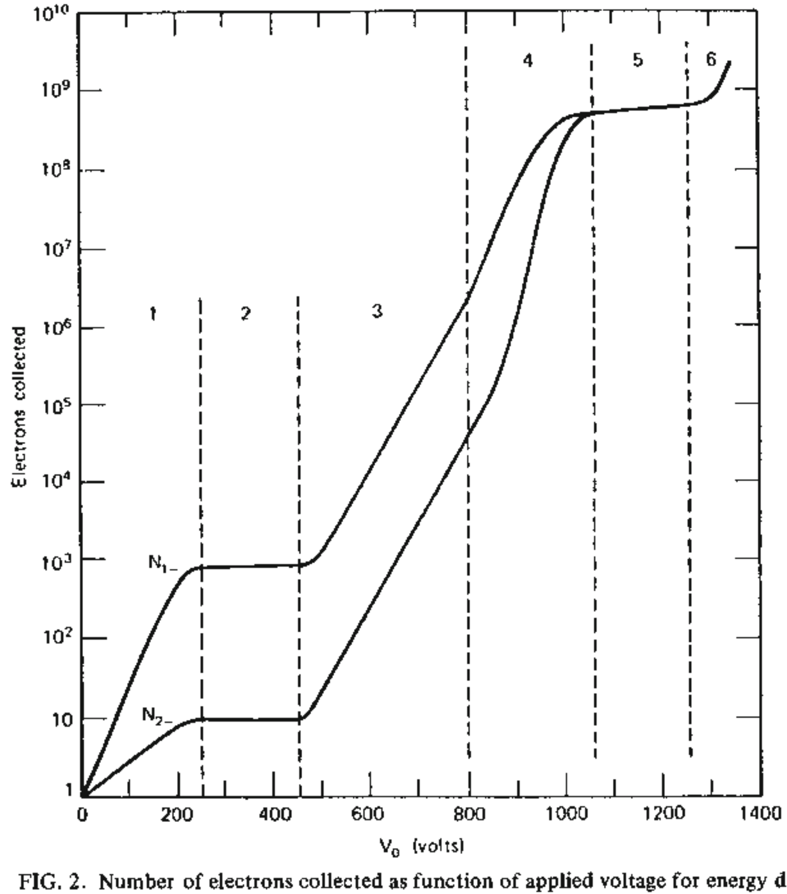

FIG. 2. Number of electrons collected as function of applied voltage for energy depositions $E_1 = WN_1$ and $E_2 = WN_2$. Region 2 corresponds to ionization chamber, region 3 to proportional counter, region 5 to GM counter. (From Profio, A. E., "Radiation Shielding and Dosimetry," New York, Wiley, 1979, p. 267.)

two different amounts of primary ionization, $N_1 = 10^3$ and $N_2 = 10$. At medium $\mathcal{E}/p$ and voltage, the electrons are accelerated sufficiently between collisions with neutral gas atoms to release more electrons on impact. These electrons can in turn release more electrons, for an overall typical gain or multiplication factor M of 10–1000. If M is not too large, gain is independent of the initial ionization, hence the output signal charge is proportional to the initial ionization and the detector can be used for energy analysis. This corresponds to region 3 in Fig. 2, the region of the proportional counter. (Actually a proportional counter may also have a different gas filling, to stabilize the gas multiplication.) In order to achieve the required $\mathcal{E}/p$ at reasonable applied voltage, it is standard to make the anode a small-diameter wire, because $\mathcal{E}$ is inversely proportional to radius in cylindrical geometry. Most of the multiplication occurs very close to the anode and collecting the electron component alone is sufficient. The low-noise gain afforded by gas multiplication makes the proportional counter suitable for detection of low energy x-rays and electrons. Gain is usually not needed for alpha particles or fission fragments, and detection efficiency for gamma rays is low although efficiencies of a few percent can be obtained with walls of a dense and high atomic number material such as bismuth. Neutrons can be detected by filling the tube with BF_3 or helium-3.

GM counters operate at high $\mathcal{E}/p$ and the gas multiplication may be 10^6 or more, corresponding to region 5 of Fig. 2. Multiple gas discharge avalanches are created and propagated by ultraviolet photons as well as electrons. The Geiger discharge can be initiated by a single primary ionization, and the amplitude of the resulting pulse is no longer proportional to the initial ionization by a nuclear particle: all pulses have the same amplitude, at a given applied voltage. In order to terminate or "quench" the discharge, the GM tube is filled with a mixture of gases, including either an organic quencher such as ethyl alcohol or ethyl formate, or a halogen (chlorine or bromine). Quenchers suppress multiple discharges otherwise started by positive ions hitting the cathode, by absorbing energy in dissociation of the molecule. An organic quencher is consumed in some 10^9 counts, but halogens are reconstituted and the tube lifetime is much longer. Because of the hundreds of microseconds for the ions to be collected and the discharge terminated, the GM counter has a correspondingly long deadtime and is limited to rather low count rates (hundreds of counts per second or less). With its large internal gain, electronics can be simple and cheap, and the GM counter is still used for simple counting of beta particles, and for monitoring gamma rays fields at low detection efficiency.

A semiconductor detector is similar to a pulse ionization chamber with the gas replaced by a semiconductor, usually silicon or germanium. (Newer materials such as cadmium telluride and mercuric iodide are under development.) A true solid insulator cannot be used, because the charges (electrons and holes) produced by ionization would not move in the applied electric field and generate a signal. On the other hand, the device must have high resistivity or the noise would be too great from the current of thermally released electrons. These requirements have been met by: (a) doped silicon operated as a reverse-biased *p-n* junction diode at room temperature; (b) *p*-type silicion or germanium compensated by drifting an electron donor, lithium, and operated at low temperature as a reverse-biased *p-i-n* junction diode; (c) ultra-high-purity germanium operated at low temperature as a reverse-biased *p-i-n* diode; and (d) mercuric iodide and other room temperature diodes. Semiconductor detectors generally have faster response times than gas detectors (order of tens of nanoseconds), and higher efficiency because of their density (2.33 g/cm^3 for Si, 5.33 g/cm^3 for Ge). Their biggest advantage over other types of detector is the low energy required per hole-electron pair (3.6 eV for Si, 2.96 eV for Ge), resulting in a larger signal amplitude and better energy resolution because of smaller statistical fluctuations in the charge collected. Their main disadvantages are sensitivity to radiation damage from heavy charged particles or fast neutrons, the relatively small sensitive volumes available, and cost in the larger sizes.

A common detector for alpha particles and other charged particles is the silicon surface barrier detector shown in Fig. 3(c). This is a type of *p-n* junction diode, where the junction occurs between the body of *n*-type (electron-donor-doped) silicon and a very thin layer of *p*-type (electron-acceptor-doped) material produced by controlled oxidation of the surface. The surface is protected by a thin evaporated layer of gold, but even so the surface barrier detector is sensitive to light and must be operated in the dark. When the diode is reverse biased (positive polarity to the *n*-type silicon contact), by a hundred volts or so, the thermally released charge carriers are swept out and a "depletion" region is left which can sustain a large electric field. The depletion region corresponds to the sensitive volume of the detector; it may be on the order of one cm^2 in area and a few hundred micrometers thick. This thickness is sufficient to stop alpha particles of a few MeV, so their energy can be measured. A small correction is needed for the loss of energy in the "window" or dead layer of gold and *p*-type material. Similar detectors are made with ion-implanted or diffused junctions. The depletion region can be made to extend entirely through a detector 1–2 mm thick, but this is still too small for stopping energetic electrons and efficiency for gamma rays is poor.

The maximum thickness of *p-n* junction depletion regions is limited by voltage breakdown. The technique of lithium drifting has been developed to make a compensated or quasi-intrinsic resistivity region up to some 10 mm thick. One starts by thermally diffusing some lithium into the surface of a crystal of rather pure but *p*-type silicon or germanium. The *p-n* junction thus formed is reverse biased and the small lithium ions caused to drift into the bulk of the crystal, at elevated temperature, by the applied electric field. After some days or weeks, nearly exact compensation is achieved automatically because the space charge remaining with imperfect compensation is sufficient to drive the lithium ions until the space charge is canceled. Figure 3(a) shows the planar geometry typical of a lithium-drifted silicon diode, designated Si(Li), where the compensated region may be a few mm thick. Such detectors are suitable for detection and spectroscopy of electrons, where the low atomic number of silicon minimizes backscattering. Si(Li) detectors are also used for low energy x-ray and gamma ray spectroscopy (below 30 keV). Figure 3(b) illustrates the coaxial design typical of lithium-drifted germanium, Ge(Li), detectors where the compensated region may have a volume of 30–150 cm^3. The volume, density, moderately high atomic number of germanium (Z = 32), and most of all the excellent energy resolution (about 0.1%) of germanium detectors have made them the instrument of choice for gamma ray spectroscopy, although efficiency is less than can be obtained with the sodium iodide scintillation detector. The Si(Li) and Ge(Li) detectors are always operated at low temperature, usually at liquid nitrogen temperature (77 K) to reduce thermal noise. A Si(Li) detector is usu-

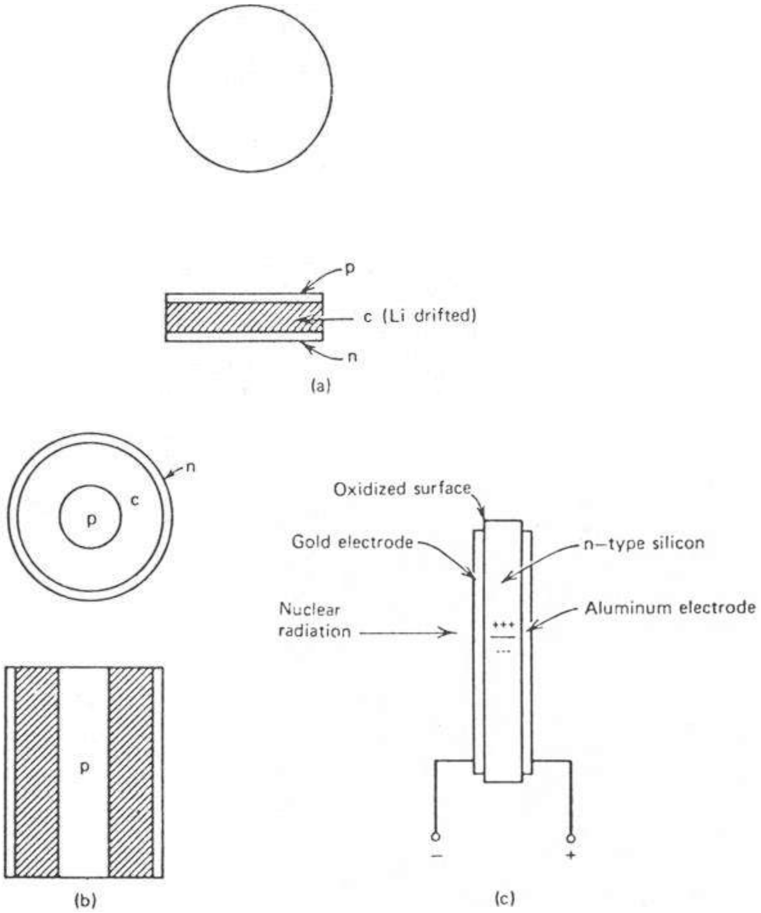

FIG. 3. Types of semiconductor detectors; (a) planar lithium-drifted; (b) coaxial cylindrical lithium-drifted; (c) surface barrier. (From Profio, A. Edward, "Experimental Reactor Physics," New York, Wiley, 1976, p. 220; reproduced in Profio, A. E., "Radiation Shielding and Dosimetry," New York, Wiley, 1979, p. 261.)

ally stored at liquid nitrogen temperature, too, but can survive an occasional warmup. The Ge(Li) detector must always be stored and used at liquid nitrogen temperature to avoid redistribution of the lithium. One warmup is sufficient to ruin a Ge(Li) detector, and while it can be redrifted, energy resolution is likely to be worse.

Figure 4 illustrates the electrical properties of a lithium-drifted *p-i-n* junction detector, as influenced by the Li concentration and starting material. As shown, after compensation there is no net space charge density within the so-called intrinsic region, but there is a potential gradient and a uniform electric field (in planar geometry) which moves and collects the electrons and holes released in this region by ionizing radiation.

The ultra-high-purity germanium detector is very expensive, but has the advantage that there is no lithium to redistribute and it can be allowed to warm up occasionally. It is still usually stored at liquid nitrogen temperature to minimize contamination of the surface by vapors, and is operated at low temperature to minimize noise. The crystal is housed in a vacuum cryostat, on a good heat conductor or "cold finger" dipping into a reservoir of liquid nitrogen in a dewar. Weekly replenishment is usually required even with a 30-liter dewar. The trouble and expense of liquid nitrogen and the bulky dewar and cryostat has led to interest in materials such as cadmium telluride and mercuric iodide, which have large enough band gaps to allow operation at room temperature. Density and their high-atomic-number constituents make them candidates for x-ray and gamma ray spectroscopy. However, trapping centers and crystal growing difficulties have so far limited the detectors to about 1 mm thickness if good energy resolution is desired. With careful atten-

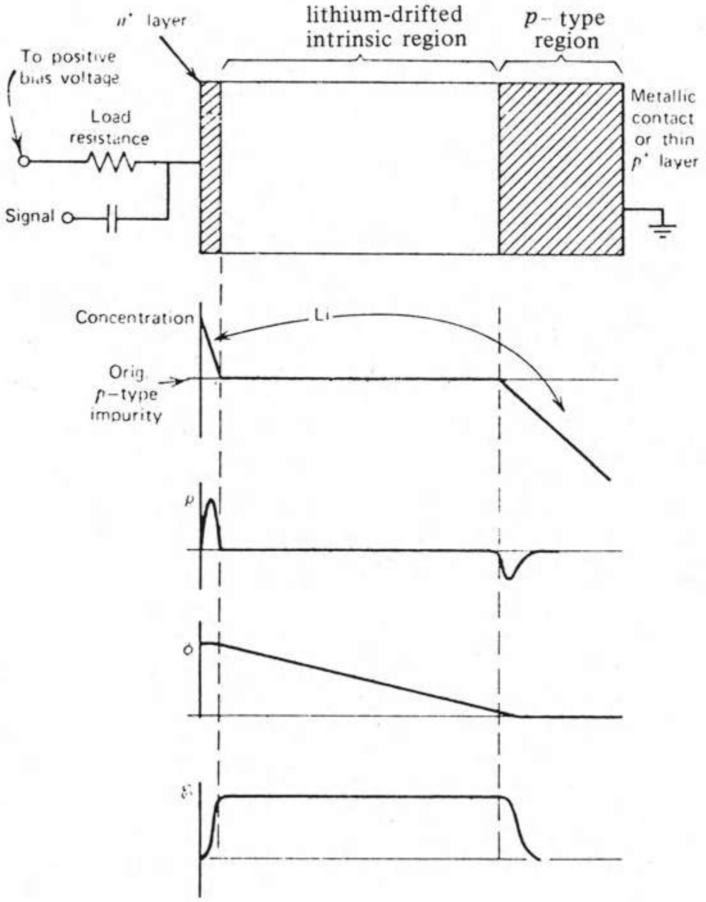

FIG. 4. Basic configuration of a lithium-drifted *p-i-n* junction detector. Also shown are the corresponding profiles for impurity concentration, charge density ρ, electric potential φ, and electric field $\&$. (From Knoll, G. F., "Radiation Detection and Measurement," New York, Wiley, 1979, p. 417.)

tion to minimizing noise sources, resolution may approach that of the Si and Ge detectors.

A scintillation detector consists of a transparent substance that fluoresces under ionization and excitation by a charged particle, optically coupled to a photomultiplier tube that detects and amplifies the weak flash of light, as shown in Fig. 5. The photomultiplier is shielded from outside light and from stray magnetic fields that could deflect the electrons in the multiplier. The scintillator is usually coated with a white reflective material and contained in a light-tight can except for the window in contact with the photomultiplier.

Table 1 summarizes properties of commonly used scintillators. Organic crystals such as anthracene may be used for detection of electrons, but are fragile and available only in thin sections. Organic liquid scintillators are used for detection and spectroscopy of fast neutrons by means of the recoil protons generated by elastic scattering on hydrogen, and for counting low-energy beta particles (e.g., from tritium and carbon-14) when the radioactive material is dissolved in the scintillator. NE213 is a proprietary formulation which is useful for separation of gamma ray and neutron induced counts by pulse shape discrimination (PSD). Plastic scintillators are made of scintillating chemicals in a solid solution with polyvinyltoluene (PVT) or other polymer. Because of their low atomic number and density, organic scintillators are not very good for gamma rays.

The inorganic crystal scintillators, especially sodium iodide doped with thallium, NaI(Tl), are well suited for detection and spectroscopy of gamma rays because of their high effective atomic number and density. A drawback to NaI(Tl) is that it is brittle and hygroscopic, and must be protected from shock and moisture. Fluorescence decay time constant is longer than for the organic scintillators (significant in fast timing, coincidence, or high count rate applications) but light output is better. Until the advent of the germanium semiconductor detector, NaI(Tl) was widely used for gamma ray spec-

TABLE 1. PROPERTIES OF SCINTILLATORS.

Type	Scintillator, Composition	Density (g/cm^3)	Relative Output (electron)	Fluor. Decay (ns)	Remarks
Organic crystal	anthracene, $C_{14}H_{10}$	1.25	1.00	30	68 eV/photon
Organic liquid	NE213, $CH_{1.21}$	0.88	0.78	4, 100	PSD
Plastic	NE102, $CH_{1.10}$	1.03	0.65	4	PVT base
Inorganic	NaI + 0.1% Tl	3.67	2.10	230	hygroscopic
Crystal	$Bi_4Ge_3O_{12}$	7.13	0.17	300	High Z
	ZnS + 0.01% Ag	4.09	3.00	200	polycrystal
Glass	NE908, glass + 8% Li	2.67	0.20	5, 75	0.1% Ce_2O_3
Gas	xenon (1 atm)	0.006	1.5	2	UV emission

troscopy, even though its energy resolution is not very good (typically 8% at 662 keV). Some 32 eV is required to generate a light photon, but only about 10% of the photons generate a usable electron in the photomultiplier, and with other inefficiencies, the energy per electron may approach 1000 eV. Bismuth germanate gives much less light than NaI(Tl), but because of its high density and atomic number, is even more efficient in detecting gamma rays in a small volume.

