Main entry under title:

The Encyclopedia of physics.

1. Physics—Dictionaries. I. Besançon, Robert M.
(Robert Martin)
QC5.E546 1984 530'.03'21 84-13045
ISBN 978-0-442-00522-1 ISBN 978-1-4615-6902-2 (eBook)
DOI 10.1007/978-1-4615-6902-2

CONTRIBUTORS

JEROME L. ACKERMAN, Department of Chemistry, University of Cincinnati, Ohio. *Magnetic Resonance.*

KÊITSIRO AIZU, Hitachi Central Research Laboratory, Tokyo. *Ferroicity, Ferroelectricity, and Ferroelasticity.*

CHRISTOPHER W. ALLEN, Department of Chemistry, University of Vermont. *Chemistry.*

DOUGLAS L. ALLEN, Emery Industries, Cincinnati, Ohio. *Vapor Pressure and Evaporation.*

CHARLES L. ALLEY, Department of Electrical Engineering, University of Utah. *Modulation.*

ROBERT C. AMME, University of Denver, Colorado. *Ionization.*

DAVID L. ANDERSON, Department of Physics, Oberlin College, Ohio. *Electron.*

C. L. ANDREWS, Emeritus, Department of Physics, State University of New York at Albany. *Doppler Effect.*

ROBERT E. APFEL, Applied Mechanics, Yale University. *Cavitation.*

H. L. ARMSTRONG, Department of Physics, Queen's University, Kingston, Ontario. *States of Matter.*

ATAM P. ARYA, Department of Physics, West Virginia University. *Simple Machines.*

P. W. ATKINS, Physical Chemistry Laboratory, University of Oxford, England. *Physical Chemistry.*

GEORGE E. BACON, University of Sheffield, England. *Neutron Diffraction.*

D. C. BAIRD, Royal Military College of Canada, Kingston, Ontario. *Measurements, Principles of.*

RADU BALESCU, Faculty of Sciences, Université Libre de Bruxelles, Belgium. *Statistical Mechanics.*

WILLIAM BAND, Department of Physics, Washington State University. *Mathematical Physics* and *Quantum Theory.*

L. E. BARBROW, National Bureau of Standards, Washington, D.C. *Photometry.*

JAMES A. BARNES, National Bureau of Standards, Boulder, Colorado. *Atomic Clocks.*

C. J. BARTLESON, Research Laboratories, Eastman Kodak Company. *Color.*

ROBERT P. BAUMAN, Department of Physics, University of Alabama in Birmingham. *Absorption Spectra.*

WILLIAM L. BAUN, The Materials Laboratory, Wright Patterson Air Force Base, Ohio. *X-rays.*

JOSEPH J. BECKER, General Electric Research and Development Center, Schenectady, New York. *Magnetism.*

ALBERT C. BEER, Battelle-Columbus Laboratories, Ohio. *Hall Effect and Related Phenomena.*

BARRY A. BELL, Electrosystems Division, National Bureau of Standards. *Electrical Measurements* (with Forest K. Harris).

DAVID A. BELL, Emeritus, University of Hull, England. *Cybernetics.*

H. E. BENNETT, Michelson Laboratory, Naval Weapons Center, China Lake, California. *Reflection.*

REUBEN BENUMOF, Department of Applied Sciences, College of Staten Island, New York. *Alternating Currents.*

M. J. BERAN, School of Engineering, Tel Aviv University, Israel. *Coherence.*

LEO L. BERANEK, Acoustical Consultant, Winchester, Massachusetts. *Architectural Acoustics.*

ERIK BERGSTRAND, *Velocity of Light.*

ARTHUR I. BERMAN, Risø Library, Denmark. *Astronautics.*

ROBERT M. BESANÇON, Editor, The Encyclopedia of Physics, 515 Grand Avenue, Dayton, Ohio. *Physics.*

GEORGE L. BEYER, Retired, Eastman Kodak Company. *Molecular Weight.*

P. J. BILLING, *Induction Heating.*

EDWARD A. BIRGE, Department of Botany and Microbiology, Arizona State University. *Molecular Biology.*

CHARLES A. BITTMANN, Solid State Laboratory, Hewlett-Packard Company, Palo Alto, California. *Transistors.*

ALFRED K. BLACKADAR, Department of Meteorology, Pennsylvania State University. *Meteorology.*

JOHN P. BLEWETT, Brookhaven National Laboratory. *Accelerators, Linear.*

N. BLOEMBERGEN, Harvard University. *Light.*

WARREN B. BOAST, Emeritus, Department of Electrical Engineering, Iowa State University. *Potential.*

ANDREW H. BOBECK, AT&T Bell Laboratories. *Ferrimagnetism* (with W. H. von Aulock).

H. V. BOHM, Department of Physics, Wayne State University, Detroit, Michigan. *Fermi Surface* (with Norman Tepley and George Crabtree).

BRUCE BOLT, Department of Geology and Geophysics, University of California, Berkeley. *Seismology.*

JILL C. BONNER, Department of Physics, University of Rhode Island. *Antiferromagnetism.*

ROBERT M. BOYNTON, Department of Psychology, University of California, San Diego. *Vision and the Eye.*

G. E. BRIGGS, Emeritus, University of Cambridge, England. *Osmosis.*

FREDERICK C. BROCKHURST, Electrical Engineering Department, Virginia Polytechnic Institute and State University. *Motors, Electric* and *Electric Power Generation.*

STANLEY J. BRODSKY, Stanford Linear Accelerator Center, Stanford University. *Quantum Electrodynamics* (with Toichiro Kinoshita).

JAMES J. BROPHY, University of Utah. *Electronics.*

LAURIE M. BROWN, Department of Physics and Astronomy, Northwestern University, Evanston, Illinois. *Gauge Theories.*

STEPHEN G. BRUSH, Department of History and Institute for Physical Science and Technology, University of Maryland. *Kinetic Theory* and *Irreversibility.*

H. A. BUCHDAHL, Australian National University, Canberra. *Thermodynamics.*

DONALD G. BURKHARD, Department of Physics and Astronomy, University of Georgia. *Irradiance Calculations, Microwave Spectroscopy,* and *Solar Concentrator Design, Optics of.*

E. R. CAIANIELLO, Laboratorio di Cibernetica del Consiglio Nationale delle Ricerche, Naples, Italy. *Field Theory.*

ELTON J. CAIRNS, Lawrence Berkeley Laboratory and University of California, Berkeley. *Energy Storage, Electrochemical.*

EARL CALLEN, Department of Physics, American University, Washington, D.C. *Magnetostriction.*

G. S. CARGILL, III, IBM Thomas J. Watson Research Center, Yorktown Heights, New York. *Amorphous Metals.*

THEODORE G. CASTNER, Department of Physics and Astronomy, University of Rochester, New York. *Electron Spin.*

NICHOLAS CHAKO, Retired, Department of Mathematics, Queens College, City University of New York. *Aberrations.*

B. S. CHANDRASEKHAR, Department of Physics, Case Western Reserve University, Cleveland, Ohio. *Superconductivity.*

FRANK CHORLTON, Department of Mathematics, University of Aston in Birmingham, England. *Differential Equations in Physics.*

BRUCE P. CLAYMAN, Department of Physics, Simon Fraser University, Vancouver, British Columbia. *Interference and Interferometry.*

KENNETH J. CLOSE, Department of Physics, The Polytechnic of Central London, England. *Vacuum Techniques* (with John Yarwood).

IRA COCHIN, Department of Mechanical Engineering, New Jersey Institute of Technology, Newark. *Gyroscope* and *Inertial Guidance.*

E. RICHARD COHEN, Rockwell International Science Center, Thousand Oaks, California. *Constants, Fundamental.*

C. SHARP COOK, Department of Physics, University of Texas at El Paso. *Fallout.*

JOHN C. CORBIN, U.S. Air Force Aeronautical Systems Division, Wright-Patterson Air Force Base, Ohio. *Skin Effect.*

H. COTTON, University of Nottingham, England. *Optics, Geometrical.*

HERMAN V. COTTONY, H. V. Cottony Consulting Service, Bethesda, Maryland. *Antennas.*

GEORGE CRABTREE, Argonne National Laboratory, Illinois. *Fermi Surface* (with H. V. Bohm and Norman Tepley).

ROBERT G. CUNNINGHAM, Manufacturing Technology Division, Eastman Kodak Company. *Static Electricity* (with D. J. Montgomery).

R. H. DAVIS, Department of Physics, Florida State University. *Proton.*

L. WALLACE DEAN, III, Pratt and Whitney Aircraft Division of United Aircraft, East Hartford, Connecticut. *Physical Acoustics.*

PETER G. DEBRUNNER, Department of Physics, University of Illinois, Urbana. *Mössbauer Effect* (with Robert L. Ingalls).

BARBARA DECKER, *Volcanology* (with Robert W. Decker).

ROBERT W. DECKER, U.S. Geological Survey. *Volcanology* (with Barbara Decker).

JOHN DESANTO, Department of Mathematics, Colorado School of Mines. *Ocean Acoustics.*

N. G. DESHPANDE, Department of Physics and Institute of Theoretical Science, University of Oregon. *Current Algebra* and *Electroweak Theory.*

R. E. DE WAMES, Advanced Technology Energy Systems Group, Canoga Park, California. *Spin Waves* (with T. Wolfram).

A. DINSDALE, Retired, British Ceramic Research Association, Stoke-on-Trent, England. *Viscosity.*

RICHARD H. DITTMAN, Department of Physics, University of Wisconsin-Milwaukee. *Heat.*

ROBERT H. DOREMUS, Materials Engineering Department, Rensselaer Polytechnic Institute, Troy, New York. *Crystallization.*

GLENN L. DOWNEY, Department of Mechanical Engineering and Engineering Mechanics, University of Nebraska-Lincoln. *Dynamics.*

G. DRESSELHAUS, Lincoln Laboratory, Massachusetts Institute of Technology. *Cyclotron Resonance (Diamagnetic Resonance).*

MILDRED S. DRESSELHAUS, Department of Electrical Engineering and Physics, Massachusetts Institute of Technology. *Semiconductors.*

H. G. DRICKAMER, School of Chemical Sciences, University of Illinois at Urbana-Champaign. *Pressure, Very High.*

ROBERT H. EATHER, Physics Department, Boston College, Chestnut Hill, Massachusetts. *Aurora.*

ERNST R. G. ECKERT, Emeritus, Department of Mechanical Engineering, University of Minnesota. *Heat Transfer.*

D. EDELSON, AT&T Bell Laboratories, Murray Hill, New Jersey. *Polar Molecules.*

JOHN A. EISELE, Space Systems Division, Naval Research Laboratory, Washington, D.C. *Tensors and Tensor Analysis* (with Robert M. Mason).

LEONARD EISNER, Norwalk State Technical College, Norwalk, Connecticut. *Radiation, Thermal.*

RAYMOND J. EMRICH, Department of Physics, Lehigh University. *Fluid Dynamics* and *Fluid Statics.*

DUANE D. ERWAY, Xerox Medical Systems, Pasadena, California. *Solar Energy Utilization* (with Abe Zarem).

HOWARD T. EVANS, JR., U.S. Geological Survey, Reston, Virginia. *Crystallography* and *Crystal Structure Analysis.*

A. G. FISCHER, Department of Electrical Engineering, University of Dortmund, West Germany. *Electroluminescence.*

GRANT R. FOWLES, Physics Department, University of Utah. *Schrödinger Equation.*

MARTIN M. FREUNDLICH. *Electron Microscope.*

SUSUMU FUKUDA, Department of Electronics, Kyoto University, Japan. *Photoelasticity.*

RICHARD M. FULLER, Department of Physics, Gustavus Adolphus College, St. Peter, Minnesota. *Density and Specific Gravity* (with Robert G. Fuller).

ROBERT G. FULLER, Department of Physics, University of Nebraska-Lincoln. *Density and Specific Gravity* (with Richard M. Fuller).