Silver-activated zinc sulfide, ZnS(Ag), is useful for counting alpha particles but is available only in polycrystalline form and light scattering limits its use to thin layers. The cerium-activated, lithium-loaded silicate glass scintillators such as the proprietary NE908 are used for slow neutron detection, but have the drawback of also being sensitive to gamma rays. The xenon gas scintillator has a fast fluorescence decay time, but emits in the ultraviolet requiring a special photomultiplier tube, and being a gas is not very efficient in stopping radiation.

The photomultiplier is a vacuum tube, usually with a thin, semitransparent layer deposited on the inside of a flat glass faceplate or window at one end. The photocathode itself may be oxidized cesium antimonide, or a multialkali (K-Cs-Sb). The low-energy photoelectrons released from the cathode are collected, accelerated, and focused on the first electrode (dynode) of the electron multiplier by an applied electric field. The dynode is treated so that two or more electrons are generated per incident electron, by secondary emission. The electrons from the first dynode are accelerated and focused on the second dynode, and so forth for perhaps 9 to 14 dynode stages. Current amplification can easily exceed 10^5. The required 100 volts or so per stage is usually supplied from a resistive voltage divider connected to a high voltage supply. The supply must be very well regulated because gain is very sensitive to voltage. The photomultiplier is selected for size of the scintillator, spectral response (e.g., to match the blue emission of NaI(Tl)), gain required hence number of stages, gain stability for spectroscopy, and pulse risetime for fast timing applications.

Another type of detector emitting light is the thermoluminescent dosimeter (TLD). Certain materials such as LiF or CaF_2 doped with Mn, trap electrons and holes generated by ionization. Upon subsequent warming the electrons and holes recombine with emission of light, which is detected by a photomultiplier tube. TLD's are widely used for personnel dose monitoring, although the materials do not respond exactly as tissue does, especially at low energies.

X-ray film and other silver halide emulsions are used for imaging and for personnel dose monitoring. The ionizing radiation activates centers in the grains, much as a latent image is formed by light. Upon later chemical development, the halide grains are reduced to metallic silver, darkening the film. The process may be considered as chemical amplification. The darkening must be calibrated against known doses measured by another instrument, and the response at low energies may be much greater than in tissue. Other chemical dosimeters exist, but are limited to high dose applications. Radiation also causes heating, which can be measured by temperature rise in a calorimeter, but heating is seldom used for radiation dosimetry because more sensitive instruments are available.

Absorbed dose, defined as energy absorbed by ionization per unit mass of material, is normally measured by an integrating or mean-level type of cylindrical ionization chamber. The walls are made of an electrically conducting plastic whose elemental composition is close to that of average soft tissue ($C_5H_{40}O_{18}N$), and the wall is made slightly thicker than the range of the most energetic electrons involved. The gas filling also has soft tissue elemental composition, and the gas pressure and electrode spacing are chosen so that the dimensions are small compared to the range of the electrons. Under these conditions, the energy absorbed per kg of wall material (and tissue) is equal to the energy absorbed per kg of gas. The latter is obtained from the measured charge, the known energy per ionization, and the mass of the gas. The special units of absorbed dose are the gray (1 Gy = 1.0 J/kg) and the rad (1 rad = 0.01 J/kg). Depending on dose rate and mass of gas, the current may be 10^{-12} A or less, and a low-noise, high-gain, high-input-impedance dc amplifier (electrometer) is required to drive a meter.

Neutrons, protons and alpha particles are more damaging per unit of absorbed dose than electrons, x-rays and gamma rays. This is taken into account by defining the dose equivalent (measured in sievert or rem) as the absorbed dose times a dimensionless quality factor that varies from 1 (for gamma rays) to 10 (for fast neutrons). The dose equivalent in a mixed radiation field can be derived from a special ionization chamber that gives information on the microscopic distribution of ionizing events along the particle path, the so called LET (linear energy transfer). Particles with higher LET have larger quality factors associated with them.

Reactor instrumentation includes several neutron-sensitive ionization chambers and associated dc amplifiers, which can be calibrated in terms of reactor power. In addition to linear, range-switched amplifiers, it is convenient to have logarithmic amplifiers and meters displaying the power over many decades during reactor startup. Also, the output of the logarithmic amplifier can be differentiated to give a signal inversely proportional to the time constant (called reactor period) of the exponential increase in power. Electronic trips are provided to shutdown the reactor, by inserting control rods, if the reactor power gets too high or the

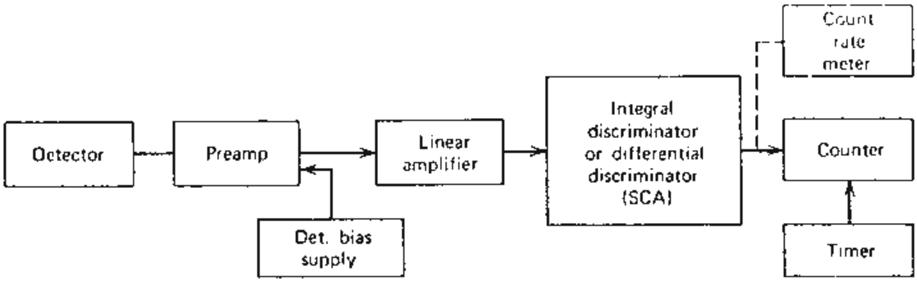

FIG. 6. Elements of a typical signal chain for pulse counting. (From Knoll, G. F. "Radiation Detection and Measurement," New York, Wiley, 1979, p. 660.)

reactor period becomes too short (rapid increase in power).

Semiconductor and scintillation detectors and the proportional counter are operated as pulse instruments. Figure 6 is a block diagram of a typical pulse counting system. The small signal pulses from the detector are amplified in the preamplifier, transmitted by coaxial cable to the main linear amplifier for further amplification and pulse shaping, and then to the integral discriminator or single channel pulse amplitude analyzer (SCA). The integral discriminator generates an output pulse only if the input pulse exceeds a set amplitude, thus rejecting noise and low-amplitude background. An SCA also has an upper-level discriminator and anticoincidence circuit, such that pulse amplitude must lie between the discriminator settings for an output pulse to be generated. The number of pulses in a given timed interval is accumulated in an electronic counter (also called a scaler), or the average count rate derived and displayed by a count rate meter.

Although pulse amplitude hence energy analysis can be performed by sequentially stepping the lower discriminator of an SCA, it is preferable to use a multichannel analyzer (MCA) instead. An MCA consists of an analog-to-digital converter for randomly arriving pulses, control unit, memory, oscilloscope display of the spectrum, and usually a printer. The ADC digitizes the pulse amplitude and the control unit adds a count to the appropriate address or channel in memory, usually for 1024 channels or 512 channels.

NUCLEAR RADIATION

Nuclear radiation results from the transitions of atomic nuclei. The two chief types of transition in natural radioactivity are those in which the number of constituent particles of a given nucleus (nuclide) is changed by the emission of one or more particles such as an alpha or beta particle and those in which there is a rearrangement of the particles of a given nuclide such that the nuclide passes to a lower energy state with the emission of high frequency electomagnetic radiation called gamma rays.

The study of nuclear radiation together with the results of high energy bombardment of nuclei has become our most important source of information about the structure of atomic nuclei and the fundamental nature of matter. And such studies now extend to the internal processes of our sun and the stars as well as our more immediate problems concerned with emission from nuclear reactors and nuclear weaponry.

The chief sources of nuclear radiation are; (1) naturally radioactive substances; (2) those substances in which radioactivity has been induced; (3) emissions resulting from collisions with cosmic rays or by particles from high energy accelerators; (4) nuclear reactors and weaponry; and (5) nuclear processes in the sun and stars. There is even a small amount of radiation from spontaneous fission of uranium in the earth.

In 1896 Henri Becquerel found that a new and penetrating type of radiation from uranium had darkened a photographic plate and he called the new phenomenon *radioactivity*. His associates Marie Curie and husband Pierre after painstaking search found other far more intensely radioactive substances including radium and polonium. Soon various radioactive substances were arranged in series showing how one type would decay into a different but related type.

Early studies of rays from different substances revealed that an alpha (α) particle was the doubly charged nucleus of a helium atom; beta (β) particles were identified as the then newly discovered negative electrons; and gamma (γ) rays were found to be similar to x-rays but could be even more penetrating. Alpha rays were emitted with speeds up to $\frac{1}{15}$ the speed, c, of light and had the unusual property of producing scintillations on a fluorescent screen by which they could be counted. Beta rays could have a range of speeds up to a maximum speed of 0.96c, a hitherto almost unbelievable speed for any particle. Beta and gamma rays could be readily detected by the ionization they produce in a gas. The rest-masses in kilograms of the two particles and their energy equivalents in million of electron volts (MeV) are

$$M_0(\text{alpha particle}) = 6.645 \times 10^{-27}\text{kg} = 3727.2 \text{ MeV}$$

$$m_0(\text{beta particle}) = 9.109 \times 10^{-31}\text{kg} = 0.511 \text{ MeV}$$

The three types of rays could be readily separated by means of a magnetic field (Fig. 1). In crossing the field the alpha rays are deflected in a direction that indicates they carry a positive charge. The beta rays are deflected in the opposite direction and the gamma rays are not deflected at all as they have no charge and are of the nature of light waves.

The penetrating power of any nuclear radiation depends on the nature of the ray, the energy of its emission and the nature of the absorption process. In general it may be said that alpha rays usually are stopped by a few sheets of paper and beta rays by a few millimeters of aluminum.

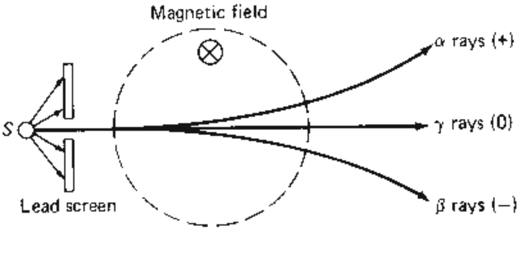

FIG. 1. Separation of alpha (α), beta (β) and gamma (γ) rays from a radioactive source (S) by a magnetic field directed into the paper. This indicates alpha rays possess a positive electric charge, beta rays a negative charge, and that gamma rays are uncharged.

Alpha and beta rays, because of their particle character, have a more sharply defined range than gamma rays, and a significant fraction of the gamma radiation may pass through a number of centimeters of metal shield. This is because particles lose speed and kinetic energy in both ionizing and non-ionizing collisions with other particles, whereas a gamma-ray-photon always travels at the same speed, and the beam of photons is usually weakened by some process such as scattering or absorption of photons. And the method of magnetic separation and the use of various absorbing materials are still basic in our far more complicated experimental procedures today.

An alpha ray can produce between 20,000 and 70,000 ion pairs per centimeter of path in a gas depending on the initial energy of the ray, maximum ionization being reached near the end of the path. A beta ray on the other hand may only produce 200 ion pairs or less per centimeter. Thus such rays lose energy rapidly in passing through a gas, and rays of a particular energy have a rather sharply defined range (see IONIZATION).

The range of alpha particles in air at 76 cm mercury pressure (15°C) varies from 2.7 cm for alpha particles from uranium to 8.62 cm for alpha particles from thorium C' (Po^{212}). The former are emitted with energies of 4.2 MeV while the latter, the most energetic of any from a naturally radioactive substance, are emitted with energies of 8.6 MeV.

How these radiations could be emitted from an atom was unknown until 1911, when Rutherford, in his famous alpha-ray scattering experiment, deduced that nearly all of the mass of an atom resides in a tiny, positively charged central region called the nucleus having a diameter in meters (m) of the order of 10^{-14} m whereas the atom itself with its encircling electrons was of the order of 10^{-10} m. Newton's idea that atoms are solid little bits of mass that last for ever was overthrown and the study of the nucleus as a complex, highly organized system began.

In 1929, Rosenblum discovered the fine structure of alpha rays. That is, alpha rays from a single type of nuclide may not all have exactly the same energy and range but often consist of two or more groups with slightly different but sharply defined ranges and consequently different initial energies. This led to the ultimate recognition of the existence of different energy levels in the nucleus.

Now the origin of gamma radiation could be explained. When an alpha particle is emitted as for instance from a radium nucleus (Ra 88) it loses four units of mass and two units of charge and forms a new nucleus in this instance emanation (Em 86). If the alpha particle does not possess enough energy to leave the product nucleus in its lowest energy state (ground state) then it can return to the ground state by emitting a gamma ray (Fig. 2) of the required energy.

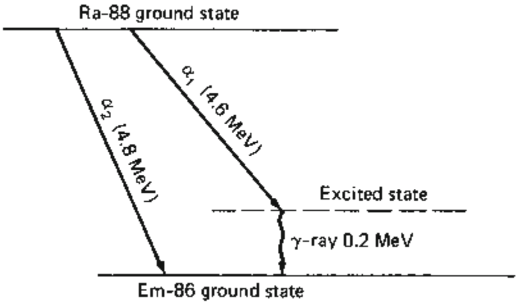

FIG. 2. Energy levels showing origin of gamma (γ) rays from radium (Ra-88) when emission of alpha ray (α_1) leaves product nucleus in an excited energy state above its ground state. It then returns to the ground state by emission of a gamma ray. By comparison, emission of α_2 carries off enough energy for the nucleus to go directly to the ground state.

The discovery of the neutron by Chadwick in 1932 made it possible to describe all atomic nuclides as simple groupings of protons and neutrons. The number of protons would be the same as the atomic number in order to give the nuclide its required charge, and the number of neutrons would be those required to give the nuclide its characteristic mass. Heisenberg then suggested that the proton and neutron be called *nucleons* and that they be considered different energy states of the same particle such that in certain nuclear changes each could decay into the other.

Since there are not beta particles (electrons) as such in the nucleus and their existence in so small a volume would not be in accord with quantum mechanics, it was assumed that the beta particle was produced at the moment of emission by conversion of a neutron to a proton. Useful as the proton-neutron picture of the nucleus was, it became increasingly evident that the nucleus was not a single system and that the nuclear forces and modes of excitation must be investigated. Neither protons nor neutrons are ever emitted by a radioactive nuclide, but certain nuclides emit alpha particles and each alpha particle consists of two protons and two neutrons closely bound together. It must be assumed that only such a grouping can gain enough energy to escape from an unstable type of nuclide.

With the discovery of what has been called "artificial" or induced radioactivity by Irene Curie-Joliot and her husband Frederick Joliot in 1933, it was found that positive electron (positron) emission may occur in nuclides whose instability results from the nucleus possessing "too much charge for its mass." This is, of course, only another form of beta emission represented as β^+, whereas ordinary electron emission is represented as β^-. Since the positron is the antiparticle of the electron it was evident that other antiparticles could also be involved in nuclear processes.

When induced radioactivity was discovered, only some forty naturally radioactive substances were known and the only known types of nuclear radiation were the alpha (α), beta (β^-), and gamma (γ) rays. To these now had to be added the positron (β^+).

In 1933 Pauli suggested that still another new particle of zero charge might be required to explain how a neutron might decay to a proton in the nucleus. The following year Fermi incorporated this idea into his theory of beta emission and assumed that a *little neutral particle* which he called the *neutrino* (ν) is also emitted. Since the beta particle is an electron and the electron had been found to spin on its axis like a top the new particle seemed required to possess spin in order not to violate conservation of angular momentum when a beta particle is emitted.

The new particle also seemed necessary to prevent violation of the law of conservation of energy. Unlike the more sharply defined energies of alpha particles the beta rays from a single type of nuclide have a wide distribution of ranges and energies, the distribution being approximately continuous up to a certain maximum or "end-point" characteristic of a particular type of nuclide. It was assumed that whenever a beta particle carried off less than its characteristic end-point energy the missing energy must also be carried off by the neutrino. This gave the neutrino the properties of spin and energy but since at that time there appeared to be no measurable loss of mass it was assumed that the new particle had zero mass along with zero charge.

The great difficulty in detecting a particle so elusive and frustrating that most would pass through the earth without hitting anything delayed experimental confirmation until 1956 when Reines, Cowan, and co-workers at Los Alamos with an intense beam of neutrinos (later found to be antineutrinos), ($\bar{\nu}$) finally achieved success. The only difference between the neutrino and antineutrino is the direction of spin.

In the meantime the discovery of two new nuclear particles revealed further complexities in nuclear processes. They were called *mesons* because their masses were intermediate between the masses of the electron and the proton. The first one, the μ meson or *muon* (μ) was discovered in cloud-chamber tracks by Anderson and Neddermeyer in 1937 while studying effects of cosmic rays. The new particle was found to have a mass 137 times that of an electron and it could have either a positive (μ^+) or negative (μ^-) electronic charge. After the war a closely related but still more massive particle the pi meson or *pion* (π) was detected by the tracks it left in nuclear emulsion plates sent aloft in balloons. It had a mass 273 times that of the electron and could have either a positive or negative charge, and could even be neutral, as found later. Both of these new particles are unstable and decay with a mean life of 2.2 × 10^{-6} sec for the muon and 2.5 × 10^{-8} sec for the charged pion, the neutral pion being somewhat shorter lived. Since these particles are found in the atmosphere as the result of collision by incoming cosmic rays they may be classed as secondary nuclear radiation. They can now be readily produced by high energy bombardment in the laboratory along with many other new particles.

The close relationship between the electron, the muon, and the pion is indicated by the fact that pions decay in several ways to form muons as follows. The positively charged pion π^+ can decay to a positive muon plus a neutrino:

$$\pi^+ \rightarrow \mu^+ + \nu$$

and the negative pion can decay to a negative muon plus an antineutrino:

$$\pi^- \rightarrow \mu^- + \bar{\nu}.$$

The muon of either charge in turn decays to an electron of the same charge plus a neutrino (ν) and an antineutrino ($\bar{\nu}$):

$$\mu^{\pm} \rightarrow e^{\pm} + \nu + \bar{\nu}.$$

In 1962, although the two neutrinos seemed to be the same they were found to not be quite identical, and this presented a problem. They seem to "remember" their parenthood and react only with their respective closely related particles. In order to distinguish them we call one the *electron-neutrino*, represented by ν_e, and the other we call the *muon-neutrino*, represented by ν_μ. A third neutrino, the tau-neutrino (ν_τ) is now recognized. Thus, with their antiparticles, we add six new particles to the list of basic nuclear radiation particles. These particles can now readily be detected in collision processes or in beams from nuclear reactors.