HAROLD P. FURTH, Department of Astrophysical Science, Princeton University. *Magnetic Field.*

T. H. GEBALLE, Department of Applied Physics, Stanford University. *Calorimetry* (with Frances Hellman).

BARRY A. GEORGE. *Electron Optics.*

H. A. GERSCH, School of Physics, Georgia Institute of Technology, Atlanta. *Boltzmann's Distribution.*

ANTHONY B. GIORDANO, Polytechnic Institute of Brooklyn. *Microwave Transmission.*

JOSHUA N. GOLDBERG, Syracuse University, Syracuse, New York, *Gravitation.*

PAUL GOLDHAMMER, Department of Physics, University of Kansas. *Nuclear Structure.*

R. H. GOOD, JR., Department of Physics, Pennsylvania State University. *Photon.*

JOHN B. GOODENOUGH, Inorganic Chemistry Laboratory, University of Oxford, England. *Diamagnetism.*

CHARLES D. GOODMAN, Department of Physics, Indiana University, Bloomington. *Critical Mass* and *Isospin.*

CLARK GOODMAN, 95 Antigua Court, Coranado, California. *Cross Section and Stopping Power.*

JOSEPH W. GOODMAN, Department of Electrical Engineering, Stanford University. *Fourier Analysis.*

S. J. GREGG (retired), Department of Chemistry, University of Exeter, England. *Adsorption and Absorption.*

CLARK B. GROSECLOSE, Lawrence Livermore Laboratory, University of California. *Positron* (with William W. Walker).

JOHN B. GRUBER, Departments of Physics and Chemistry, Portland State University, Oregon. *Rare Earths* (with Richard P. Leavitt).

VINCENT P. GWINN, Department of Chemistry, University of California, Irvine. *Neutron Activation Analysis.*

Y. M. GUPTA, Shock Dynamics Laboratory, Department of Physics, Washington State University. *Shock Waves.*

CECIL W. GUINN, Physicist-Consultant, U.S. Air Force Department of Defense (retired). *Bionics.*

WALTER J. HAMER, Washington, D.C., *Electrochemistry.*

A. O. HANSON, Department of Physics, University of Illinois, Urbana-Champaign. *Compton Effect.*

W. HAPPER, Department of Physics, Princeton University. *Optical Pumping.*

AKIRA HARASIMA, Emeritus, Tokyo Institute of Technology, Japan. *Surface Tension.*

FOREST K. HARRIS (retired), Electricity Division, National Bureau of Standards. *Electrical Measurements* (with Barry A. Bell).

ROLAND H. HARRISON, National Institute for Petroleum and Energy Research, Bartlesville, Oklahoma. *Gases: Thermodynamic Properties.*

R. W. HART, Applied Physics Laboratory, Johns Hopkins University. *Light Scattering.*

RYUKITI R. HASIGUTI, Faculty of Engineering, University of Tokyo, Japan. *Lattice Defects.*

SHERWOOD K. HAYNES, Emeritus, Department of Physics, Michigan State University. *Auger Effect.*

G. E. HAYTON, Department of Electronic Engineering, University of Hull, England. *Feedback* (with P. M. Taylor).

RAYMOND W. HAYWARD, National Bureau of Standards, Washington, D.C. *Lorentz Transformations, Parity.*

JOHN HEADING, Department of Applied Mathematics, University College of Wales, Aberystwyth. *Matrices.*

EUGENE HECHT, Department of Physics and Astronomy, Adelphi University, Garden City, New York. *Mechanics.*

FRANCES HELLMAN, Department of Applied Physics, Stanford University. *Calorimetry* (with T. H. Geballe).

ANTONY HEWISH, Cavendish Laboratory, Cambridge, England. *Pulsars.*

FRED A. HINCHEY, Department of Mathematics, Northeastern University, Boston. *Vectors in Physics.*

RUSSELL K. HOBBIE, Space Science Center, University of Minnesota. *Biomedical Instrumentation.*

JOHN F. HOGERTON, S.M. Stoller Corporation, New York. *Atomic Energy.*

CHARLES A. HOLT, Department of Electrical Engineering, Virginia Polytechnic Institute and State University. *Induced Electromotive Force.*

ROBERT E. HOPKINS, Optizon Corporation, Rochester, New York. *Lens.*

ROLF HOSEMANN, Gruppe Parakristallforschung, % Bundesanstalt für Materialorufung, Berlin. *Colloids, Thermodynamics of*; *Diffraction by Matter and Diffraction Gratings*; *Microparacrystals*; *Microparacrystals, Equilibrium State of*; *Paracrystals.*

KAREL HUJER, Emeritus, Department of Physics and Astronomy, University of Tennessee at Chattanooga. *History of Physics.*

McALLISTER H. HULL, JR., Department of Physics, University of New Mexico. *Calculus of Physics.*

T. S. HUTCHISON, Royal Military College, Kingston, Ontario. *Ultrasonics* (with S. L. McBride).

ROBERT L. INGALLS, Department of Physics, University of Washington. *Mössbauer Effect* (with Peter Debrunner).

MAX JAMMER, Bar-Ilan University and Hebrew University, Israel. *Statics.*

J. V. JELLEY, Nuclear Physics Division, Atomic Energy Research Establishment, Harwell, England. *Čerenkov Radiation.*

R. J. JOENK, IBM Information Products Division, Boulder, Colorado. *Ferromagnetism* (with T. R. McGuire).

RUSSELL H. JOHNSEN, Department of Chemistry, Florida State University. *Elements, Chemical.*

FRANCIS S. JOHNSON, University of Texas at Dallas. *Space Physics.*

ROBERT A. JOHNSON, Materials Science Department, University of Virginia. *Irradiation, Displaced Atoms.*

JESS J. JOSEPHS, Department of Physics, Smith College, Northampton, Massachusetts. *Musical Sound.*

P. K. KABIR, Department of Physics, University of Virginia. *Weak Interactions.*

G. MICHAEL KALVIUS, Physik-Department Technische Universität, München, Federal Republic of Germany. *Magnetometry* (with H. J. Litterst).

WILLIAM M. KAULA, Department of Earth and Space Sciences, University of California, Los Angeles. *Geodesy.*

ROBERT W. KENNEY, Lawrence Berkeley Laboratory, University of California. *Bremsstrahlung and Photon Beams.*

D. W. KERST, Department of Physics, University of Wisconsin, Madison. *Betatron.*

WILLIAM F. KIEFFER (retired), Department of Chemistry, College of Wooster, Ohio. *Mole Concept.*

ALLEN L. KING, Emeritus, Department of Physics and Astronomy, Dartmouth College. *Refrigeration.*

GERALD W. KING, Department of Chemistry, McMaster University, Hamilton, Ontario. *Molecules and Molecular Structure.*

RUDOLPH KINGSLAKE (retired), Institute of Optics, University of Rochester, New York. *Refraction.*

R. H. KINGSTON, Lincoln Laboratory, Massachusetts Institute of Technology. *Laser.*

TOICHIRO KINOSHITA, Laboratory of Nuclear Studies, Cornell University. *Quantum Electrodynamics* (with Stanley Brodsky).

RANDALL D. KNIGHT, Department of Physics, Ohio State University. *Molecular Spectroscopy.*

HENRY J. KOSTKOWSKI, Spectroradiometry Consulting, Fairfax, Virginia. *Pyrometry, Optical.*

ALLAN D. KRAUS, U.S. Naval Postgraduate School. *Circuitry.*

REINOUT P. KROON (retired), University of Pennsylvania. *Dimensions.*

H. G. KUHN, Emeritus, Clarendon Laboratory, Oxford University. *Atomic Spectra.*

KAILASH KUMAR, Research School of Physical Sciences, Australian National University, Canberra. *Many-Body Problem.*

A. BARRY KUNZ, Department of Physics and Materials Research Laboratory, University of Illinois at Urbana-Champaign. *Solid State Theory.*

C. G. KUPER, Department of Physics, Technion-Israel Institute of Technology, Israel. *Polaron.*

DONALD W. KUPKE, Department of Biochemistry, School of Medicine, University of Virginia. *Centrifuge* (with Ralph A. Lowry and Houston G. Wood, III).

K. O. KUTSCHKE, Division of Chemistry, National Research Council of Canada, Ottawa. *Photochemistry.*

ROBERT T. LAGEMANN, Emeritus, Department of Physics, Vanderbilt University. *Wave Motion.*

HELMUT E. LANDSBERG, Institute for Physical Science and Technology, University of Maryland. *Geophysics.*

C. T. LANE. *Superfluidity.*

KENNETH R. LANG, Department of Physics, Tufts University. *Cosmology.*

PAUL LANGACKER, Department of Physics, University of Pennsylvania. *Grand Unified Theories.*

D. F. LAWDEN, Emeritus, University of Aston in Birmingham, England. *Mathematical Principles of Quantum Mechanics.*

RICHARD P. LEAVITT, Applied Physics Branch, Harry Diamond Laboratories, Adelphi, Maryland. *Rare Earths* (with John B. Gruber).

REUBEN LEE, Consulting Engineer. *Transformer.*

R. J. W. LEFÈVRE, Emeritus, School of Chemistry, Macquarie University, North Ryde, Australia. *Dipole Moments (Electrical and Magnetic).*

MARC D. LEVENSON, IBM Research Division, San Jose, California. *Kerr Effects.*

SUMNER LEVINE, Department of Materials Science and Engineering, State University of New York at Stony Brook. *Thermionics.*

DAVID R. LIDE, JR., Standard Reference Data, National Bureau of Standards. *Chemical Physics.*

INGOLF LINDAU, Electronics Laboratory, Stanford University. *Photoelectricity.*

ROBERT .LINDSAY, Department of Physics, Trinity College, Hartford, Connecticut. *Resonance.*

RAPHAEL M. LITTAUER, Laboratory of Nuclear Studies, Cornell University. *Pulse Generation.*

F. JOCHEN LITTERST, Physik-Department Technische, Universität München, Federal Republic of Germany. *Magnetometry* (with G. Michael Kalvius).

MICHAEL G. LITTMAN, Department of Mechanical and Aerospace Engineering, Princeton University. *Zeeman and Stark Effects.*

A. L. LOEB, Department of Visual and Environmental Studies, Harvard University. *Heisenberg Uncertainty Principle.*

JOSEPH J. LOFERSKI, Division of Engineering, Brown University. *Photovoltaic Effect.*

EDWARD J. LOFGREN, Lawrence Berkeley Laboratory, University of California. *Cyclotron* and *Accelerators, Particle.*

RALPH R. LOWRY, School of Engineering and Applied Science, University of Virginia. *Centrifuge* (with Donald W. Kupke and Houston G. Wood, III).

ROBERT A. LUFBURROW, Department of Physics, St. Lawrence University. *Carnot Cycles and Carnot Engines.*

H. R. LUKENS, IRT Corporation, San Diego, California. *Radioactive Tracers.*

PAUL S. LYKOUDIS, School of Nuclear Engineering, Purdue University. *Magneto-Fluid-Mechanics.*

DAVID N. LYON, Department of Chemical Engineering, University of California, Berkeley. *Liquefaction of Gases.*

WILLIAM J. MACKNIGHT, Polymer Science and Engineering, University of Massachusetts. *Polymer Physics* (with Lawrence E. Nielson).

J. D. MACKENZIE, School of Engineering and Applied Science, University of California, Los Angeles. *Vitreous State.*

ALFRED U. MAC RAE, AT&T Bell Laboratories, Holmdel, New Jersey. *Electron Diffraction.*

S. M. MAHAJAN, Institute for Fusion Studies, University of Texas at Austin. *Plasmas.*

FRED C. MAIENSCHEIN, Oak Ridge National Laboratory. *Nuclear Radiation Shielding.*

B. W. MANGUM, Temperature and Pressure Division, Center for Basic Standards, National Bureau of Standards. *Temperature and Thermometry.*

STEPHEN P. MARAN, Laboratory for Astronomy and Solar Physics, NASA-Goddard Space Flight Center. *Radio Astronomy.*

D. MARCUSE, AT&T Bell Laboratories, Holmdel, New Jersey. *Fiber Optics.*

HUMPHREY J. MARIS, Physics Department, Brown University. *Phonons.*

JOHN W. MARTIN, Department of Metallurgy and Science of Materials, University of Oxford, England. *Metallurgy.*

ROBERT M. MASON, Consultant, CLEF, Peterborough, New Hampshire. *Tensors and Tensor Analysis* (with John A. Eisele).