With the increasing complexity of nuclear structure had come recognition that two new forces exist that operate only in the confines of the nucleus. They are called simply the *weak force* and the *strong force* and are required to explain particle emission. These are now added to the well-known electromagnetic force and the gravitational force of classical physics. The strong force acts to bind nucleons together; it must be charge-independent because it binds neutrons to neutrons as well as to protons. The emission of light-weight particles such as the beta particle and the muon (now classed along with neutrinos as *leptons*), is now recognized as connected with the weak force. Those heavy particles such as neutrons and protons that are bound by the strong force are now classed as *hadrons*. And the emission of such particles either spontaneously or by bombardment is therefore concerned with overcoming these basic nuclear forces.

Since hadrons are believed to be composed of quarks, and since atoms in general can be described as combinations of leptons and hadrons, then according to one theory, leptons and quarks may be the ultimate particles from which all matter is made. Quarks are not radiated, being bound too strongly to escape (see QUARKS).

When the muon was discovered it was thought to be the particle predicted by Yukawa that would hold nucleons together by means of an *exchange force* derived from the newly developed theory of quantum electrodynamics. But muons failed to interact sufficiently with nuclei. Than when the pion was discovered it appeared to be the desired particle because it did interact. However, matters soon became more complicated with the discovery of *K* mesons, found by Rochester and Butler in 1947 as secondary nuclear radiation in cosmic ray experiments. The masses of *K* particles were found to be a little more than half that of a proton or neutron, and they could be either positively or negatively charged or neutral. Along with pions they are our most important particles now classed as mesons. The charged *K* mesons have a mean life of 1.2 × 10^{-8} sec before usually decaying in various ways into one or more π mesons plus a few other particles. The mean life of the neutral *K* particle is somewhat less.

Following the discovery of *K* mesons came a great profusion of new particles. Although the mean lives of *K* mesons seem short on our time scale they actually live an enormously long time compared to the many far more evanescent particles heavier than a proton that have mean lives as little as 10^{-24} or 10^{-26} sec. Such particles obtained by very high energy bombardment may be created with their antiparticles, and some may be identified as higher excited states of other particles.

The determination of which particles are *fundamental* and which ones are not became more complicated and seemed to thwart all attempts at a simplified theory of the nature of matter, until a new development by the theorist Gell-Mann and others suggested all matter may be composed of still smaller basic particles called *quarks*. Although quarks may never be found outside the nucleus they have led to much success in theory by showing how it is possible that many observable particles can have a simple and basic underlying relationship (see QUARKS).

Recent attempts to measure the mass of the neutrino have given more positive results than earlier ones. The newer experiments now indicate the neutrino may possibly have a small but measurable mass of a few electron volts in terms of its energy equivalent. This is to be compared with the electron, itself a tiny particle, which in the same units has an energy equivalent mass of 511,000 eV. The neutrino mass must be a very small quantity, but if the universe is full of neutrinos it could add up to a very large amount.

We are continually bathed in the streams of neutrinos from the sun which result from the nuclear processes that sustain the sun's heat, and the most noteworthy attempt to measure some of the billions of billions of neutrinos that must be radiating from the sun is that of Davis, using a 100,000 gallon tank of detecting fluid a mile deep in a South Dakota mine. The smaller than expected result which has so far been obtained may result from difficulties of detection or other reasons not yet clear.

Although 90% of the neutrino radiation which we receive most likely comes from our sun the number of stars radiating into space could fill all of space with neutrino radiation. Such a profusion of neutrinos, if they possess appreciable mass, might even affect our ideas about the expanding universe: it presents the astronomers with another source of mass to consider in figuring if there is enough mass to cause the expansion to ever stop and reverse itself.

Nuclear radiation presents both hazards and benefits. Radiation from experimental nuclear reactors at various centers now furnishes rich opportunities for further study of the nature of matter and the properties of different radiations. At the same time the hazards of radiation from nuclear power plants and nuclear warfare are becoming more widely recognized and have led to an intense study of such radiation including the long-range as well as the short-range physiological effects. Closely related are the dangers resulting from aging and deterioration of the materials in a reactor plant itself that are continuously exposed to radiation.

The rapid development of nuclear weaponry has led not only to the many problems of the physiological effects but to military problems such as the development of a "clean" bomb and to the possible enhancement of neutron radiation at the expense of explosive power, or the reverse. With all of this the subject of nuclear radiation has expanded out of the laboratory and has become more and more deeply involved in our lives.

NUCLEAR RADIATION SHIELDING

Nuclear reactors, based upon the fission of heavy nuclei, have become an important power source for the generation of electricity. The great intensity of nuclear radiations produced in the reactors requires radiation shielding. Fast neutrons and gamma rays are by far the most penetrating of the radiations produced; therefore, most shield design is concerned with reducing their levels by factors of as much as 10^{15}.

A variety of other systems gives rise to shielding problems which are related more or less closely to those of the fission reactor and these are treated with many of the same methods which are used in reactor shielding. After discussing these various areas of application, the problem of calculating and confirming the design or performance of a radiation shield is outlined.

Areas of Application *Fission Reactors.* In the United States and much of the rest of the world, the fission power plants now being installed for electricity generation (or ship propulsion) are based upon the use of water as the reactor moderator and coolant. As a shield, water has no cracks and it offers simplifications following from the fact that it tends to produce an equlibrium neutron energy distribution due to the inverse dependence upon energy of the hydrogen neutron cross section. This equilibrium fast-neutron spectrum has allowed the use of simple attenuation methods with empirically derived constants to solve many design problems which do not require much detail in the answer. The outstanding problem for light-water reactors has been the streaming of neutrons in the cavity outside the reactor pressure vessel, where rather detailed calculations are required. A summary of approaches to this problem has recently been made available.[1]

Current interest in the development of advanced reactor types centers upon the breeders, especially the liquid-metal-cooled fast breeder reactor (LMFBR) using the ^{238}U to ^{239}Pu breeding cycle. Breeders are essential if nuclear fission is to make a long-term contribution to our energy needs. The LMFBR operates at high temperatures (~500 to 600°C) and with neutrons of high energy (~100 keV average energy for neutrons producing fission). Both conditions tend to exclude hydrogenous materials from the vicinity of the reactor, and sodium, the liquid-metal coolant usually considered, is the dominant medium near the core. The fast-neutron spectrum does not attain an equilibrium after attenuation in any thickness of sodium (to 15 ft) so far as is presently known, and much more detail in the neutron spectra must be predicted for LMFBR shield design.

Fast-neutron streaming through clearance gaps and sodium-filled pipes, which necessarily surround or penetrate the LMFBR shields, must be calculated for geometries which become quite complex in actual practice. For the coolant pipes, both the sodium and the insulation required by the high temperatures are of low density and constitute significant gaps in the shield. Specific shielding problems of liquid metal fast breeder reactors have been reviewed by Farinelli and Nicks.[2]

Finally, for fission reactors used to propel or to provide auxiliary power for space vehicles, the weight of the power plant becomes crucial to the feasibility of the mission. Since the radiation shield may account for as much as two-thirds of the total power-plant weight, the radiation shield design must be made with the highest attainable accuracy. Efforts are centered upon methods of optimizing the shield design with respect to weight. This can now be done directly and accurately insofar as the power plant can be considered one-dimensional. Two-dimensional optimization methods are less developed.

A thorough review of radiation shielding for fission reactors was published by the U.S. AEC in 1973.[3]

Fusion Reactors. Potential advantages of safety and unlimited fuel supply justify current efforts to develop controlled thermonuclear reactors (CTR) based upon the fusion of light nuclei. The most commonly considered reaction of deuterium and tritium produces 14-MeV neutrons which must be absorbed to prevent radiation damage, to breed more tritium as a fuel, and to gain the energy (heat) which the fast neutrons carry from the reaction. A major requirement of the radiation-transport calculations for CTR systems is to insure radiation levels that will not destroy components of the system; e.g., the cyrogenic magnet used to contain the fusion reaction. Radiation-shielding calculations for fusion systems are closely related to the neutronic design of the lithium-containing blanket which is used to breed tritium. An example of a calculation of this type is given in Ref. 4 for a Tokomak fusion reactor, one of the most highly developed types. Neutron streaming through necessary penetrations of the reactor shield for any type of fusion reactor now visualized will limit the attenuation of the shield and require careful study.[5] Validation of the analytical methods used will be based upon specifically designed shielding experiments.

Nuclear Weapons Radiations. Nuclear explosives may produce radiations by both the fission and fusion processes and there are substantial overlaps in the radiation-shielding problems with the reactors considered above. For the protection of military or civilian systems against radiations from nuclear weapons, initial attention must be given to the radiation transport through air from the source to the system. As a result of many years of study of this basic problem, air-transport methods and results are now available in detail with accuracies (except for problems with the cross sections for the production of secondary gamma rays by fast neutrons) of the order of 10 to 20 percent.[6]

An overview of the problem of shielding military systems against weapons radiations is given in the multivolume DNA Handbook.[7] For the specific consideration of the shielding protection offered by structures against weapons fallout radiation, a comprehensive review has recently been published.[8]

Accelerators. Radiation of virtually all types (including neutrons and gamma rays) and energies can be produced by the many types of charged-particle accelerators. Over the energy range to ~20 MeV there may be quite direct overlap in the radiation-shielding problems with reactors or weapons radiations. For higher-energy accelerators additional reactions and new particle types such as mesons may be involved. High-energy particles which are slowed down (reduced in energy) in the shield eventually pass through or give rise to additional particles in the lower energy range applicable to fission and fusion reactors. Thus methods developed at low energy may be incorporated as part of the solution of accelerator shielding problems. In any case, the methods of solution tend to be closely related.

Space Vehicles. The space environment includes charged particles ranging from the electrons (trapped by the magnetic field of the earth) through protons and alpha particles (helium nuclei) to heavier nuclei. The protons tend to be the most numerous and their interactions the best understood. Nuclear interactions of heavy nuclei are little understood and may constitute a major problem for future manned interplanetary space travel.

All of the charged particles lose energy dominantly by ionization which creates essentially no transport or shielding problems. Nuclear reactions do occur, however, at energies above a few MeV and ignoring these may lead to dosimetry estimates in error by 25 per cent or much more depending upon the incident-particle energy spectrum and system geometry.

The methods employed for space radiation shielding are largely those also used for accelerator shield design. However, in general, the requirements in space radiation shielding are for highly accurate calculations for thin shields. For accelerators, less accuracy is usually required but much thicker shields (approaching or surpassing the attenuations of reactor shields) may be required. Space radiation shielding is treated in a comprehensive handbook.[9]

Nature of the Problem Stated generally, the problem of radiation shielding is to solve the Boltzmann transport equation which describes the radiation transport. It is possible in principle, of course, to make direct measurements of the necessary radiation attenuations, but in practice this is seldom practical. Thus, given the necessary nuclear data, radiation-shielding analysis reduces largely to (1) developing necessarily approximate methods of solving the Boltzmann equation, (2) testing their validity, usually against measurements in simplified geometries, and (3) applying these methods to design problems.

The Boltzmann equation may be considered simply as a balance equation tabulating the sources and disappearances of particles. In this sense, and ignoring time dependence, it may be written as:

$$\begin{aligned}&\nabla \cdot \overline{\Omega}\phi(\bar{r}, E, \overline{\Omega}) + \Sigma_t(\bar{r}, E)\phi(\bar{r}, E, \overline{\Omega})\\&\quad = S(\bar{r}, E, \overline{\Omega}) + \iint \Sigma_s(\bar{r}, \overline{\Omega}' \rightarrow \overline{\Omega}, E' \rightarrow E) \times\\&\qquad \phi(\bar{r}, E', \overline{\Omega}')\, dE'\, d\overline{\Omega}'\end{aligned}$$

where ϕ is the number flux of particles of energy E, at position $\bar{r}$, with angular direction $\overline{\Omega}$. The left side of the equation represents all losses including leakage out of the region of interest and disappearance by reactions of all types with probability $\Sigma_t\phi$. On the right side, S represents all neutron sources such as fission and the integral includes in-scattering into the spatial and energy region of interest of particles scattered from elsewhere. This "scattering" process may in the most general sense include the production of gamma rays upon the interaction of neutrons.

Solving this integro-differential equation requires input for the radiation sources S and interaction probabilities Σ including details about secondary particles which may be produced. The allowable radiation levels corresponding to ϕ(E) are generally provided as constraints determined by the radiosensitivity of man, materials, or systems which may be exposed to the radiations. Then one solves for the minimum shield thickness (or weight or cost) consistent with the constraints.

Nuclear Data *Sources of Radiation.* Fission produces neutron and gamma-ray sources important for shield design. The characteristic and much-studied distribution in energy of neutrons (~5 MeV/fission total energy release with $\overline{E}$~2 MeV) varies with the isotope undergoing fission and slowly with the energy of the neutron producing fission. Delayed neutrons, which follow β-decay of fission fragments, have an intensity relative to the "prompt" neutrons of the order of 1 to 2 per cent and become important largely for fluid fuel reactors where they may be emitted beyond part of the primary shield and thus enhanced in importance. Gamma rays are emitted at essentially all times after fission but a major share (~8 MeV/fission) appear within a few nanoseconds. Gamma rays following isomeric transitions in fission-fragment nuclei (important for times after fission $\lesssim$ 1 sec) and following β-decay (for $t > 1$ sec) together amount to another ~7 MeV/fission.

The 14-MeV neutrons produced in fusion of light nuclei constitute the dominant radiation for a fusion source. For high-energy accelerators or space vehicles, the sources of penetrating radiations are dominantly due to nuclear interactions of the primary charged particles. μ-mesons, formed from the decay of other particles, are extremely penetrating due to their small interaction cross sections, and they tend to dominate parts of the shield for accelerators with energies > 10 GeV.

A broad review of radiation sources is given in the "*Engineering Compendium of Radiation Shielding.*"[10]

Cross Sections. The probability of interaction or cross section must be treated in great detail in radiation-shielding problems, especially for neutrons. The cross sections are strongly energy-dependent, in part with rapid variations or fluctuations with neutron energy. Neutrons may (1) disappear, giving rise only to charged particles of no consequence for the radiation transport; (2) produce fission or fusion with the sources these reactions imply; (3) scatter, changing energy and direction, thus introducing "new" particles into the transport equation; (4) scatter as in (3) with the additional production of deexcitation gamma rays; or (5) be "captured" with the emission of capture gamma rays. For shielding, one requires the sum of gamma rays produced in fission, capture, and inelastic scattering.

The vast amount of cross-section information required for accurate shielding calculations constitutes a central problem, and perhaps more effort is applied altogether in cross-section preparation than in transport calculations. Neutron cross sections are measured at many "points" in energy. These detailed point sets are then commonly reduced to a limited number of energy groups (~30 to ~300 groups) with the energy variation in cross section within each group represented by a weighted average. Weighting schemes approximate the proper but unavailable weighting by $\phi(E)$ for the problem being considered. Since $\phi(E)$ is a function of position, no single set of weights can be exact. The group structure must be especially selected for difficult problems. The validity of sets of group cross sections must be established by comparing the results of calculations using them with values obtained from calculations with point cross-section sets or from benchmark experiments.

The use of group cross sections allows treating scattering by introducing group-to-group transfer matrices with a large reduction in necessary information storage. Similarly, group cross sections can be readily generated to handle secondary gamma-ray production.

As for neutrons, gamma-ray cross sections can be considered as point or group-averaged functions of energy. Gamma-ray cross sections tend to be known more accurately than those for neutrons, and the production of other particle types (e.g., neutrons) by gamma rays can usually be ignored for low-energy transport problems.

Nuclear Data Stores. The wealth of cross-section detail demands computer-based handling and efficient storage. A National Nuclear Cross Section Center (NNCSC) has been established at the Brookhaven National Laboratory for storing neutron and gamma-ray cross sections, and this is the appropriate primary source of information in the United States.[11] Very important is the fact that a cooperative group (The Cross Section Evaluation Working Group or CSEWG) has been set up to identify the "best" set of data for each reaction type and nuclei. This choice may require choosing among sets of experimental measurements with different values for the same quantities, or may require filling gaps covered by no measurements, on the basis of nuclear-model calculations or systematics. This Evaluated Nuclear Data File (ENDF), which changes with time as new data become available, is also available from NNCSC.[11] Similar, but more preliminary, data and sets of groups of cross sections derived from them are available from the Radiation Shielding Information Center (RSIC) at the Oak Ridge National Laboratory.[12]

Methods of Solution Exact analytic solutions of the transport equation are not possible for practical shielding problems, but numerous approximate, basically numerical methods are available. Two of these have assumed the greatest importance today, the discrete ordinates and Monte Carlo methods. Applied in their most highly developed forms, the residual approximations become unimportant. The effort and cost required for such applications may be substantial, however. Other methods which are easier to use offer approximations to the desired solution which have more or less vailidity depending upon the complexity of the problem and its similarity to those from which the approximate method has been derived. A review of transport methods is available in the revised Chapter 3 of the "Weapons Radiation Shielding Handbook."[7]

Virtually all solutions of problems of practical interest depend upon use of a digital computer, and the type of computer available and its cost of operation may constrain the choice of methods. The availability of computer codes developed by others is very important. Codes of shielding interest are collected and made available by the Radiation Shielding Information Center,[12] which also assists new users in making them operable.

Discrete Ordinates. The nature of the Boltzmann transport equation as a balance of particle flow is closely matched by the discrete ordinates formulation as a finite difference equation, and the equivalence has been demonstrated for one-dimensional geometries. Thus, few approximations are necessarily required in the application of this method, which obtains the desired flux $\phi(\bar{r}, E, \bar{\Omega})$ by successive iterations over the difference cells. A derivation and a method of solution of the finite-difference equations which are required for a one-space dimension time-independent problem are given in Ref. 7.

The adaptation of the discrete ordinates method, which was originally developed for other purposes, to radiation shielding required special attention to several features of the method. In particular, the steep flux gradients characteristic of good shields have required modified schemes for iteration within the difference cells. For deep penetration in a shield, the angular distributions of scattered particles become very important since the forward-scattered radiation can penetrate most readily. To handle the anisotropic scattering in a practical manner, the angular distributions after scattering from energy group to energy group are approximated by a Legendre series. A low order of expansion, P_3, usually suffices.

The discrete ordinates methods have been expanded to two dimensions and widely applied to practical design problems. Demands upon computer time have provided incentives for developing improved forced-convergence techniques including those which concentrate upon the spatial or energy region of interest. Flux aberrations have been frequently observed in two-dimensional problems for small radiation sources. These "ray effects" preserve indications of the finite angular directions in the flux solution, and various methods have been devised to eliminate or control them.

Practical computer codes are available[12] which incorporate the discrete ordinates method. One-dimensional calculations are very fast and have been used as the basis of iterative shield optimization procedures which perform a series of flux solutions in one pass on the computer. Two-dimensional calculations require fast computers with large memory stores. It should be noted that the division of neutron energies into groups allows a convenient method of handling the production of secondary gamma rays by neutron capture and inelastic scattering. Proper treatment of these secondary gamma rays is essential in almost all radiation-shielding problems which include fission or fusion sources.

Overall, discrete ordinates is the method of choice for most one- or two-dimensional radiation-shielding problems. The major complication which is encountered in its use is that there is no clear a priori approach to defining the best (or even certainly adequate) sets of directions, space meshes, and energy groups for a given problem. Experience is the best guide to these choices and it must be based upon detailed comparison of test calculations with benchmark experiments which are designed for for the purpose.

Monte Carlo. Under the pressure of necessity, many components of radiation shields may be approximated in one or two dimensions. There remain, however, complicated problems, such as the streaming of neutrons through holes, which require a three-dimensional treatment. At present, the Monte Carlo method is the only approach to such problems which is free of serious approximations.

The Monte Carlo method depends upon stochastic estimation or random sampling from the probabilities describing the stochastic processes that determine the solution of the transport equation. This mathematical analog for a problem of interest may be made as exact as desired, limited only by the investment of effort and computing time. The size of the sample of particles of interest (i.e., those penetrating the shield) determines the statistical accuracy achieved.

The major determinant of the success of the Monte Carlo method for problems whose important parameters depend on very unlikely events, such as penetration through thick shields, is the method of sampling. Through "importance sampling," larger numbers of particles can be chosen which contribute to the unlikely events of interest.[7] Thus the sampling is biased without, hopefully, biasing the result, since correction factors are applied. The most powerful biasing technique uses an importance or value function based upon an adjoint solution of the transport equation, using the best available method, which will usually be one- or two-dimensional discrete ordinates. Such biasing in energy and space is routine but angular biasing has usually been limited to one-dimensional problems. Estimates of the variance calculated upon the basis of a normal distribution may be grossly in error, since Monte Carlo distributions are frequently nonnormal, and unfortunately, error estimates are usually too low. This difficulty must be kept in mind in using the Monte Carlo method for shielding problems.

Several powerful and general Monte Carlo codes are available[12] for a variety of computer types. The inherent flexibility of the method, however, requires considerable effort on the part of the user for solving a given problem. Recent developments in Monte Carlo methods have tended toward systems, such as those using standard neutron energy groups, which ease the user's burdens. Using the same energy groups as those of the discrete ordinates method greatly facilitates comparisons of results. The ultimate verification of results from Monte Carlo calculations as for all other methods must rest upon comparisons with benchmark experiments. A current review of Monte Carlo methods gives most emphasis to shielding applications.[13]

For reactor-design problems the attenuations may exceed those which may be practically treated with Monte Carlo techniques, but parts of the geometry may require three-dimensional analysis. Therefore, coupling codes have been developed[12] which enable solving part of the problem using two-dimensional discrete-ordinates and part in three-dimensional Monte Carlo.

Other Transport Methods. Many other methods have been considered and used to a limited extent for solving the transport equation. In one approach, the angle-dependent terms are represented by expansions in spherical harmonic polynomials, P_n. Development of the method has been restricted by the requirement to consider many terms in the scattering representation and the difficulty of treating multidimensional shielding problems. Limited use of the P_3 approximation has been made for one-dimensional problems, but no two-dimensional calculations are known. Diffusion theory, which corresponds to the P_1 approximation, is widely used for reactor criticality calculations because of its relative simplicity, and multidimensional versions are available. Its validity is limited to nearly isotropic fluxes, however, as opposed to the highly forward-directed fluxes characteristic of shields. Diffusion theory can sometimes be used for the inner portions of a reactor shield or to provide a source for transport shielding calculations, but the current trend is to use the transport calculation throughout the system.

Another approach to solving the transport equation consists of transforming the problem by constructing spatial moments of the flux and calculating in the transform space. This moments method has a number of computational advantages and it was used widely for gamma-ray transport. It is, however, greatly restricted in the geometries that can be considered, and has been applied largely to infinite homogenous media. Furthermore, for neutron transport, difficulties persist in reconstructing the flux from the moments.

The so-called invariant imbedding, or matrix, method does not solve the transport equation directly, but rather solves for reflection and transmission functions throughout the medium. A particular (shield) configuration is imbedded in a larger class of configurations, and solutions are obtained for all in one calculation, an obvious efficiency. Definition of reflection and transmission functions and their solution by numerical methods do not differ greatly from other approaches to the transport equation. Boundaries are precisely included in the formulation, it is well suited for heterogeneous shields, it is efficient for thick shields and inefficient for thin. The outstanding limitation is that applications have been made only for slab geometries.

Approximate Methods. Before large computers made transport solutions practical, the kernel technique for radiation transport based upon the use of a Green's function was widely used. The point kernel, $K(|\bar{r} - \bar{r}'|)$, relates the desired response of a detector at point $\bar{r}$ to a radiation source at point $\bar{r}'$. Integration over a source volume yields the solution to problems of arbitrary geometry. However, values for the kernels have been obtained from solutions by methods valid only for infinite homogeneous media, and these kernels give results which are in error when applied to finite media. Scattering may be approximated by adding one of a variety of build-up factors as a function of energy E and separation $|\bar{r} - \bar{r}'|$. For gamma rays, useful build-up factors were derived from moments-method calculations.

For neutron attenuation, many shields contain large regions of water following other materials. This water has the effect of filtering out scattered neutrons, making the material appear as an absorber. The absorption or removal cross section, as derived empirically from experiment, was used in defining a kernel applicable for shields with outer hydrogenous regions. Other kernel approaches have been used in order to parameterize the results of transport solutions.

A logical extension of the removal concept was to follow the deep penetration of neutrons as described by the removal process by moderation in energy using diffusion theory. This removal-diffusion method has been highly developed and widely applied, especially in Europe, in the design of shields for power reactors using fission induced by thermal neutrons. The basic assumptions upon which the method is based are not fulfilled for fast reactors. The removal process is considered for many energy groups (to 18) from which neutrons can be transferred to other energy groups used to describe the diffusion process. The key step then becomes derivation of the group-transfer matrices from experiments which determine the penetration of monoenergetic neutrons in various materials. A modern reference to approximate shield-design methods is available in a survey of nuclear reactor engineering.[14]

Validation of Calculations Mock-up experiments, which are universally used to validate reactor-core criticality calculations, are much less common for shielding calculations. The penalty for error or overdesign tends to be less and the costs for meaningful mockups excessive. An obvious exception would be the space reactors for which the shield design is crucial. Measurements on reactors as built can in principle be used to validate calculation methods. In practice, however, access to interesting portions of reactor or accelerator shields is limited and down time required for performing meaningful measurements is very expensive. The test is also rather late for judging methods for anything other than serial production of power plants.

The most useful tests of transport methods follow from comparisons with experiments specifically designed for the purpose. Such experiments attempt to reproduce in the simplest arrangement attainable the essential features of the system of interest (e.g., a fast-neutron spectrum for applications to fast reactors or large attenuations in the pertinent materials for thick shields). The experimental results must be accurate, reliable, and unambiguously interpretable above all else. Measurements include the neutron energy distributions penetrating the shield, using one or more of the various neutron spectrometers which have been developed for the purpose. An example of the test of a two-dimensional discrete-ordinates code against measurements of neutron spectra serves to illustrate the process.

Sensitivity Analysis and Channel Theory The complexity of radiation shielding problems has made worthwhile developing sensitivity analysis. The sensitivity of a desired response R (such as a radiation dose outside a complex shield) to changes in input parameters σ_x (such as the neutron cross sections) is just the functional derivative $\partial R/\partial \sigma_x$. Using generalized perturbation theory, it is possible to obtain for a single response sensitivities to all input parameters. This allows identification of those data which are most significant in obtaining accurate attenuation predictions. When combined with estimates of uncertainties in the input data, knowing the sensitivities allows estimating the uncertainty in the desired response. Uncertainties in the model (i.e., effects of choice of energy groups or angular quadrature for discrete-ordinates calculations) can also be taken into account.

Examination of the sensitivity profile (sensitivity as a function of energy, for example) may offer insights into the physical processes (such as "holes" in the cross-section variations with energy) which are important or crucial in determining shield penetration. Sensitivity analysis can and should be used in the design of shielding experiments to demonstrate that the important parameters of the experiment correspond to those in the shield design of interest. A session was devoted to this topic at the last international conference on reactor shielding.[15]

While sensitivity analysis has tended to consider energy regions of greatest importance in attenuation, spatial channel theory is used to locate regions in space that may be of dominant importance. Thus streaming paths for neutrons can be identified and visualized, even for the very complicated geometries of fast breeder reactors.[16] The additional insight into the radiation-transport process thus gained may be used to determine weaknesses in shield designs and/or the optimum placement of shielding materials.

For Further Information The development of radiation-shielding technology is almost entirely dependent upon high-speed digital computers. This dependence of reliable solutions to transport problems upon computer codes with masses of nuclear data required as input precludes the handbook approach to practical design problems. Therefore, a Radiation Shielding Information Center has been established to assist in providing the necessary tools for solving shielding problems and in providing means of retrieving the pertinent literature. The Center does not attempt to solve problems directly. It does provide coverage of the literature for all of the indicated areas of application. It also collects, packages, evaluates, and makes available to users the computer-based methods and data which have been developed. Feedback from users regarding their problems and successes in applying the methods is important in leading to improvements. The Center may be contacted at the address given.[12] The Center was responsible for publication of the "Proceedings of the Fifth International Conference on Reactor Shielding," held in Knoxville in 1977.[15] Included here are a wide range of relevant papers.

A general text on radiation shielding and dosimetry was written by A. E. Profio and published in 1979.[17]

NUCLEAR REACTIONS

Several years after the discovery of the nucleus by scattering α-particles from gold, Rutherford and his collaborators noticed that if air were exposed to the flux of α-particles, occasionally a very penetrating particle was observed. After some nuclear detective work, this phenomenon was explained in the following way: the nitrogen nucleus and the α-particle react to produce an isotope of oxygen and an energetic proton. In chemical notation, such a reaction may be written as $^{14}N + \alpha \rightarrow {}^{17}O + p$, where the superscripts are the atomic mass numbers of the elements in question.

Nuclear reactions may take place only when a target nucleus and a projectile come close enough together for the nuclear forces to take effect. The range of nuclear forces is very short, about 1.5 fermis (1 fermi = 10^{-13} cm). Since nuclei and all the massive projectiles except neutrons are charged positively, they repel each other; and if they are to be brought into sufficiently intimate contact to interact, the energy of the projectile must equal or surpass the repulsive electrostatic force. Typically, for protons on light nuclei, the energy required for a reaction to take place is 1 or 2 MeV rising to 15 MeV for protons on very heavy, highly charged nuclei. Thus to produce nuclear reactions by the collision of charged particles, we must first accelerate one of them to an energy sufficient to overcome the electrostatic repulsive force. In all nuclear reactions, energies are usually given in million electron volts (MeV) and masses in atomic mass units (amu). One MeV is the energy acquired by a particle of one electronic charge as it is accelerated by an electrical potential of one million volts. An atomic mass unit is defined as one-twelfth the mass of a neutral carbon-12 atom.

A nuclear reaction, like its chemical counterpart, may be exoergic (kinetic energy is liberated) or endoergic (kinetic energy is absorbed). For example, Rutherford's original reaction is endoergic, consuming 1.19 MeV which is converted into mass of the product particles according to Einstein's $E = mc^2$. In the case of endoergic reactions, energy must be supplied in the form of projectile kinetic energy to make the reaction possible.

In the course of a nuclear reaction, the projectile and the target may fuse completely or parts of nuclear matter, neutrons, protons, or clusters of these may be transferred from the target to the projectile or vice versa.

The projectiles used to produce nuclear reactions are usually energetic charged particles. In the early studies of nuclear reactions, the most common projectiles were the ISOTOPES of hydrogen, protons or deuterons, as well as α-particles. Because these projectiles have small electric charges, they feel the lowest electrostatic repulsion from the target and need the least amount of energy to accomplish their purpose. Recently, however, increasing emphasis is being placed on heavy ion projectiles, from lithium to uranium. Because the heavy nuclei carry a large charge, they require much more energy to approach the target closely enough for the nuclear matter to interact. Usually the energy is expressed in terms of MeV per nucleon (MeV/A); and for heavy ions the desirable energy for nuclear reactions is around 10 MeV/A; thus, for example, the total energy for uranium nucleus would be 2,380 MeV. Another field of nuclear reactions that is increasing in popularity uses very high energy electrons (500 MeV to 5 GeV) usually produced by linear accelerators.

Neutrons form a special class of projectiles, since they are not charged and need not possess any large amount of energy to overcome a repulsive electrostatic barrier. In fact, the slower the neutron, the more likely it is to interact with a target simply because it spends more time in the vicinity of the target nucleus. Nuclear reactions may also be initiated by PHOTONS (electromagnetic radiation quanta) of very high energy, greater than 5–10 MeV. The photons are produced as x-rays when high-energy electrons impinge on a target. Since photons are not charged electrically, there is no barrier; but all photonuclear reactions are endoergic, that is, they require several-million-electron-volt x-rays to take place. High energy accelerators produce copious amounts of unusual projectiles: π- and K-mesons and other exotic particles with a sufficiently long half-life. While research with these projectiles is not terribly common at the present time, there are indications that their use will increase.

Rutherford's original reaction would now be written thus: $^{14}N(\alpha, p)^{17}O$. The target nucleus comes first, the projectile and the emitted particle or particles appear in that order inside the parentheses, and the residual nucleus is last. The superscript gives the atomic mass of the isotope. Some common abbreviations are p for proton, n for neutron, d for deuteron (^2H), t for triton (^3H), γ for γ-ray or photon.

The projectile energy range over which nuclear reactions are studied varies from a fraction of an electron volt for neutrons to several hundred million electron volts per atomic mass unit for charged particles. At very high energies, lighter projectiles appear to interact with the individual neutrons and protons of the target rather than with the nucleus as a whole, and we leave the domain of nuclear reactions to enter the field of ELEMENTARY PARTICLE interactions.

Nuclear reactions are literally the foundation on which our world is built. The energy of the sun is nuclear in origin deriving principally from the fusion of four protons into a helium nucleus in the course of which 22.7 MeV are released in each fusion. The fusion is not a direct four-body reaction but rather proceeds by stages through many two-body reactions (see SOLAR ENERGY SOURCES). Not only is our chief source of energy of nuclear origin, but the constituents of the earth are also the result of long-gone nuclear reactions, principally a series of (n, γ) processes which served to build up the elements in the earth as we now find them. One particularly pleasing success of nuclear reaction theory and experiment is the fact that the abundance of the elements and their isotopic ratios as they occur in nature can be calculated simply on the basis of the probability with which neutrons are captured by various nuclei, these probabilities having been measured in nuclear research centers.

Not only nature's energy source is of nuclear origin. The two mightiest sources of man-made energy, nuclear FISSION and nuclear FUSION, derive from nuclear reactions.

In fission, a neutron is captured by a uranium nucleus which splits (fissions) into, say, a Ba and Zr nucleus, in the process releasing about 200 MeV of energy and some neutrons which in turn split other U nuclei in the vicinity. This leads to the familiar chain reaction which, if controlled, is used to produce power by converting the fission energy (heat) into electricity. If the chain reaction is allowed to proceed without control, a violent explosion results, i.e., an atomic bomb. (We note parenthetically that what is commonly known as atomic energy should really be called nuclear energy since its source is not the entire atom, but only its nucleus. Burning of coal, on the other hand, is atomic energy since heat is derived from the combination of a carbon atom with two oxygen atoms to form CO_2.)

Fusion as a source of energy derives from a reaction such as $^2H(d, n)^3He$ in which 3.3 MeV are released. This process is similar to the source of solar energy in that hydrogen nuclei fuse to produce helium. Controlled fusion reactions that proceed slowly and are contained spatially are being studied at many laboratories, and much progress has been made to the ultimate goal: a controlled fusion reactor, which however is still several decades in the future. An uncontrolled fusion reaction has been achieved—it constitutes the energy source of the hydrogen bomb.

It is clear that reserves of coal and oil must someday be exhausted. When this happens, mankind will require new sources of energy. Two candidates for this are derived from nuclear reactions, fission or fusion. With due care, either one could become the source of energy for the next several millennia; and in fact, fission energy is likely to be the major source of electrical power in many countries by the end of the century.

The terrors of war and the blessings of abundant power both come from nuclear reactions. But that is not all. Perhaps the most significant contribution to science has been the use of radioactive elements produced in nuclear reactions. Let us take a typical example. Consider the reaction $^{13}C(n, \gamma)^{14}C$. This reaction produces radioactive ^{14}C which has a half-life of 5700 years. The radioactive carbon decays with the emission of an electron, which can be counted with a suitable detector. Thus we are able to locate individual atoms of carbon and separate them from all others which are not radioactive. Such radioactive atoms are called tracers; and by using a variety of them, ^{13}C, ^{18}F, ^{32}P, ^{35}S, ^{131}I, ^{198}Au, all produced by some sort of nuclear reaction, unprecedented advances have been made in biology, geology, chemistry, metallurgy, physiology, and medicine. Furthermore, radioactive isotopes in large amounts can be used instead of x-rays for treatment of cancer, for metallography, and for food preservation.

By means of nuclear reactions such as $^{241}Am(^{11}B, 4n)^{248}Fm$, scientists have been able to make new elements not found in nature. Some of these, for example plutonium and californium, have found important uses as reactor fuels or portable power sources. The preparation of new elements has played a decisive role in our understanding of the chemistry of heavy elements.

We turn now to a description of nuclear reactions. These may be regarded as proceeding in two principal ways. First, the colliding particles may fuse, their components get thoroughly mixed in a very "hot" compound nucleus. This compound nucleus may exist in a heated state for a period varying between 10^{-16} and 10^{-20} second, a time we normally consider imponderably short but which is nevertheless long on the nuclear time scale when compared with the transit time of a nucleon across the nucleus (10^{-22} second). The compound nucleus boils off fragments, mainly neutrons, protons, α-particles, and γ-rays, and in this way cools down to a normal energy content. In its final state, it is called a *residual nucleus;* and it may be radioactive or stable depending on the details of the reaction. If the target, the projectile, and the energy of the projectile are known, it is possible to predict what the residual nucleus will be; and thus, if certain isotopes are wanted, one can tailor the reaction accordingly. We note here, however, that the exact mechanism of these reactions is very complicated and is not really understood in a fundamental way.