P. T. MATTHEWS, Department of Applied Mathematics and Theoretical Physics, University of Cambridge, England. *Strong Interactions.*

R. D. MATTUCK, Physics Laboratory I, H. C. Ørsted Institute, University of Copenhagen. *Feynman Diagrams.*

JOSEPH E. MAYER, University of California, San Diego. *Liquid State.*

S. L. MCBRIDE, Royal Military College of Canada, Kingston, Ontario. *Ultrasonics* (with T. S. Hutchison).

DAVID E. MCCULLOUGH, Tektronix, Inc., Beaverton, Oregon. *Oscilloscopes.*

C. B. A. MCCUSKER, School of Physics, University of Sydney, Australia. *Quarks.*

D. K. MCDANIELS, Physics Department, University of Oregon. *Solar Energy Sources.*

RAYMOND H. MCFEE, Consultant, Laguna Hills, California. *Infrared Radiation.*

T. R. MCGUIRE, IBM Thomas J. Watson Research Center, Yorktown Heights, New York. *Ferromagnetism* (with R. J. Joenk).

A. E. E. MCKENZIE (deceased). *Optical Instruments* (with Nigel C. McKenzie and J. D. Walker).

NIGEL C. MCKENZIE. *Optical Instruments* (with A. E. E. McKenzie and J. D. Walker).

G. T. MEADEN, The Journal of Meteorology, Tornado and Storm Research Organization, Bradford-on-Avon, England. *Conductivity, Electrical.*

HOWARD C. MEL, Donner Laboratory, University of California, Berkeley. *Radiation, Ionizing, Basic Interactions* (with Paul Todd).

MAEL A. MELVIN, Emeritus, Department of Physics, Temple University. *Antiparticles.*

HAROLD METCALF, Physics Department, State University of New York, Stony Brook. *Biophysics.*

DIETRICH MEYERHOFER, RCA Laboratories, Princeton, New Jersey. *Tunneling.*

WOLFGANG E. MOECKEL (retired), NASA-Lewis Research Center, Cleveland. *Electric Propulsion.*

ORREN C. MOHLER, Emeritus, Department of Astronomy, University of Michigan. *Solar Physics.*

D. J. MONTGOMERY, College of Engineering, Michigan State University. *Static Electricity* (with Robert G. Cunningham).

KARL Z. MORGAN, School of Nuclear Engineering, Georgia Institute of Technology. *Health Physics.*

A. H. MORRISH, Department of Physics, University of Manitoba, Canada. *Paramagnetism.*

J. MORT, Webster Research Center, Xerox Corporation. *Photoconductivity.*

ERWIN W. MÜLLER, Emeritus (deceased), Department of Physics, Pennsylvania State University. *Field Emission* (with Tien T. Tsong).

RAYMOND L. MURRAY, Emeritus, Nuclear Engineering, North Carolina State University. *Nuclear Reactors.*

RAYMOND R. MYERS, Department of Chemistry, Kent State University (Ohio). *Rheology.*

NORMAN H. NACHTRIEB, Department of Chemistry, University of Chicago. *Diffusion in Liquids.*

GÉRARD NADEAU, Département de Physique, Université Laval, Québec. *Elasticity.*

PAUL NELSON, Department of Mathematics, Texas Tech University. *Transport Theory* (with G. Milton Wing).

JACOB NEUBERGER, Department of Physics, Queens College, City University of New York. *Expansion, Thermal.*

LAWRENCE E. NIELSON, Redmond, Oregon. *Polymer Physics* (with William J. MacKnight).

JOHN S. NISBET, Ionosphere Research Laboratory, University of Pennsylvania. *Ionosphere.*

JOHN F. NOXON, Fritz Peak Observatory, Aeronomy Laboratory, NOAA, Boulder, Colorado. *Airglow.*

ALLEN NUSSBAUM, Department of Electrical Engineering, University of Minnesota. *Fourier Optics* and *Optics, Geometrical, Advanced.*

R. F. O'CONNELL, Department of Physics and Astronomy, Louisiana State University. *Faraday Effects.*

HARRY F. OLSON, late of RCA Laboratories. *Noise, Acoustical.*

JOHN M. OLSON, Institute of Biochemistry, Odense University, Denmark. *Photosynthesis.*

STEPHEN J. O'NEIL. *Servomechanisms.*

D. D. OSHEROFF, AT&T Bell Laboratories. *Cryogenics.*

RALPH T. OVERMAN. *Radioactivity.*

THORNTON PAGE, NASA Johnson Space Center, Houston, Texas. *Astrophysics.*

WILLIAM E. PARKINS, Consultant, Woodland Hills, California. *Energy Levels, Atomic* and *Work, Power and Energy.*

ROBERT PETERS, Speech and Hearing Sciences, University of North Carolina. *Hearing.*

NORMAN E. PHILLIPS, Department of Chemistry, University of California, Berkeley. *Heat Capacity.*

RICHARD A. PHILLIPS, Foster Grant Corporation. *Optics, Physical.*

JULIAN M. PIKE, National Center for Atmospheric Research, Boulder, Colorado. *Coriolis Effect.*

J. J. PINAJIAN, Oak Ridge National Laboratory. *Isotopes.*

MARTIN A. POMERANTZ, Bartol Research Foundation of The Franklin Institute, University of Delaware. *International Solar-Terrestrial Physics Programs.*

ALAN Y. POPE, Albuquerque, New Mexico. *Aerodynamics.*

G. M. POUND, Materials Science Department, Stanford University. *Condensation.*

R. D. PRESENT, Department of Physics and Astronomy, University of Tennessee. *Gas Laws* and *Intermolecular Forces.*

A. EDWARD PROFIO, Department of Chemical and Nuclear Engineering, University of California, Santa Barbara. *Nuclear Instruments.*

JOHN E. PRUSSING, Department of Aeronautical and Astronautical Engineering, University of Illinois at Urbana-Champaign. *Kepler's Laws of Planetary Motion.*

ERNEST RABINOWICZ, Department of Mechanical Engineering, Massachusetts Institute of Technology. *Friction.*

S. RAIMES, late of Imperial College, London. *Wave Mechanics.*

LAWRENCE L. RAUCH, Jet Propulsion Laboratory, California Institute of Technology. *Telemetry.*

FREDERICK REINES, Department of Physics, University of California, Irvine. *Neutrino.*

JOHN R. REITZ, Research Staff, Ford Motor Company. *Propagation of Electromagnetic Waves.*

D. C. REYNOLDS, Air Force Wright Aeronautical Laboratories, Avionics Laboratory, Wright-Patterson Air Force Base, Ohio. *Excitons.*

J. A. REYNOLDS, Culham Laboratory, United Kingdom Atomic Energy Authority, Abington, Oxfordshire. *Fusion Power* and *Laser Fusion.*

JAMES A. RICHARDS, JR., Agricultural and Technical College, State University of New York, Delhi. *Brownian Motion* and *Fermi Dirac Statistics and Fermions.*

WOLFGANG RINDLER, Department of Physics and Mathematics, University of Texas at Dallas. *Relativity.*

PETER H. ROGERS, School of Mechanical Engineering, Georgia Institute of Technology. *Electroacoustics.*

JACQUES E. ROMAIN, Centre de Recherches Routières, Belgium. *Time.*

DONALD M. ROSS, Propulsion Consulting Engineer. *Flight Propulsion Fundamentals* (with G. P. Sutton).

THOMAS D. ROSSING, Department of Physics, Northern Illinois University. *Acoustics.*

MILTON A. ROTHMAN (retired), Department of Physics, Trenton State College (New Jersey). *Conservation Laws and Symmetry.*

ROGERS D. RUSK, Emeritus, Department of Physics, Mount Holyoke College. *Nuclear Radiation.*

HAJIME SAKAI, Department of Physics and Astronomy, University of Massachusetts. *Spectroscopy.*

R. T. SANDERSON, Emeritus, Department of Chemistry, Arizona State University. *Bond, Chemical* and *Periodic Law and Periodic Table.*

ROBERT B. SCHAINKER, Electric Power Research Institute, Palo Alto, California. *Energy Storage, Thermal Mechanical.*

J. E. SCHIRBER, Sandia National Laboratories. *DeHaas-van Alphen Effect.*

H. M. SCHLICKE, Consulting Engineer, Milwaukee, Wisconsin. *Capacitance.*

PETER A. SCHROEDER, Physics Department, Michigan State University. *Thermoelectricity.*

WILLIAM T. SCOTT, Department of Physics, University of Nevada. *Electricity.*

GLEN T. SEABORG, Lawrence Berkeley Laboratory, University of California. *Transuranium Elements.*

ARTHUR H. SEIDMAN, Department of Electrical Engineering, Pratt Institute. *Diode (Semiconductor).*

J. M. H. LEVELT SENGERS, Institute for Basic Standards, National Bureau of Standards. *Compressibility, Gas.*

R. S. SHANKLAND, late of Case Western Reserve University. *Michelson-Morley Experiment.*

A. G. SHARKEY, JR., Pittsburgh Energy Technology Center. *Mass Spectrometry.*

WILLIAM F. SHEEHAN, Department of Chemistry, University of Santa Clara (California). *Chemical Kinetics.*

ERIC SHELDON, Department of Physics, University of Lowell (Massachusetts). *Neutron.*

HOWARD A. SHUGART, Department of Physics, University of California, Berkeley. *Atomic and Molecular Beams.*

WILLIAM A. SHURCLIFF, Harvard University, *Polarized Light.*

R. P. SHUTT, Brookhaven National Laboratory. *Spark and Bubble Chambers.*

W. A. SIBLEY, Oklahoma State University. *Color Centers.*

MIRIAM SIDRAN, Department of Natural Sciences, Baruch College/City University of New York. *Photography.*

LESTER S. SKAGGS, Cancer Therapy Institute, King Faisal Specialist Hospital, Riyadh, Saudi Arabia. *Medical Physics.*

MERRILL I. SKOLNIK, Radar Division, Naval Research Laboratory. *Radar.*

L. SLIFKIN, Department of Physics, University of North Carolina. *Diffusion in Solids.*

J. SMIDT, Laboratorium voor Technische Natuurkunde, Technische Hogeschool Delft, The Netherlands. *Relaxation.*

HOWARD M. SMITH, Eastman Kodak Company, Rochester, New York. *Holography.*

M. G. SMITH, Faculty of Computing, Management Science, Mathematics and Statistics, City of London Polytechnic. *Laplace Transforms.*

CHARLES P. SMYTH, Emeritus, Department of Chemistry, Princeton University. *Dielectric Theory.*

B. A. SOLDANO, Physics Department, Furman University. *Mass and Inertia.*

S. L. SOO, Department of Mechanical and Industrial Engineering, University of Illinois at Urbana-Champaign. *Equilibrium.*

DAVISON E. SOPER, Institute of Theoretical Science, University of Oregon, *Quantum Chromodynamics.*

J. W. T. SPINKS, University of Saskatchewan. *Radiation Chemistry* (with R. J. Woods).

M. T. SPRACKLING, Department of Physics, Queen Elizabeth College, University of London. *Mechanical Properties of Solids.*

J. C. SPROTT, Department of Physics, University of Wisconsin-Madison. *Electron Tubes.*

H. EUGENE STANLEY, Center for Polymer Studies and Department of Physics, Boston University. *Critical Phenomena.*

ROBERT L. STEARNS, Department of Physics, Vassar College. *Bose Einstein Statistics and Bosons.*

SAMUEL STEIN, Time and Frequency Division, National Bureau of Standards. *Frequency Standards.*

K. AA. STRAND, (formerly) U.S. Naval Observatory, Washington, D.C. *Astrometry.*

E. C. G. SUDARSHAN, Center for Particle Theory and Department of Physics, University of Texas at Austin. *Elementary Particles.*

G. P. SUTTON, Consulting Engineer, Danville, California. *Flight Propulsion Fundamentals* (with Donald M. Ross).

J. D. SWIFT, School of Physics, University of Bath, England. *Electrical Discharges in Gases.*

S. M. SZE, AT&T Bell Laboratories, Murray Hill, New Jersey. *Semiconductor Devices.*

P. M. TAYLOR, Department of Electronic Engineering, University of Hull, England. *Feedback.*

R. E. TAYLOR, Department of Anthropology, University of California, Riverside. *Radiocarbon Dating.*

PREFACE TO THE THIRD EDITION

Welcome to physics, the science of relativity and gravitation, matter and energy, quarks and quanta, lasers and masers, and many other intriguing scientific areas.

Since the appearance of the second edition many new developments have become important, and this edition has been expanded to include as many as possible of these new ideas without neglecting older, but still valid, concepts.

In a major effort to strengthen coverage of the rapidly moving and vitally significant field of particle physics, four new articles were added: Gauge Theories, Quantum Chromodynamics, Electroweak Theory, and Grand Unified Theories. In addition, many revisions were made in second edition articles in this field, including Elementary Particles, Weak Interactions, Strong Interactions, Parity, Current Algebra, and Quantum Theory.