In the other kind of reaction, the nuclei do not fuse but only part of the nuclear matter is transferred from one nucleus to the other. This is often called a *direct reaction* and includes stripping reactions, pickup reactions, and transfer reactions. A typical example is $^{27}Al(d, p)^{28}Al$, where a neutron is stripped from the deuteron and caught by the Al nucleus while the remaining proton stays relatively undisturbed on its original course. The nuclei in such reactions do not come into intimate contact, and the reaction is fast on the time scale of 10^{-22} second.

In general, light projectiles are used to study individual states of nuclei. For example, if a proton is scattered inelastically, it will deposit a certain amount of energy in the target nucleus before it emerges from the collision. By studying the amount of energy deposited, the angle at which the proton leaves its target, and sometimes by measuring the spin of the proton before and after collision, physicists are able to obtain detailed information about the energy levels in the nucleus such as the spin and parity of a particular state. The most common reactions used for this kind of study are inelastic scattering, stripping and pickup reactions such as (d, p) or (d, t) reactions. In order to interpret reactions of this type, physicists employ an *optical model*, in which the nucleus in all its complication is replaced by a complex potential containing a real part, an imaginary part responsible for nuclear absorption, and a spin-orbit part that accounts for the fact that many of the projectiles have spin which influences the reaction process. The optical model and the distorted wave Born approximation calculations for direct reactions have been very successful in analyzing the details of the nuclear reactions and enable physicists to interpret reaction data and thus learn more about the structure and properties of nuclei, as well as about the reaction process itself.

Heavy ion reactions are used to study an entirely different set of nuclear properties. Instead of learning about details of the nucleus, with heavy ions physicists can study the nucleus as a whole, learn about its viscosity, about oscillations and deformability of nuclei, about the compressibility of nuclear matter and even about the possibility of observing nuclear shockwaves. The nuclear model that is most useful here is the *liquid drop model* invented in the early 1940s to describe fission. In this model, the nucleus is represented by a liquid drop that rotates, changes shape, has a surface tension, and in other ways mocks up a nucleus. A particularly interesting heavy ion reaction is *deep inelastic scattering*, a process in which two nuclei just touch then rotate together for a fraction of a full rotation while they exchange between them significant amounts of nuclear matter and energy. These reactions are intermediate between compound nucleus and direct reactions. Another useful property of heavy ion reactions is the capability to produce isotopes far from stability simply by the appropriate selection of the target and projectile. For example, nuclides such as tin-100 are now being looked for in heavy ion experiments. (Recall that the most stable tin isotope is ^{120}Sn, and the lightest stable tin nuclide is ^{112}Sn.)

Electrons are used almost exclusively for the detailed study of nuclear structure. Electrons have the advantage that their interaction with nuclei is purely electromagnetic and thus understood theoretically. In principle, then, when the interaction is understood the information about nuclei is much cleaner and more readily interpreted. There is also hope that with high-energy electrons one can probe the subnuclear structure due to quarks in nuclear matter.

Exotic projectiles such as π- or K-mesons at the present time provide interesting information about the nuclear surface, or what one might even call the nuclear stratosphere. It is well known that nuclear densities fall off rapidly with radius, and it is a matter of considerable controversy just what the structure of the surface is, whether there are mostly neutrons or mostly protons, and how the density decreases for various nuclei. π- and K-mesons form mesic atoms in quasi-electronic states. If the state is known, its radius is known, and its interaction with the nucleus then provides information about nuclear density at that radius.

In spite of many years of research, a deep understanding of nuclei and a theoretical ability to predict their properties still elude us. Nuclear reactions are a prime tool for the investigation of nuclei. By careful study of nuclear reactions in all their multiplicity of detail, including the precise knowledge of the projectile, its energy and its spin direction, the nature, as well as energy, angle of emission, and the spin of the reaction product, a good deal of information has been gained about this realm. A deep understanding of nuclei yet eludes us. We have no accurate predictive theory, even though we have searched for it for many decades. The prize, however, is worth reaching for: its promise is to reveal the nature of nuclei, the smallest stable constituents of matter, and the laws which govern their interactions to give man immense power for war or for peace.

NUCLEAR REACTORS

Definition A nuclear reactor is a device in which the fission of a nuclear fuel releases large amounts of energy in a controlled chain reaction involving neutrons. Reactors serve as important heat sources for the commercial generation of electricity and can as well supply neutrons and useful radioactive isotopes.

Fission and the Chain Reaction When a uranium-235 nucleus absorbs a neutron, an excited compound nucleus of uranium-236 is formed. In about 15% of the cases this results in gamma ray emission, while in 85% there is a splitting of the nucleus into two fragments. These fly apart with high speed, with total kinetic energy around 200 million electron volts (MeV). In this fission process beta particles, gamma rays, and an average of about 2.5 high-energy neutrons are emitted. The neutrons induce additional fissions, and under proper conditions a neutron chain reaction results.

Since only one neutron is needed to continue the chain, extra neutrons are available. Depending on the size and materials of the reactor, these neutrons will be captured in nonfissionable materials or will escape from the reactor, a process called *leakage*. If uranium-238 is present, neutron capture can lead to the production of plutonium-239.

Fission fragments consist of a great variety of isotopes, with the most likely split in the mass ratio 3 : 2. They bear most of the kinetic energy that can be transformed into thermal energy and then into electrical energy. The heavy particles resulting from fission constitute the collection of material called *fission products*. Many of the isotopes are radioactive, with half-lives ranging from a fraction of a second to millions of years. Although there are some useful radioisotopes among them, the bulk must be regarded as a waste, to be disposed of in some safe manner.

When on the average each neutron reproduces another neutron, the assembly is said to be *critical*. Similarly, if fewer or more neutrons are produced per cycle, the system is *subcritical* or *supercritical*. These three cases correspond to a neutron multiplication factor of exactly 1, less than 1, and greater than 1, respectively.

The chance of capture or fission of nuclei tends to vary inversely with neutron energy. Low energy neutrons (~0.025 eV) are thus said to have a higher cross section than high energy neutrons (~1 MeV). A target isotope is classed as *fissile* if slow neutrons can induce fission.

History The discovery of fission in Germany in 1939 led to the initiation of a major effort in the United States in World War II to exploit the new energy source for military purposes. Two paths of research were followed—(a) to separate the desired uranium-235 (0.7% of uranium as found in nature) from uranium-238 and (b) to produce plutonium by means of neutron capture in uranium-238. Each of the programs was successful and eventually led to peacetime applications.

The first "pile" (nuclear reactor) was built at the University of Chicago by Enrico Fermi and his colleagues. The reactor consisted of lumps of natural uranium metal and oxide imbedded in a large block of graphite. On December 2, 1942 it "went critical" and demonstrated that a self-sustained chain reaction was possible. The reactor served as a model for plutonium production reactors constructed at Hanford, Washington. Uranium isotope separation was achieved at Oak Ridge, Tennessee by two different processes—electromagnetic and gaseous diffusion—leading to uranium enriched to about 90% in uranium-235. Atomic bombs were developed at Los Alamos, New Mexico, in the period 1942–1945. One was composed of U-235, the other of Pu-239. The war with Japan was terminated through the use of these weapons, and a new era of peacetime applications of nuclear energy began.

During the period 1945–1960 many reactor concepts were studied by industry in cooperation with the U.S. Atomic Energy Commission. Out of these, three favored types emerged: the pressurized water reactor (PWR), developed and marketed by companies such as Westinghouse Electric, Babcock and Wilcox, and Combustion Engineering; the boiling water reactor (BWR), mainly a product of General Electric; and the high-temperature gas-cooled reactor (HTGR), built by General Atomic. In Canada, the heavy-water reactor CANDU was developed, and in Great Britain the main power source was the gas-cooled natural uranium graphite reactor.

The number of power reactors in operation throughout the world, as of June 30, 1982, is given in Table 1. The United States has 77 in operation and a comparable number on order or under construction. Worldwide, 23 countries have 265 reactors in use.

Reactor Components The only ingredients required for a chain reaction are a fissile isotope and neutrons. The main fissile materials are uranium-235, plutonium-239 and -241, and uranium-233, produced by neutron capture in thorium-232. Neutrons of high energy (~0.9 MeV) are required to cause fission in uranium-238. Practical operation demands as well a variety of components for heat removal, radiation protection, and control.

Fuel. Various combinations of heavy isotopes comprise the "fuel" of a reactor. This fuel is "burned" in the sense that it is consumed and gives up energy. Examples of fuel are natural uranium, uranium slightly enriched (~3%) in uranium-235, and highly enriched uranium (~90%).

Control Absorption. A reactor that is to be operated steadily for long periods of time requires fuel in excess of the amount required to be critical. Thus, at the start of operation, an excess of neutron-absorbing material such as boron must be present. Typically this control absorber is in solution or in the form of movable rods.

TABLE 1. WORLD REACTORS
(As of 30 June 1982).

	Number of Operable Reactors	Electrical Capacity, Megawatts
United States	77	57,977
France	29	19,988
Japan	25	16,652
USSR	31	16,515
Germany FR	12	9,801
United Kingdom	32	8,048
Sweden	9	6,400
Canada	10	5,476
All Others	40	17,492
TOTAL	265	158,349

Moderator. The neutron fission cross section for uranium-235 for neutrons of energy 0.025 eV is around 580 barns (1 barn = 10^{-24} cm^2). At 2 MeV, the initial energy of fission neutrons, the cross section is only 1.3 barns. Thus to maintain a chain reaction with a small amount of fuel, it is desirable to reduce ("moderate") the neutron energy through collisions with nuclei of a light element such as hydrogen or carbon. Moderators such as light water (H_2O), heavy water (D_2O), graphite (C), and beryllium oxide (BeO) slow neutrons to the energy corresponding to thermal agitation in reactors called "thermal." In contrast, a reactor without moderator is called "fast" because the neutrons remain at high speed.

Coolant. In order to prevent melting and to extract useful heat, a cooling agent is needed. Most reactors use ordinary water as coolant; a few use heavy water, liquid sodium, or helium. Reactor types are sometimes distinguished by the coolant used, e.g., light water reactors (LWR's). These are of two types. In pressurized water reactors (PWR's) the coolant is at pressure over 2000 pounds per square inch and at temperature around 600 degrees Fahrenheit. Heat is transferred from a primary circulating coolant loop by use of a heat exchanger (steam generator). In boiling water reactors (BWR's) at somewhat lower pressure and temperature, steam is generated within the reactor.

Structure. The fuel in typical reactors is formed into small cylindrical pellets of UO_2 of volume about 1 cm^3. These are placed in long (3 m) metal tubes to form what are called fuel rods. The tubes provide structural support and also prevent fission products from escaping into the coolant. Fuel rods are spaced to allow coolant flow between them to remove fission heat generated in the UO_2. Around 200 rods form a bundle called a *fuel assembly;* around 180 assemblies form the reactor *core*, the region of the system in which the chain reaction takes place. The core is supported within a thick-walled steel container called a *pressure vessel*.

Shielding and Containment. To protect workers against radiation released by the reactor, concrete shielding is erected. The reactor vessel and coolant system are located in a large cylindrical building with steel-reinforced and steel-lined concrete walls. This containment is designed to withstand pressure in the event of an accident to the coolant system.

Reactor Physics The specialized branch of physics that deals with experiments and theory of reactors is called *reactor physics*. This consists of measurements and calculations of neutron cross sections, the number and energy distribution of fission neutrons, multiplication factors, critical sizes and masses, and power reactor performance. The latter involves the amount of control absorption required, neutron and power spatial distributions, fuel consumption and production, and isotope generation. Studies are made of both static (steady state) and dynamic (transient) behavior, using neutron diffusion theory based on Fick's law for approximate calculations, and transport theory based on the Boltzmann equation for more precise analysis. The quantity of interest is called neutron flux, which is the product of neutron number density and neutron velocity. In combination with material cross sections, it determines reaction rates.

The simplest mathematical description of a reactor was devised in the early 1940s. Neglecting neutron losses by leakage, the number of neutrons produced per initial neutron is given by the (infinite) multiplication factor k, which is a product of four components: ϵ, the fast fission factor, representing the effect of high energy neutrons; p, the resonance escape probability, the chance of not being absorbed during slowing; f, the thermal utilization, as the fraction of neutrons absorbed in fuel; and η, the reproduction factor, as the number of neutrons per absorption in fuel. Thus if $k = \epsilon pf\eta$ is greater than 1 a chain reaction is possible. If not, as is the case of natural unmoderated uranium, a chain reaction is impossible. The earliest task of researchers during World War II was to find the combinations and purity of materials that would yield a k value greater than 1. The efforts of those who design, operate, and analyze modern reactors are still directed toward the optimization of k during the operating cycle.

Nuclear Fuel Cycle The principal raw material for nuclear fuel is uranium. It is mined, chemically purified, enriched in the isotope uranium-235, and fabricated into fuel assemblies. These are shipped in special casks by truck or rail to the power plant for storage until needed.

A typical reactor is operated on a one-year cycle, in which it produces steady power except for occasional interruptions for repairs. At the end of the period the reactor is shut down, and about one-third of the assemblies are removed from the core as spent fuel. The remaining two-thirds of the assemblies are relocated in the core and fresh fuel is added. The loading pattern is designed to give a power distribution that is as uniform as possible and to obtain maximum energy from the fissile material. The reactor is brought again to operating pressure and temperature.

The spent fuel, which is highly radioactive, is stored in metal racks in water-filled pools. In some countries such as Great Britain, France, and Japan, the spent fuel is reclaimed by *reprocessing*, which consists of cutting fuel rods into small pieces, dissolving out the uranium oxide, and separating uranium and plutonium from the fission products by chemical treatment. In the United States, spent fuel continues to be stored.

Reactor Safety The physical processes that govern the operation of a reactor in themselves provide inherent safety against accident. One effect is the delayed emission of a small fraction of neutrons, as a consequence of beta-decay governed by a half-life. The time constant of power rise in a slightly supercritical system is very much longer (of the order of seconds) than it would be without delayed neutrons (of the order of milliseconds or microseconds). Another is the negative feedback effect of temperature increase of fuel, as in a power rise. Increased thermal agitation of fuel molecules causes a broadening of neutron resonance cross sections in what is labeled the *Doppler effect*. This has the effect of reducing neutron multiplication, which tends to counteract the initiating power increase.

Other safety factors are provided by equipment design. If it becomes necessary to reduce the power of the reactor quickly, "safety rods" are rapidly driven into the reactor core. These neutron absorbing components are composed of boron carbide or an alloy of cadmium, silver, and indium.

There is residual heat being produced, however, by the radioactive decay of the fission products. Although this heat power amounts to only a small percentage of the fission power, it is high enough to melt fuel if adequate cooling is not provided. In the event of a loss-of-coolant accident (LOCA) in which a pipe in the primary reactor cooling loop breaks, equipment called the *engineered safeguards* (ES) *system* comes into play. Its central feature is the emergency core cooling system (ECCS) which injects cooling water from various sources using special pumps.

Much attention has been given to an accident that occurred in March 1979 at the Three,Mile Island reactor in Pennsylvania. The cause was a combination of inadequate design, equipment failure, and reactor operator misinterpretation of events and consequent error in handling the situation. As a result, some radioactive material was released, the reactor was damaged, and the building was seriously contaminated. The incident prompted corrective action in all nuclear power plants by industry and the U.S. Nuclear Regulatory Commission.

Radioactive Wastes from Reactors No use has yet been found for most of the radioactive materials produced in a reactor. Among the fission products are isotopes of short half-life such as iodine-131 (8 days) which constitute a hazard only if radioactive gases are released from the reactor. The longer-lived krypton-85 (about 11 years) does not pose a major problem since it is a noble gas, and being essentially inert it disperses throughout the earth's atmosphere. Two isotopes provide the main radioactivity for the first hundred years after nuclear fuel is removed from a reactor. These are strontium-90 (~29 years) and cesium-137 (~30 years), which are beta and gamma emitters, respectively. For the long term, isotopes such as plutonium-239 (~24,000 years), technetium-99 (214,000 years), and iodine-129 (15.7 million years) are of principal concern.

Several techniques for disposal of radioactive wastes obtained by the chemical reprocessing of spent fuel have been studied. The most likely method will involve immobilizing the fission products by solidifying them in glass and burying them in corrosion-resistant waste containers deep in the earth. Favored geologic media are rock salt, basalt, or granite.

Purpose and Uses of Reactors The principal use of nuclear reactors is in commercial electrical power generation, serving as an alternative to heat sources using coal, oil, or natural gas. These reactors typically generate around 1000 megawatts of electrical power. Figure 1 is a schematic diagram of a pressurized water reactor, showing the reactor vessel, the primary loop, the heat exchanger, turbine, generator, and condenser. Figure 2 shows a group of three reactors at a site in South Carolina.

Reactors are used for propulsion of naval vessels, including submarines and aircraft carriers. Reactors are also used to generate plutonium for military purposes.

Research/training reactors are generally of low power, up to a few megawatts. They are used in universities and government laboratories throughout the world for education and nuclear research, including studies of the effects of neutrons and gamma rays on materials.

Reactors serve as a major source of radioisotopes for a variety of peaceful and beneficial purposes. Neutrons produced by fission are the primary agents by which isotopes are produced, either through capture or through fission.

Uses of Radioisotopes Some examples of radioisotopes and their uses are listed. Cobalt-60, of half-life 5.3 years, emits two gamma rays of average energy 1.25 MeV. These rays are alternative to x-rays for medical diagnosis and treatment of cancer and for industrial radiography. The isotope is also a very promising source for irradiation of food to eliminate pests or to sterilize the food for long-term preservation. Plutonium-238, half-life 86 years, is an alpha emitter produced by neutron irradiation of a neptunium isotope. This isotope serves as an excellent source of heat from which electric power is produced for space vehicles. Tritium, the heaviest isotope of hydrogen (H-3) has a half-life of 12.3 years. Its low-energy beta particles make it a good "tracer" to follow biological processes by measurement of the radiation. Reactors are widely used to irradiate samples to induce radioactivity and thence to determine chemical composition by measurement of characteristic radiation. This process, called *neutron activation analysis*, is valuable for studies of environmental pollution because it can detect minute amounts of impurities.