Similarly, to increase emphasis on the important role of physics in medicine and biology, articles were added on Molecular Biology and Biomedical Instrumentation, and second edition entries on Biophysics, Medical Physics, Health Physics, and Bionics were brought up-to-date. Many other fields of physics, such as optics and energy storage, have received additional emphasis.

The general plan of this edition follows that of the first two editions and is discussed in their prefaces which follow. A reader with a limited background in physics should find it worth while to start by reading the article on "Physics," and then reviewing the articles on major areas of physics mentioned in that article and listed as cross-references at the end of the article.

The major credit for this book must go to the contributors who made it possible. Thanks are also due to the staff at the Van Nostrand Reinhold Company, who suggested the third edition, did a large amount of editing, and made a book out of a collection of manuscripts. To my wife, Leigh, goes my deep appreciation for accomplishing the vast amount of record keeping and secretarial work needed, and for doing much of the checking of manuscripts and proof-reading.

ROBERT M. BESANÇON

Dayton, Ohio

PREFACE TO SECOND EDITION

This second edition of the *Encyclopedia of Physics* follows the same general plan as was used for the first edition; that is, each article is written so as to be of primary value to the type of reader who is most apt to look for the particular topic. There are articles on major areas of physics which are at a low technical level, so as to be of maximum value to the reader with little prior knowledge of physics. There are also articles on major divisions and subdivisions of these areas. In general, these latter start with an introduction intended to define the topic and describe the concepts involved. This is followed by more detailed and advanced treatment for the reader with a stronger background in physics.

To cover more of physics, the book has been considerably expanded, both by adding new articles and by including new material on topics in the first edition. Many of the articles have been completely rewritten, others received major changes, while others, particularly those on major areas of physics, required little or no change.

As in the first edition, the major credit for any success the book may achieve belongs to the authors, many of whom not only contributed a tremendous amount of time and effort in preparing articles, but made valuable suggestions for other parts of the book.

The editors at the Van Nostrand Reinhold Company contributed a great deal to the readability and accuracy of the book, and to my wife, Leigh, goes credit for much careful proofreading, for the preparation of the extensive index, and for the typing and detailed record-keeping required in assembling a book of this magnitude.

To all of these workers my heartfelt thanks are due.

PREFACE TO FIRST EDITION

THE AIM of this book is to provide in one volume concise and accurate information about physics. It should be of use to physicists who need information outside of their own special areas of interest, to teachers and librarians who must answer inquiries, to students who wish to add to their funds of knowledge, and to engineers and scientists who encounter physical concepts in pursuit of their professions. The book has been made possible by the thoughtful and generous cooperation of more than 300 authors, both in this country and abroad, who have unstintingly contributed their time, skill and knowledge. Their names and affiliations are shown immediately before this preface.

The most challenging problem for the editor was deciding which topics to include and which to leave out, since the space available was very limited compared with the vast amount of knowledge that could have been included. The approach used was to provide short introductory articles on physics, on the history of physics, on measurements, and on symbols, units and nomenclature, plus general articles on the major areas of physics: heat, light, mechanics, acoustics, etc. To these were added entries on divisions and subdivisions of the major areas; these are more detailed and pitched at somewhat higher technical levels than the broader, more general articles. Other topics lie on the interfaces between major areas of physics or are on subjects that include both physics and other disciplines. These include, among others, astrophysics, geophysics, biophysics, and mathematical biophysics. Finally, a few articles cover sciences that are so closely related to physics that the differences are frequently merely matters of emphasis.

Each article attempts to provide not just a definition of a term but an explanation of an area of physics. No attempt was made to hold all articles at the same technical level; on the contrary, the level for each entry was aimed at those readers who would be most apt to look for information on that specific topic. The contents of each article was left to the discretion of the author as the one most capable of making the proper selection. Some of the authors found it necessary to use mathematics, as is done in many books on physics. However, the reader with a limited mathematical background will find many articles with no mathematics at all, and others with very little, while the reader who is so inclined can sink his teeth into the more mathematical paragraphs.

Most of the authors have provided references to summary articles and books, and in addition, cross-references to other articles in this book have been added wherever it was felt that they might be of particular help to the reader. A few cross-references are shown by the use of small capitals in the body of the text (thus, MECHANICS); others are listed at the end of the article. The index should serve to locate particular topics that might not be subjects of complete articles.

I should like to extend my heartfelt thanks to the authors who contributed so much and to Mr. G. G. Hawley and Mr. H. Simonds of the Reinhold Publishing Corporation who invited me to compile and edit this book as one of the series of scientific and technical encyclopedias published by that company. I also owe a very great deal to Mrs. Alberta Gordon and her staff, who did much of the editing and proofreading, and to my wife, Leigh, who contributed the bulk of the tremendous amount of clerical work involved as well as adding a great deal of enthusiasm and inspiration.

THE ENCYCLOPEDIA OF PHYSICS

A

ABERRATION

1. Introduction* When light is considered as an electromagnetic process or disturbance, it is characterized as a vibration phenomenon taking place in time and space. It propagates from one region to another in the form of waves. Mathematically, such a vibratory motion is governed by certain second-order partial differential equations—wave equations—which are derived from Maxwell's equations of the electromagnetic field. The solutions of these equations are distinguished by the presence of certain quantities accompanying periodic motion in space and time, namely wavelength λ and frequency ν. They depend on the medium in which propagation of waves takes place. However, in the classical description of light propagation it was assumed that the process acts like a stream of particles; consequently such light phenomena are described as *rays*—the old corpuscular hypothesis. In this description, the periodicity of waves is lost, i.e., the wavelength λ does not have any direct effect on the paths of the light rays through a medium. In analogy to the motion of particles, the propagation of light as rays must be governed by differential equations similar to the equations of particles. Indeed, the equations of light rays and of particles are derived from variational principles, the *Fermat Principle* for light propagation as rays and the *Principle of Least Action* for charged or uncharged particle motion, namely,

$$V(A, B) = \int_B^A \mu(x, y, z)\, ds, \qquad (1.1a)$$

$$S(A, B) = \int_A^B \sqrt{h - \varphi(x, y, z)}\, ds, \qquad (1.1b)$$

where $\mu(x, y, z)$ is the refractive index of the medium and $\sqrt{h - \varphi}$ is the action function of mechanics, h being the constant of energy and φ the potential energy function. In both problems, the first variation along the paths from A to B must vanish.†

The differential equations satisfying the variational conditions are known as the *Euler-Lagrange equations* of light rays and particles, respectively.