Breeder Reactor Most reactors in current operation are based on thermal neutrons and consume slightly enriched uranium, obtained by an

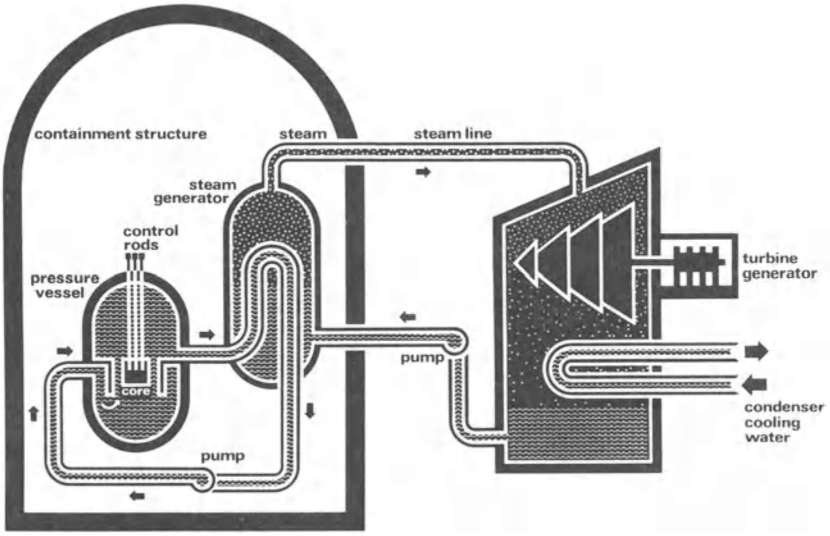

FIG. 1. Fluid flow diagram of pressurized water reactor system. (Courtesy of Atomic Industrial Forum, Inc.)

isotope separation process. Since the main fissile material is the U-235 in natural uranium, large amounts of uranium ore are required. These reactors are classed as converters, with a rather small amount of plutonium production.

In contrast, reactors that do not have a moderator can operate with fast neutrons, where the number of neutrons per absorption in fuel is high (~3). For each neutron used to perpetuate the neutron multiplication cycle, slightly more than one neutron on the average is available to produce Pu-239 from capture in U-238. The plutonium then can serve as new fuel. The breeding ratio (fissile atoms produced)/(fissile atoms consumed) is greater than 1 and the reactor is classed as a breeder. Such a reactor uses

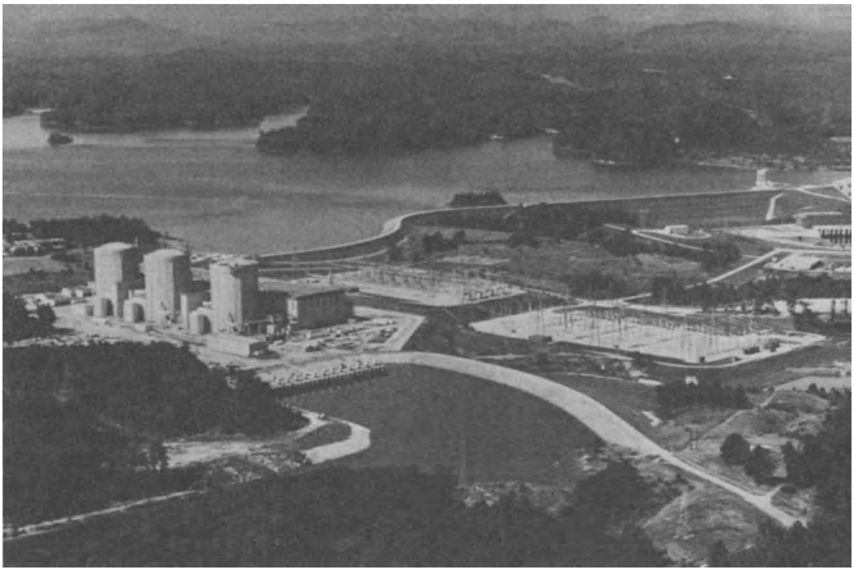

FIG. 2. The three-reactor Oconee nuclear power plant near Seneca, S.C. (Courtesy of Duke Power Company.)

all the scarce U-235 and indirectly the abundant U-238 as fuel. Employment of breeders instead of converters would reduce the amount of uranium ore required by a factor of about 50. The length of time before resources are seriously depleted could be increased from less than a hundred years to thousands of years. Prototype breeder reactors have been built and development is proceeding, notably in France.

Safeguards and Proliferation Several nations have nuclear weapons capability while many others do not. On the premise that the more countries that have weapons the greater the chance they will be used, there is general apprehension about nuclear proliferation. Reactors can be employed to produce plutonium of weapons grade; plutonium separated from commercial reactor fuel can be made into a crude weapon. Other avenues to nuclear arms capability are available, however, including uranium-235 isotope enrichment. It is believed that any country can go nuclear if it wishes to dedicate enough of its resources, but it is generally felt that every effort should be made to discourage countries from doing so.

Public Attitudes toward Nuclear Reactors The rate of development of nuclear power has been influenced by diverse public opinion over the years. The use of nuclear weapons to end World War II was acclaimed at the time as serving to save lives, but in recent years the continued expansion of nuclear arsenals has become a source of great concern. This fear has been carried over to the peaceful use of fission, with many people believing incorrectly that a reactor can explode like a bomb.

The public generally concedes a need for alternative sources of energy in view of the high cost of oil, but many believe that reactors are unacceptable because of the chance of accident that could release radioactive material.

Concern is also expressed about the accumulation of radioactive wastes and the apparent inability of government and industry to implement a plan for disposing of the wastes.

When nuclear energy first became available, it was believed that electrical power would be extremely inexpensive. Over the years, however, total costs increased because of the introduction of additional safety equipment, escalated construction expense, delays in licensing, and changes in regulatory policy. Nuclear power is cheaper than power from oil-fired plants but about the same as that from coal-fired plants. The high capital cost of modern nuclear power plants—well over a billion dollars for a 1000 MWe facility—is regarded by many consumers of electricity as too large a burden for them to bear.

Because of uncertainties in the regulatory situation, public attitude, and economic factors, new nuclear plants have not been ordered by utilities in the U.S. for several years and construction has been delayed or suspended on some reactors already ordered. In contrast, nuclear plant construction is going ahead in several foreign countries where energy needed cannot be met by the use of coal and where the regulation and construction situation permits more rapid completion of facilities than is possible in the U.S.

It is likely that nuclear reactors will provide a significant amount of the world's electric power for several centuries. For the longer term, fusion reactors using deuterium as fuel might be found to be feasible and practical as an alternative nuclear energy source.

NUCLEAR STRUCTURE

The basic problem of nuclear structure was first sharply defined in 1932 when Chadwick discovered the neutron. The nucleus was then recognized to be a system of A particles (nucleons) of nearly equal mass (Z protons and $N = A - Z$ neutrons). The forces binding the "nucleons" together must be quite distinct from the well-known electromagnetic interactions which will evidently operate to push the nucleons apart, as well as gravitational forces which appear to be too weak to have any influence in the nucleus at all.

The nuclear forces are found to be of short range ($\sim 10^{-13}$ cm). Within their short radius of interaction, they become strongly attractive (depths near 100 MeV), but at very small distances the interaction becomes so powerfully repulsive that nucleons seldom come closer than about 0.4×10^{-13} cm from one another. This character of the nuclear force produces "saturation." The binding energy per nucleon is nearly constant ($\sim 8.0 \pm 1$ MeV) throughout the periodic table, while each nucleon occupies a volume which may be approximated by a sphere of radius 10^{-13} cm.

The forces described above are assumed to operate between each pair of nucleons. Their exact nature is rather complicated and depends upon the motion, and even the orientation of the nucleons. The two-body portion of the nuclear force is now reasonably well determined through studies of nucleon-nucleon scattering, meson-nucleon scattering, and basic quantum field theory. Considerable attention is now being focused on the investigation of multi-nucleon interaction operators. In particular, since two-pion exchange is now known to make a very important contribution to the two-body part of the interaction, the three nucleon force arising from two-pion exchange must be carefully investigated.

Even if the nuclear force were precisely known, the structure of the nucleus would not be immediately understood in its entirety. Methods are not at present available for solving the three-body problem in closed form for simple interactions, and for more than three bodies, drastic approximations must be used to make the problems tractable. For this reason, considerable attention in physics is devoted to constructing simplified models of the nucleus. The purpose of these models is to isolate the salient characteristics of the nucleus, and thereby obtain some understanding of its behavior.

Two very general classes of nuclear models have received considerable attention. The simplest may be described as "powder models." Here it is assumed that the motion of nucleons within the nucleus is so complicated that statistical mechanics may be employed. In one version of this model, the nucleus is treated in analogy to a drop of liquid (the nuclear forces described above are qualitatively quite similar to forces between the molecules of a liquid). Such a chaotic state seems to ensue if the nucleus is highly excited, so that the nucleons have a great deal of kinetic energy. For this reason, powder models have found their greatest usefulness in describing the nucleus during a nuclear reaction, and especially in describing nuclear fission.

In the shell model (sometimes called the independent particle model), the motion of the individual nucleons is assumed to be much more simple. Each nucleon is, in fact, assigned a definite orbit within the nucleus. The resultant motion is then reminiscent of our usual picture of electrons within the atom, all revolving nearly independently of each other about the nucleus. The motivation for introducing this model into nuclear physics came from the early (1934) observation that nuclei that contained certain numbers of protons or neutrons were unusually stable and abundant. These numbers are generally referred to as magic numbers. The set we recognize today as magic are

$$N \text{ or } Z = 2, 6, 8, 14, 20, 28, 50, 82, \text{ and } 126$$

The major details which focus attention on these numbers may be summarized as follows:

(1) *Stability and abundance*. Nuclei with N or Z magic are unusually tightly bound and correspondingly very abundant. If both N and Z are magic (${}_2\mathrm{He}_2$, ${}_6\mathrm{C}_6$, ${}_8\mathrm{O}_8$, ${}_{14}\mathrm{Si}_{14}$, ${}_{20}\mathrm{Ca}_{20}$, ${}_{20}\mathrm{Ca}_{28}$, and ${}_{82}\mathrm{Pb}_{126}$), then the nucleus is even more tightly bound (here, the left subscript is the number of protons; the right is the number of neutrons). The last nucleon to complete a magic number has sometimes nearly twice the binding energy of an average nucleon. Furthermore, nuclei with Z magic possess an unusually large number of stable isotopes, and nuclei with N magic have an unusually large number of stable isotones.

(2) *Neutron capture cross sections*. Nuclei with neutron number one short of a magic number have a large neutron capture cross section, while nuclei with a magic number of neutrons exhibit a small neutron capture cross section.

(3) *Islands of isomerism*. Long lived γ-active nuclear states (half-life$\sim$1 second) appear just prior to the completion of a magic number.

(4) *Electric quadrupole moments*. Nuclear quadrupole moments tend to be small near magic numbers and large far from magic numbers. A nucleus with N or Z magic appears, therefore, to prefer a spherical shape.

(5) *Delayed neutron emission*. Delayed neutron emitters (e.g., ${}_{36}\mathrm{Kr}_{51}$, ${}_{54}\mathrm{Xe}_{83}$, and ${}_8\mathrm{O}_9$) appear when N is one greater than a magic number.

The data clearly point to an interpretation of the magic numbers in terms of shell closures, analogous to the atomic structure of noble gases. Thus it appears that the nucleon-nucleon interaction somehow averages out within the nucleus so that each nucleon, to a reasonable first approximation, sees a fairly smooth potential. Such a potential should be flat near the origin (like an harmonic oscillator), and should go rapidly to zero outside the nucleus (like a square well). A suitable form which has undergone much study is the Fermi function.

$$V(r) = V_0 [1 + \exp \alpha(r - a)]^{-1} \qquad (1)$$

In order to reproduce the magic numbers one must add a spin-orbit term:

$$f(r)\mathbf{l}\cdot\mathbf{s} \qquad (2)$$

to this central potential. Here $\mathbf{l}$ is the orbital angular momentum of a nucleon, and $\mathbf{s}$ its spin. The effect of this $\mathbf{l}\cdot\mathbf{s}$ interaction is to couple the orbital and spin angular momenta so that the states with total angular momentum $j = l + \frac{1}{2}$ will be lower in energy than states with $j = l + \frac{1}{2}$. Shell closures obtained with such a potential are found to reproduce the observed magic numbers in a simple and striking manner.

The fact that the shell model works at all in nuclei is somewhat surprising since the theoretical motivation that enhances its success in atomic structure is lacking. One has no strong central field originally in nuclei, and furthermore the nucleons are much more closely packed. Consequently, collisions, which should tend to scatter a nucleon out of its orbit, should be more frequent. It is found that the Pauli exclusion principle plays a vital role here. When such a collision occurs, the orbit into which a nucleon would tend to be scattered is actually occupied by another nucleon. This fact makes the shell model a far better first approximation than one would originally suspect.

The main effect of the nucleon-nucleon interaction is to produce the average shell model (single-particle) potential. This, of course, is not the sole effect. Many refinements are required before an adequate description of nuclei may be attained.

Consider, for example, a nucleus with just two nucleons beyond a double closed shell. One of the nucleons will go into an orbit j, and the other into an orbit j'. These two orbits may orient themselves such that the nucleus may have total angular momentum J anywhere within the range

$$|j - j'| \leqslant J \leqslant j + j' \qquad (3)$$

so long as one is consistent with the Pauli exclusion principle. If one only had single-particle potentials all states of this configuration would have the same energy independent of J. To determine the level order actually observed, one must recognize that not all of the original nucleon-nucleon interaction is used up in constructing the single-particle potential. Some "residual interaction" is left over. This residual interaction will still be of the two-body type, and it will remove the degeneracy between states of the same configuration.

The most important feature of the residual interaction is that it produces a pairing force for like orbitals (i.e., $j = j'$). If $j = j'$, and we have like nucleons, the interaction is by far the strongest if $J = 0$. This has the important consequence that for nuclei with both an even number of protons and an even number of neutrons, one must have net angular momentum equal to zero. This rule is never violated. If one adds one nucleon to this even-even nucleus, the result will be a J equal to the j of the odd nucleon. This rule is violated in only a very few cases.

There are a few nuclear phenomena which the shell model cannot describe at all. The sign of the static, nuclear, electric quadrupole moments are generally given correctly by a single-particle model, but the magnitude is frequently found to be larger than that predicted by more than a factor of ten. Similarly, electric quadrupole transition rates are frequently much faster than those given by the shell model. It seems that even in low-lying nuclear levels it is not possible to attribute all of the properties of the nucleus to the nucleons in unfilled orbits. One must take into account possible distortions of the orbits of nucleons in the closed shells.

This line of thought gives rise to the "collective model," in which the nucleons in the core (closed shells) are treated as an incompressible, irrotational fluid capable of surface oscillations. Nucleons in unfilled shells will exert a centrifugal force on this fluid and tend to deform it into a nonspherical shape. In regions of the periodic table where several shell model orbitals are nearly degenerate in energy ($90 \leqslant N \leqslant 114$ and $Z > 88$), the nuclear core takes on a rather large spheroidal deformation. The formalism of the theory is reminiscent of that for diatomic molecules. Low-lying excited states are generated through a rotation of the entire system about an axis perpendicular to the axis of symmetry. This gives rise to a band of energy levels:

$$E_J = E_0 + (\hbar^2/2I)J(J+1) \qquad (4)$$

where I is a moment of inertia. The identification of spectra in nuclei which could be empirically fitted to Eq. (4) was a great truimph of the collective model.

It should be noted that I is not the moment of inertia of the entire nucleus. It is only the moment of inertia of the part of the nucleus which participates in the rotation, and this is, of course, always less than the "rigid body" value.

We note that the shell model and collective model appear to be quite different in their basic assumptions. The collective model presumes that the nucleon motions are so closely correlated that we can treat a rotation of the nucleus on the whole, while the shell model begins with independent orbitals. It is very important to remember, in this regard, that the shell-model orbitals must be properly coupled together in the nucleus. The Pauli exclusion principle must be satisfied, angular momentum must be a good quantum number, and so on. These orbitals are, therefore not so independent as it might seem. They may very well give rise to collective effects depending upon the exact way in which they are coupled together to obtain the final nuclear wave function.

Various coupling schemes have recently been examined to investigate this, but these are beyond the scope of this article. We present here a simple illustrative example. Consider a set of identical particles attracted by means of identical springs to a common origin. At time $t = 0$ each particle is at the origin and is given some arbitrary velocity. Even though each particle has a different initial velocity, and moves independently of every other particle, the system will undergo a periodic dilation and contraction due to the fact that the frequency of vibration is the same for each particle. Thus we have a collective motion exhibited by a set of independently moving particles.

The next step in the investigation must be to attain a quantitative interpretation of the individual particle motion itself. This must come directly from a full treatment of the many-body nuclear problem using realistic nucleon-nucleon interactions. This problem is complicated by the fact that nuclear forces become sharply repulsive at very short nucleon-nucleon separations. Thus the nuclear wave function exhibits strong correlations between nucleons which must be accounted for in any final theory. The two-body correlations seem well accounted for by a formalism devised by Bruechner, Bethe, and Goldstone, but the effects attained when three or more nucleons all come into close proximity are yet to be completely evaluated in finite nuclei.

O

OCEAN ACOUSTICS

Introduction Ocean Acoustics is the study of the correlation between oceanic variability and its effect on underwater acoustic signals. A vast range of scales is involved: time scales from seconds to months, acoustic frequencies from a few hertz to several hundred kilohertz, both deterministic and random ocean inhomogeneities ranging from centimeter size to circulations and currents extending hundreds of kilometers. It encompasses not only physics but also aspects of biology and chemistry. Signal propagation ranges can vary from meters to thousands of kilometers, through a strongly inhomogeneous medium whose effects alter the sound speed of the acoustic signal in many ways. We separate the description, not inconveniently, into the effects of the ocean surface, its bottom, and the interior domain on acoustic propagation and scattering.

The Ocean Surface The ocean surface is an example of a complex wave motion formed through the action of the wind. Its properties can be understood in terms of the statistical properties of wave heights. Both the wave height probability distribution and its correlation function, or the Fourier transform of the latter, the surface (spatial) spectral function, play an important role. The major height parameter is the Rayleigh roughness parameter, $\Sigma = k\sigma \cos\theta$, where k is the wavenumber, σ the rms surface height, and θ the angle of incidence of an acoustic wave (measured from the normal). Values of $\Sigma > 1$ describe a very (strong) rough surface.

For a fully developed sea (one where the wind has blown long enough so that the surface is in equilibrium) the surface height and slope are nearly Gaussian distributed, although the distribution is skewed due to the creation of broad troughs and narrow swells on the surface. Additional discrete spectral contributions can result from periodic surface components. In regions where the surface is composed of ice, other models must be considered.

For shallow surfaces the surface spectral function can be directly related to the scattering coefficient. Little direct data is available on the spatial spectrum itself, but it can be inferred from frequency spectra and the ocean gravity wave dispersion relation. In addition, the scattering coefficient depends on wind speed and direction, the direction of propagation of a wave on the surface, and the angular distribution of ocean wave energy.

Acoustic signals propagating in the ocean scatter from the surface both coherently and incoherently. Models of this scattering include perturbation methods for small wave height surfaces, tangent plane or Kirchhoff scattering for surfaces with large radii of curvature, and multiple scattering techniques for strongly rough surfaces. Multiscale surface models containing a long-scale periodic component on which is superimposed a small-scale random surface have met with success. The coherent wave propagates in the specular direction and is formed by averaging the wave field over the statistical ensemble of random surfaces. For shallow surfaces it is a Gaussian function of the Rayleigh roughness parameter. For rougher surfaces multiple scattering must be incorporated. Backscattered sound can be modeled as arising from the glitter due to a facet model of the surface. At very high frequencies trapped air bubbles near the surface are the main mechanism of surface sound scattering. The frequency spectrum of the scattered field is thus composed of a single spectral line (due to specular reflection) and a broad background due to the incoherent contributions.

The Ocean Interior The ocean is a strongly inhomogeneous medium. The inhomogeneities are of two types, regular and random. The fundamental cause of a regular inhomogeneity is the dependence of the ocean sound speed on position. In fact, because of this inhomogeneous structure, the sound speed (or index of refraction) in the ocean acts like a converging lens to the propagating acoustic field, and results in the creation of an effective ocean duct or waveguide. This is called the SOFAR channel (for sound fixing and ranging) or the underwater sound channel (USC). Its net effect is to refract and focus the acoustic signal. Sound trapped in this duct can propagate for thousands of kilometers.

The mean speed of sound in the ocean is about 1500 m/s and can vary approximately ±50 m/s. Even though changes from the mean are small, they can significantly alter sound propagation over long ranges because their effects are cumulative. The sound speed c can be parameterized in two ways. The first way is as a function of temperature T, salinity S, and pressure P, that is, $c(T, S, P)$. Near the ocean surface, c varies primarily due to the seasonal or diurnal temperature changes. Near the ocean bottom (below about 1.5 km in the Atlantic for example) the temperature and salinity are nearly constant and the major functional dependence is on pressure. In the deep ocean this latter yields a stable monotonic increase in c as a function of depth. In general then the sound speed is largest near the surface and bottom with a minimum at what is referred to as the SOFAR axis. Examples are illustrated in Fig. 1.

The second parametrization of c is a functional dependence on spatial coordinates (depth z, range r, angle θ) and possibily on time t, that is, $c(z, r, \theta, t)$. The temporal dependence is often ignored since the ocean is usually considered to be temporally frozen on the time scale of most ocean acoustic experiments. Although surface ducting can occur due to temperature variability and, if an experiment occurs over long periods of time, longer-scale effects on the system (such as tides) must be considered, the main effect arises from the depth dependence. There is a slower (adiabatic) range dependence, and a slower still angular variability.

Other examples of regular inhomogeneities in the ocean are bottom protrusions such as seamounts, which can occur on a horizontal scale of hundreds of kilometers and a vertical scale on the order of kilometers, and, in general, sea depth variability even when more gradual such as near coasts and shores. Large-scale highly energetic variability also occurs in the upper ocean regions in the form of circulating spin offs from large current flows such as the Gulf Stream and Kuroshio current near Japan. Due to their size they are generically called *mesoscale phenomena*. Examples include the synoptic mesoscale eddies and rings which can move as well-defined rotating water masses for long times at speeds of about 10 cm/s with the actual circulation speeds about an order of magnitude larger. Their scale sizes are roughly 100 km in the horizontal and about 1 km in the vertical. Thus they are highly anisotropic, as is much of the oceanic variability. Their net effect on sound propagation is again due to the fact that they modify the sound speed structure. For example, counterclockwise rotating eddies pull colder water up towards the surface thus lowering the effective sound speed and producing a deeper refraction.

Additional ocean inhomogeneities can be

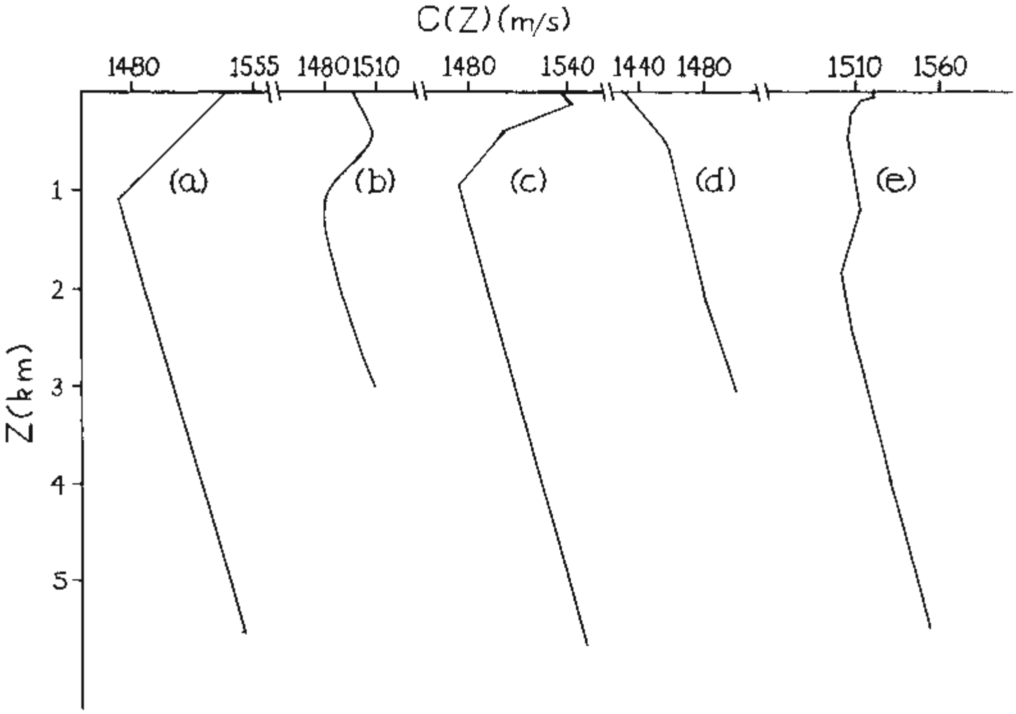

FIG. 1. Examples of typical vertical sound speed profiles $c(z)$. Profile (a) is a two-layer sound speed with each layer approximated by a linear segment in depth; (b) illustrates a sound speed which can form a surface sound channel; (c) is a typical profile from the Pacific; (d) is an Arctic profile illustrating a steep gradient and the effect of colder water; and (e) is a representative northeastern Atlantic profile.

classed as randomly varying on the acoustic time scale. The ocean can be considered as a density-stratified fluid. Displacement of a fluid particle from equilibrium and the action of a restoring (gravitational) force on the particle produces a wavelike motion in the ocean called an internal wave. Scale sizes of these waves are as large as 10 km in the horizontal and 100 m in the vertical. They have periods of anywhere from a few minutes to about a day. For fixed source and receiver they are a major source of fluctuations of the sound speed and hence of the acoustic intensity within a frequency interval of cycles per day and cycles per hour. Considerable effort has been expended in attempting to understand the fluctuation effects of internal waves on acoustic propagation and extensive results are available on the resulting acoustic amplitude and phase-rate spectra. Internal waves contain much less energy than the mesoscale phenomena.

For many purposes it is useful to treat the ocean as a layered medium. It is sometimes nearly exactly so. For example, the vertical profiles of temperature, density or salinity can have an almost steplike structure, with layer thicknesses from tens of centimeters to meters and horizontal extent on the order of kilometers. This ocean *fine structure*, as it is termed, affects acoustic propagation, since the vertical layer gradients can alter the sound speed field. The trajectories of acoustic rays can be changed due to the gradients, or wavelike reflection properties from the layers can be significantly altered. Currents in the ocean can also contribute to these effects. Periods for the fine structure are on the order of minutes, and fine structure is less energetic than internal waves.

Note that both the internal waves and fine structure as well as the deterministic mesoscale phenomena are highly anisotropic. An example of random isotropic ocean variability is the homogeneous isotropic turbulence due to ocean microstructure. Here horizontal and vertical scales are about 10 cm with periods of about a minute. This turbulence is generally confined to the upper mixed layer of the ocean and is due to atmospheric effects. Examples include wave breaking and bubble cavitation. It is the least energetic of the inhomogeneities we have described.

There is an added problem in treating many of the above phenomena, since they often do not occur with any particular regularity in the ocean. Not only is there the problem of understanding the effects of mesoscale, internal waves, etc., there is the additional problem of identifying the existence of the particular phenomenon or combinations of phenomena which may be contributing to an ocean experiment or interrupting or modifying the performance of some system. As we have mentioned, all the above inhomogeneities affect the sound speed.

The sound speed in the ocean can thus be modeled as a large deterministic refraction (due to the depth variation of temperature, salinity, and pressure), additional multidimensional deterministic variability due to mesoscale phenomena, and random modifications due to smaller scale phenomena such as internal waves, fine structure and turbulence. Functionally it can be written as

$$c(\mathbf{x}, t) = c_0(z) + c_1(\mathbf{x}) + c_2(\mathbf{x}, t).$$

Here c_0 is the purely depth-refractive contribution; c_1 the deterministic spatial mesoscale addition depending on the spatial vector $\mathbf{x}$ and smaller than c_0 by about two orders of magnitude; and c_2 the spatial and possibly temporal variation due to random effects, which is smaller than c_0 by about four orders of magnitude.

The ocean is also a very noisy environment. At low frequencies (below 10 Hz) the major noise source is geophysical (earthquakes, volcanic activity, etc.), with additional contributions from turbulence and nonlinear wave interactions. At higher frequencies (40–400 Hz) ship traffic produces a steady background noise because of low sound absorption. In the lower kilohertz regime the wind and ocean surface interactions (such as breaking waves and trapped air bubble collapse) produce the majority of the noise. At still higher frequencies molecular effects can produce some thermal noise. In addition there is biological noise produced at various ocean locations due to the presence of marine organisms.

There are several different mathematical models for acoustic propagation in the ocean. They depend of the dimensionality of the problem and on whether the oceanic variability is deterministic of random. The acoustic field in the ocean is the solution of a Helmholtz equation which can be derived from the perturbation solution of the fundamental fluid equations. If this solution is represented as an amplitude and phase term and diffraction is neglected, then the most widely used propagation method, ray theory, can be derived. It is valid at high frequencies, and the wavelength should be much less than any significant length scale. It is invalid when the phase curvature does not change as rapidly as the projection of the amplitude gradient on the phase gradient (e.g., shadow regions, edges of obstacles, caustics, or focal points) and when the fractional change in the refraction index is not small with respect to a wavelength (as at the ocean surface and bottom). Its advantages are that the rays can be found independently of the amplitude, and the amplitude derived from the intensity along a ray where the ray coupling (diffraction) is neglected. It is computationally simple to implement and yields at the least a good qualitative picture of the acoustic field. It also can be used multidimensionally.

If the sound speed profile is one-dimensional (depth-dependent) and the propagation regime can be modeled as a waveguide, then the z-dependent part of the acoustic field constitutes an eigenvalue problem or a normal mode problem. The boundary conditions on the acoustic velocity potential at the air-water interface are nearly perfectly reflecting (soft or Dirichlet conditions) and at the bottom either perfectly reflecting (hard or Neumann conditions) or are varied to include bottom loss. The discrete modes can be found numerically or, in certain cases for exactly solvable profiles, analytically. Statistically rough boundaries can be incorporated using perturbation methods, and, depending on the model chosen for the bottom, a continuous spectral contribution can be included. The latter is important at short ranges, while the discrete spectrum is the dominant contribution at long ranges. If the profile has an additional slow variability in range, an adiabatic mode theory has been developed which treats the range variation as a succession of static depth-dependent problems whose solutions are matched at successive range interfaces.

General range dependence of the profile can be modeled using the parabolic approximation to the Helmholtz equation coupled with a fast Fourier transform algorithm so that the solution can be computationally marched in range. The approximation consists in neglecting the term involving the ratio of the second to first range derivative of the field divided by the wavenumber. It has been shown that this is a narrow spectral approximation centered about the wavenumber term (which is arbitrary). The latter can be used to define an equivalent ray angle about which the parabolic approximation is also a narrow angle approximation in a forward direction. In most presently available codes the ray angle is along the horizontal. It is also possible to relate the parabolic approximate solution rigorously to the Helmholtz solution and from this to correct the parabolic solution particularly in the phase term where the original approximation fares badly. Other corrections can also be included, such as the inclusion of the earth's curvature for long-range propagation. The small dependence on angular variability can also be incorporated into a three-dimensional parabolic code.

When the ocean is random, propagation codes become more complicated. Unlike the atmosphere, the major propagation effect in the ocean is refraction which is deterministic. Thus perturbation methods for random oceanic variability must be based on ray- or modal-type solutions which include the deterministic depth dependence. Random propagation methods have also been applied to investigate the effect of internal waves on acoustic propagation, and to explain acoustic signal fading.

Experimental ocean frequencies vary over six orders of magnitude, from a few hertz up to the megahertz regime. The lower the frequency the longer the propagation range and the lower the absorption. The absorption is mainly due to liquid shear viscosity and oceanic chemical relaxation processes. Inhomogeneities (air bubbles, marine organisms) also scatter the sound and it is usually the combined effect of absorption and scattering (called *attenuation*) which is measured. The attenuation coefficient is roughly proportional to frequency squared so that low frequency sound can, as we remarked, propagate thousands of kilometers. As a comparison, laser energy in the ocean would be totally absorbed in less than a kilometer.

One final ocean topic should be included. We have mentioned direct propagation problems where the sound speed is given and the resulting acoustic field is computed. Potentially far more important are inverse methods, where from a knowledge of the source and received signal (or its travel time in ray theory) one infers the intermediate oceanic properties such as the sound speed. This latter research in ocean tomography is presently in progress and is a precursor of much of the future oceanic monitoring effort.

The Ocean Bottom The acoustic field interaction at the ocean surface can be generally decoupled from the effects in the air. That is, the major air-water interface effect is a geometric effect. This is not so with the ocean bottom interaction. Bottom topography, sub-bottom layering, and the elastic properties of the bottom can significantly alter low frequency propagation in the ocean. Thus, not only is there the bottom geometry to consider, but also its material properties such as density and compressibility. Shear as well as compressional waves are present.

Bottom geometry varies on the horizontal scale from the size of small ripples due to currents on sand to hundreds of kilometers (e.g., large ocean ridges). Vertical protrusions occur on the scale of kilometers (e.g., seamounts). The sound speed in the shallow bottom is near that in the water bottom (about 1550 m/s). It can be less (for clay, 1530 m/s) or greater (sandy clays, about 1700 m/s) or much greater (about 1800 m/s for low-porosity sediment). In the sub-bottom substrate the compressional speed is 3–4 times greater than in the water, with shear speeds roughly twice as large (3000 m/s). Estimates of the bottom sound speed can be obtained using seismic reflection techniques. Sound absorption in the bottom is roughly proportional to frequency. At low frequencies the material bottom properties dominate the sound reflection whereas above a few kilohertz the bottom topography plays an important role.

Forward scattering from the bottom can significantly contribute at low frequencies since the sound can first penetrate the bottom and, at a distance couple back into the water. It is generally insensitive to correlation lengths of the topography. Backscattering at normal incidence is quite large, and for larger incidence angles roughly follows the cosine squared dependence of Lambert's law.

OPTICAL INSTRUMENTS

Optical instruments create images of objects by altering the direction of travel of light rays. They are of two types. One type creates a real image that is projected onto a surface such as a screen or a piece of film. The other type creates a virtual image that can be perceived only by an observer. The observer's eye further redirects the light rays so that a final image of the object falls across the retina. The major advantage of optical instruments is that they afford an image of an object that could not be easily perceived with the unaided eye. With microscopes one can see or photograph details of an object totally inaccessible with unaided viewing. With telescopes one can see details of truly distant objects whose image to the observer would otherwise be imperceptible. Here simple microscopes and refracting telescopes will be examined.

Magnification in Microscopes The fineness of the detail that one can see in an object with unaided sight depends in part on how close the object can be brought to the eye. However, for a normal eye an object can be no closer than about 25 cm if a clear image is to form on the retina. If an optical lens is positioned appropriately between the object and the eye, the lens produces a virtual image at a distance of 25 cm. This image subtends a larger angle in the observer's field of view than the object would have at 25 cm. The ratio of the angle subtended by the virtual image to the angle subtended by the object in the first case is called the *magnifying power* of the lens. It depends on the focal length of the lens. For example, if the lens has a focal length of 2.5 cm and if the virtual image is created 25 cm from the observer, then the lens has a magnifying power of $25/f + 1$, or 11. This value is approximately the upper limit for a single lens providing convenient viewing without major aberrations to the image.

Compound microscopes employ two lenses (the objective and the eyepiece) in order to further magnify the object. The objective is closer to the object and provides a real and inverted image that falls within the focal distance f_2 of the eyepiece. In Fig. 1, u is the distance between the object and the objective and v is the resulting image's distance. The ratio of the size of the image to the size of the object is called the *magnification by the objective* and is equal to v/u. The image serves as an object to the eyepiece which functions as a magnifying glass since it produces a virtual image (the final image of the microscope). It is this image that an observer sees. The combined magnifying power of the instrument is the multiplication of the magnification of each component: $(v/u)\ (25/f_2 + 1)$ where f_2 is the focal distance of the eyepiece. The magnification is increased if u is decreased and v increased. However, a practical limit of 16 cm for the length of the microscope tube restricts improvement. Also, resolution is eventually lost. The magnifying power of most microscope designs is limited to about 2000.

Magnification in Refracting Telescopes Refracting telescopes are normally employed to see objects that cannot be brought close to the objective. The magnifying power is defined as the ratio of the angle subtended by the image provided by the telescope to the angle that would be subtended in the observer's field of view with normal sight. A refractive telescope employs two lenses as in a microscope: an objective and an eyepiece. In the usual adjustment of a telescope the objective produces a real image at the focal point of the eyepiece, which then creates a virtual image that is essentially infinitely far away. The magnifying power is equal to the ratio of the objective's focal length to the eyepiece's focal length.

Astronomical telescopes are often classed according to a magnifying power that depends on the diameters of the apertures through which the light must pass. The entrance pupil is simply the objective lens. The exit pupil is defined, in principle, with an experiment in which a diffuse light source (such as an illuminated ground glass screen) is placed in front of the objective. The light rays passing through the eyepiece are focused on a surface to form an image called the exit pupil (Fig. 2). (Often a metal cap with

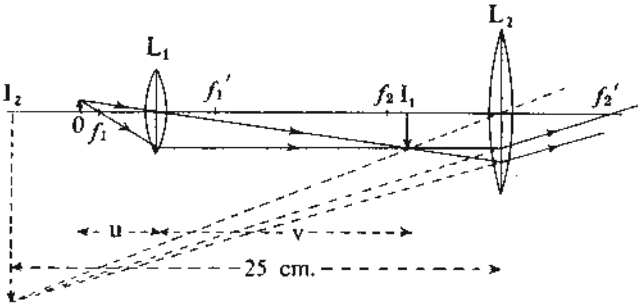

FIG. 1

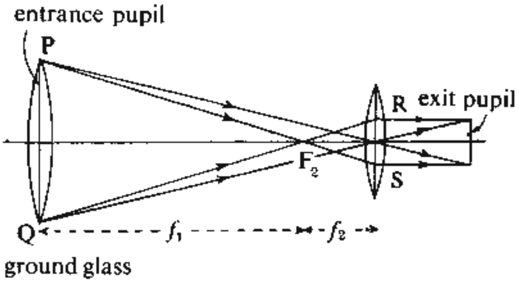

FIG. 2

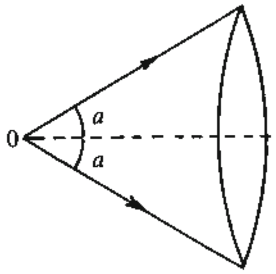

FIG. 3

a circular hole lies at the site of the exit pupil.) The magnifying power is defined as the ratio of the diameter of the entrance pupil to the diameter of the exit pupil. In a simple refracting telescope the light must pass through the pupil of the eye. In a good design the exit pupil of the telescope is no larger than the diameter of pupil in the eye.

For example, at night the diameter of the pupil in the eye is about $\frac{1}{3}$ in. For a 6-in telescope (telescopes are often classed according to the diameter of their objective) the magnifying power should be

$$\text{Magnifying power} = 6/\tfrac{1}{3} = 18.$$

If the exit pupil of the telescope is larger than the diameter of the pupil, the full light gathering capability of the objective is wasted.

Resolving Power and Limit of Resolution of Microscopes The limit of resolution of the objective of a microscope is the least distance x between two points that can just be resolved. Abbe calculated this limit as

$$x = \frac{\lambda}{2\mu \sin a}$$

where λ is the wavelength of the light, μ is the refractive index between the points and the objective, and $2a$ is the angle subtended by the objective in the field of view from the points (Fig. 3). The term $\mu \sin a$ is often called the numerical aperture of the objective. The maximum value of $\sin a$ is 1. For air μ is 1. Thus the limit of resolution in air is $\lambda/2$, or half the wavelength of the light employed. Closer spacing of the point objects would eliminate one's resolving them separately.

In practice the resolution is partially limited by how close the object can be brought to the objective so that $\sin a$ is a large as possible. Therefore objectives with short focal lengths ($\frac{2}{3}$, $\frac{1}{6}$, or $\frac{1}{12}$ inch) are employed in microscopes.

The limit of resolution can also be improved by increasing the index of refraction of the medium between the object and the objective. Commonly oil such as cedar oil is placed between a cover slip lying over the object and the objective (Fig. 4).

Another technique for improving the limit is to employ ultraviolet light whose wavelength

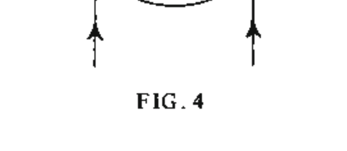

FIG. 4

is about half that of visible light. With UV the resolving power is doubled but a camera is needed to capture the image since the eye does not respond to UV.

Resolving Power and Limit of Resolution of Telescopes The limit of resolution of a telescope is given as an angle ϕ subtended at the objective by two points on an object. The limit is the smallest angle such that the two points can just barely be resolved and is given by

$$\phi = 1.22\lambda/a$$

where λ is the wavelength of the light and a is the diameter of the objective. Thus telescopes with larger objective diameters yield better resolving power. However, to insure full advantage of the objective in a simple refracting telescope, one must be certain that the exit pupil is not larger than the diameter of the pupil of the eye.

For example the Yerkes telescope has an objective of 40 inches in diameter. With 6×10^{-7} m as a typical wavelength for visible light its resolution limit is given by

$$\phi = \frac{1.22 \times 6 \times 10^{-7}}{40} = 0.15 \text{ second of arc.}$$

The resolution limit of the unaided eye is about 1 minute of arc.

Depth of Focus and Depth of Field The *depth of focus* for a camera is the distance the plate (or film) in the camera can be moved from the object without spoiling the resolution of the image. The *depth of field* is the corresponding distance the object can be moved. In practice these two limits depend on how the final photograph is to be viewed. Suppose that a point object lies at a distance from the camera such that it creates a well focused point on the plate. Another point object at a different distance creates a blurred circle on the plate. Whether or not these adjacent images can be resolved depends on the resolving power of the eye, whose limit is about 1 minute of arc. Assuming that the eye is normal and that the closest separation between the print and the eye is 25 cm, the two images must be no closer than

$$\frac{x}{25} = 1 \times \frac{\pi}{180 \times 60} \text{ radians}$$

$$x = 0.007 \text{ cm}$$

if they are to be at the limit of resolution. Usually a larger value of 0.025 cm is employed in cameras as being a useful limit. However, if the print is enlarged, then the compromise on the resolution becomes apparent.

The depth of focus of a lens can be increased by reducing its aperture with a stop. In Fig. 5 a point object creates a circular image on a plate after passing through a lens. The stop can be used to reduce the size of the image to an acceptable diameter of 0.025 cm.

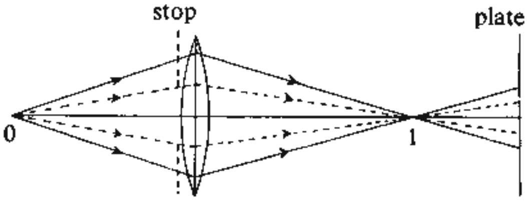

FIG. 5

The depth of focus of a microscope is approximately inversely proportional to the square of the numerical aperature. At a magnification of 1000X an objective with a numerical aperture of 1.40 has a depth of focus of only 0.0005 mm.

Field of View The field of view of an instrument is the angle subtended at the observer's eye by an object when the whole of the object can just barely be seen. In the case of a simple refracting telescope having two lenses this angle is given by $a_2/(f_1 + f_2)$, where a_2 is the aperture of the eye lens and f_1 and f_2 are the focal lengths of the objective and eyepiece respectively. (See Fig. 6.) If f_1 is doubled so as to double the magnifying power of the telescope, then the field of view is nearly halved.

Vignetting is the fall off in brightness at the edge of the field of view provided by a telescope or microscope. It is due to the loss of the rays that pass through the objective but which do not pass through the eyepiece. Vignetting is reduced by inserting a circular opening (called a field stop) at the point where the image from the objective is formed.

Illumination in Microscopes The final image in a microscope magnifying 1000X has an area one million times that of the object. The image is therefore only one-millionth as bright, assuming no loss of light in the instrument. To improve the illumination on a transparent object the light is concentrated on it by means of a *substage condenser.*

Dark ground illumination is used for viewing tiny particles or very fine lines. The illumination is made too oblique for light to pass directly from the condenser into the objective. The objects are seen by scattered and diffracted light against a dark background.

Phase contrast illumination is a method of making the structure of transparent objects visible. The arrangement consists of an annular stop at the condenser. Beyond the objective lies a phase plate consisting of a glass plate on which there is an annular layer of material to increase the optical path of the light by a quarter of a wavelength. Interference between direct and diffracted light augments the diffraction pattern of the image.

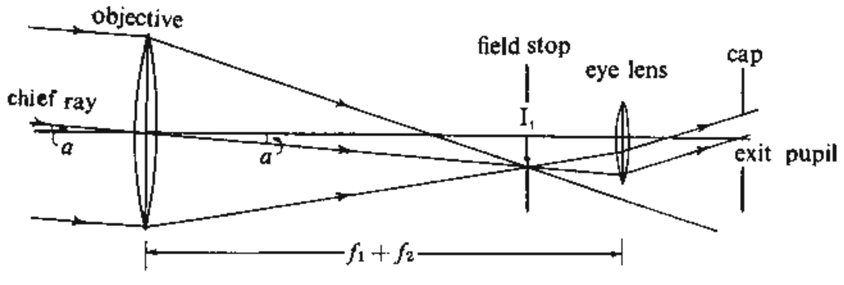

FIG. 6

Interference microscopy is another method of making fine structure visible. The transparent object is placed between two semi-silvered surfaces. The interference between light passing through the object and light passing by it is then observed.

Polarized light, obtained by a suitable polarizer below the condenser, is used in microscopes designed for geological testing of constituents in rock specimens.

Other Instruments The range of modern optical instruments and technology is vast. Here only a few items can be mentioned. Photography itself is a large area of ongoing research with continuous improvement in picture quality and reduction in size of the equipment. (See PHOTOGRAPHY.) Computer-designed lenses have revolutionized popular cameras. Highly sophisticated photography is currently employed in weather monitoring, earth resource research, and intelligence gathering. High-speed photography has captured images of events far too fleeting to be seen otherwise. Even a short pulse of light has been photographed in midflight.

The medical profession employs optical instrumentation to view inside the human body without surgery. Bundles of optical fibers illuminate the interior of a patient. They also carry an image of the interior out to a monitor to allow the doctor to see the interior. A number of ophthalmic instruments now enable a doctor to see into and perform various measurements on the human eye. The military employs telescopic gun sights, binoculars, periscopes and range finders. Many of these designs use infrared radiation and lasers in both the visible and infrared ranges. Civil engineers use theodolites and lasers for surveying. There is a variety of optical instruments used in the machine tool industry for angular measurements, aligning, and inspection for faults in the products.

Especially important for science and technology have been optical instruments designed to disperse light into its constituent wavelengths. These spectrometers have been crucial in the study of the fundamental nature of atoms and molecules and continue to play a role in many areas of research in chemistry, physics and astronomy. Spectrophotometers split the light from a source into its constituent wavelengths while measuring the intensity at each wavelength. Interferometers are used for fine distance measurement and instrument testing. Refractometers measure the index of refraction of a substance. Radiometers are employed for measurements of high temperatures.

One area of optical instrumentation that has exploded into a tremendous number of applications is that using coherent radiation in the infrared, visible, and ultraviolet. Lasers have been used in diverse applications ranging from cutting fabric to reattaching loose retinas. Laser beams allow one to measure precisely the distance to the moon as a check on the current theories of gravitation. They also allow one to monitor shifts in the tectonic plates as a prewarning of earthquakes.

Holography is an imaging process using coherent radiation. Once a novelty for its ability to present three-dimensional pictures, it has since proved valuable in industrial testing such as in searching for defects in rapidly rotating tires. Although not yet fully realized, three-dimensional movies may incorporate it.

OPTICAL PUMPING

Optical pumping describes the transfer of order from a beam of light or other electromagnetic radiation to matter. Some examples are the use of optical pumping to produce spin polarization of ground-state or excited-state atoms, molecules or ions; the optical production of metastable populations in matter, the optical excitation of spin-polarized conduction electrons in semiconductors, and the optical pumping of masers and lasers.

The antecedents of optical pumping go back to the original studies of atomic resonance absorption by Bunsen and Kirchhoff in the 19th Century. Zeeman, Wood, Hanle, Heydenburg, and others contributed to the early development of optical pumping. Kastler in 1949 coined the term *pompage optique* and suggested the combination of optical pumping with radiofrequency or microwave fields which resulted in the fruitful spectroscopic technique of optical double resonance, pioneered by Brossel and Bitter. The use of optical pumping to produce large numbers of spin-polarized ground-state atoms was also suggested by Kastler, who received the Nobel Prize in 1966 for his work.

To be effective as an optical pumping source, the light must differ from the normal blackbody radiation at the temperature of the matter. For example, the optical pumping source may produce a beam rather than isotropic radiation, the light may be polarized, or the spectral profile of the light may consist of a single narrow frequency band rather than the broad spectral distribution of thermal radiation.

Light which is effective for producing order in matter is also useful for detecting the existence of order in matter. For example, spin-polarized atoms attenuate and scatter resonance radiation differently than unpolarized atoms. Since light can be detected as single photons, the sensitivity of optical pumping experiments often is limited by photon counting noise (shot noise) rather than thermal noise as is the case with conventional microwave or nuclear magnetic resonance spectroscopy. Thus, optical pumping methods can be sensitive to only a few atoms in the pumping beam when optical detection is used.

A simple optical pumping experiment to produce spin-polarized excited atoms is illustrated in Fig. 1(a). There atoms are contained in a transparent cell C which is located in a static magnetic field H which defines the z axis of a coordinate system. The atom has angular momentum $J_g = 0$ in the ground state g and $J_e = 1$ in the excited state e, and the energy levels are split by the magnetic field as shown in Fig. 1(b). Resonance radiation, for example the 2537-Å line of mercury, is

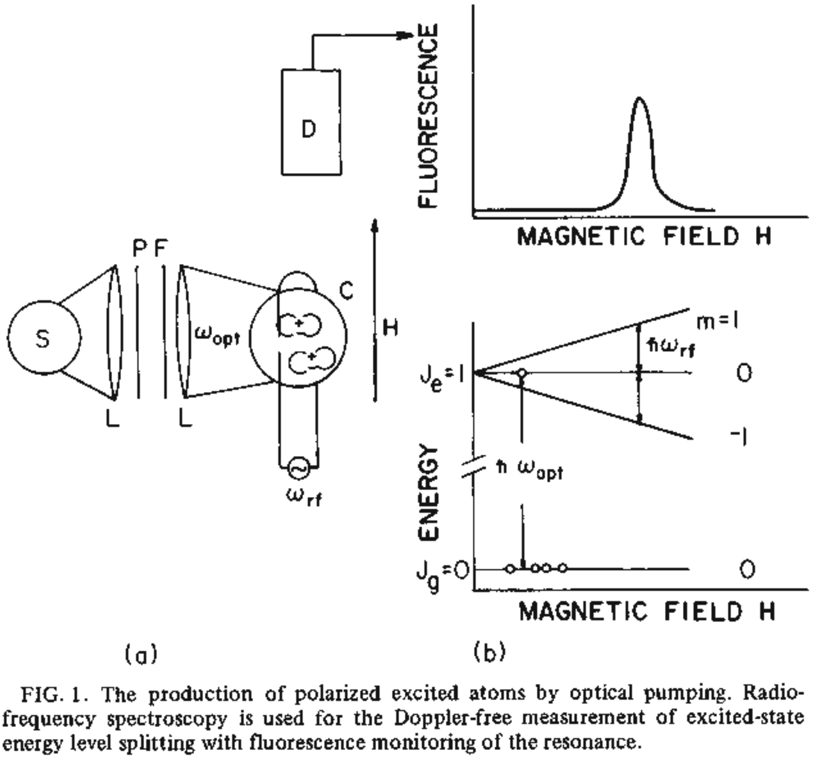

FIG. 1. The production of polarized excited atoms by optical pumping. Radiofrequency spectroscopy is used for the Doppler-free measurement of excited-state energy level splitting with fluorescence monitoring of the resonance.

isolated from the sources with the filter F, is linearly polarized with the polarizer P along the magnetic field and is used to pump the atom from the ground state to the sublevel of the excited state with azimuthal quantum number $m = 0$. Angular momentum selection rules prevent the light from exciting atoms into sublevels with $m = \pm 1$.

The fluorescent radiation has the characteristic angular distribution and polarization of an electric dipole antenna, so little radiation is received by a detector D located in the null of the antenna pattern. The pattern can be perturbed by driving transitions from the excited-state sublevel with $m = 0$ to the sublevles with $m = \pm 1$ with radiofrequency (rf) radiation of sufficient intensity and appropriate frequency. The atoms in the sublevels $m = \pm 1$ radiate strongly along the direction of the magnetic field and the rf transition is therefore detected as an increase in the intensity of light received by the detector. By observing the detected intensity as a function of the radiofrequency, a resonance curve can be plotted out which determines the splitting of the energy levels. The arrangement in Fig. 1 is typical of optical double resonance experiments which have been widely used to determine small energy splittings of excited atoms or molecules. It is important to note that the rf resonance curve is not affected by the doppler broadening of the optical lines used to detect the energy splittings.

Closely related to the optical double-resonance experiment of Fig. 1 are the methods of level-crossing spectroscopy, light-modulation spectroscopy, decoupling spectrosopy, the Hanle effect, and various other spectroscopic techniques which may be described by the term *perturbed fluorescence spectroscopy*, by analogy with the related nuclear field of perturbed angular correlations.

The production of ground-state or metastable-state polarized atoms is illustrated in Fig. 2. The atom has angular momenta $J = \frac{1}{2}$ in both the ground state and in the excited state. The atom is situated in a magnetic field H and is pumped by circularly polarized light which carries one unit of spin angular momentum along the magnetic field direction. Atoms in the ground state sublevel with azimuthal quantum number $m = -\frac{1}{2}$ can absorb light, but atoms in the sublevel with $m = +\frac{1}{2}$ cannot be-

cause of angular momentum selection rules. When the excited atoms decay they may fall back to the sublevel with $m = +\frac{1}{2}$ where they no longer absorb light. The result of repeated absorption and reemission of light is to pump the atoms into the ground-state sublevel with $m = +\frac{1}{2}$ where they no longer attenuate or scatter light. The pumping can be detected by a decrease in the fluorescence recorded by detector D_f. In contrast to the situation shown in Fig. 1, where only a small fraction of the atoms are maintained as polarized excited atoms, under favorable conditions substantially all of the atoms in the sample can be polarized for situations like Fig. 2 where ground-state atoms are pumped. However, the pumpup times in Fig. 2 are limited by the light intensity and can be as long as seconds, while the pumpup times in Fig. 1 are equal to the spontaneous decay times of the excited atoms and are typically some tens of nanoseconds.