The equations of ray paths in a medium of refractive index $\mu(x, y, z)$ and of relativistic (fast) electrons in an electromagnetic field E, H are:[3,4]

Light Optics

$$\frac{d}{ds}\left(\mu \frac{dx}{ds}\right) = \frac{\partial\mu}{\partial x}$$

$$\frac{d}{ds}\left(\mu \frac{dy}{ds}\right) = \frac{\partial\mu}{\partial y} \qquad (I)$$

$$\frac{d}{ds}\left(\mu \frac{dz}{ds}\right) = \frac{\partial\mu}{\partial z}$$

Electron Optics

$$\frac{d}{ds}\left(\sqrt{\varphi(1+\epsilon\varphi)}\,\frac{dy}{ds}\right) = -\frac{1}{2}\,\frac{1+2\epsilon\varphi}{\sqrt{\varphi(1+\epsilon\varphi)}}\,E_x + \lambda_0\left(B_y \frac{dz}{ds} - B_z \frac{dy}{ds}\right)$$

$$\frac{d}{ds}\left(\sqrt{\varphi(1+\epsilon\varphi)}\,\frac{dy}{ds}\right) = -\frac{1}{2}\,\frac{1+2\epsilon\varphi}{\sqrt{\varphi(1+\epsilon\varphi)}}\,E_y + \lambda_0\left(B_z \frac{dx}{ds} - B_x \frac{dz}{ds}\right) \qquad (II)$$

$$\frac{d}{ds}\left(\sqrt{\varphi(1+\epsilon\varphi)}\,\frac{dz}{ds}\right) = -\frac{1}{2}\,\frac{1+2\epsilon\varphi}{\sqrt{\varphi(1+\epsilon\varphi)}}\,E_z + \lambda_0\left(B_x \frac{dy}{ds} - B_y \frac{dx}{ds}\right)$$

$$\lambda_0 = \frac{e}{2m_0}, \qquad \epsilon = \frac{e}{2m_0c^2}$$

*This article gives a theoretical treatment of optical aberration. For an introductory discussion, see the articles entitled LENS and OPTICS, GEOMETRICAL. For astronomic aberrations, see VELOCITY OF LIGHT.

†The differential ds is the element of arc of the path of the rays or particles. *Fermat's Principle* is of *least time*, i.e., $\int_{t_0}^{t_1} c\, dt = 0$, from which (1.1a) is derived by writing $dt = (1/v)\, ds$. The corresponding statement in mechanics is Hamilton's Principle, i.e., $\delta \int_{t_0}^{t_1} L\, dt = 0$, from which (1.1b) is derived, provided t does not enter explicitly into the Lagrangian L.

where ϵ is the relativistic correction factor, φ is the electric potential, and $E = -\text{grad } \varphi$. If $\epsilon = 0$, the electron optics equations reduce to the equation for electrons of nonrelativistic velocity.

A heuristic procedure for deriving the equations of geometric optics is to assume a waveform solution of the scalar wave equation $\Delta u - (1/v^2) U_{tt} = 0$, i.e.,

$$u(x, y, z, t) = A(x, y, z) \cdot \exp[ik(V(x, y, z) - ct)] \quad (1.2)$$

Substituting (1.2) into the wave equation and afterwards letting $\lambda \to 0$ or the propagation constant $k \to \infty$, the remaining terms involve only the phase function V:

$$[\text{grad } V(x, y, z)]^2 = \frac{c^2}{v^2} = \mu^2(x, y, z) \quad (1.3)$$

where μ is the refractive index of the medium. This equation is called the *characteristic equation of Hamilton* or the *Eiconal Equation*. The solution of this equation will give all the information about the imaging properties of a medium with refractive index μ. Unfortunately, complete (closed) solutions of (1.3) are known for only a few cases.

The phase function V = constant represents surfaces which propagate through the medium. At each point of the surface or wavefront a light ray intersects it normally. The amplitude on the surface Σ is given by $A(x, y, z)$, so each intersection point of a light ray with the phase function surface Σ becomes a source or disturbance which propagates from it in the form of a surface or wavefront, the *wavelets* of Huygens.

Equation (1.2) is equivalent to the propagation of light as rays, since grad V is proportional to a vector $\mathbf{s}^0$ which is normal to the wavefront. To account for the optical properties of the medium, the direction of the rays is $\mathbf{s} = (p, q, r^0)$, derived from $\mathbf{s}^0$ as follows. If α, β, γ are the geometric directions, so that $\mathbf{s}^0 = (\alpha, \beta, \gamma)$, then we have $\mathbf{s} = \mu \mathbf{s}^0$, with

$$p = \mu\alpha, \qquad q = \mu\beta, \qquad r^0 = \mu\gamma, \qquad \mathbf{s} \cdot \mathbf{s}^0 = 1.$$

Therefore, we have grad $V = \mathbf{s}^0$, with

$$\text{grad } V \cdot \mathbf{s}^0 = \frac{dV}{ds} = \mu(\mathbf{s} \cdot \mathbf{s}^0) = \mu. \quad (1.4)$$

Furthermore, multiplying by the element of arc ds (along the rays), we obtain

$$\int_A^B (\text{grad } V \cdot \mathbf{s}^0)\, ds = \int_A^B \frac{dV}{ds}\, ds$$

$$= V(B) - V(A) = \int_A^B \mu\, ds \quad (1.5)$$

which is the Fermat formulation (1.1a).

The expression $V(B) - V(A)$ gives the optical distance of the path of a ray from a point $A(x, y, z)$ of the wavefront Σ_0, $V(A) = c_0$, to the corresponding point $B(x', y', z')$ on Σ', $V(B) = c_1$. Since the rays are normal (normal congruence) to the wavefronts, the latter are optically equidistant from each other—a two-parameter of *transversal* surfaces. They may be regarded as an optically parallel (transversal) family of surfaces, the rays constituting the geodesics of the optical medium. Now each point $P(x, y, z)$ on the wavefront $V(A) = C_0$ may be regarded as giving rise to a source, or disturbance of a wave at an instant t', with amplitude $A(x, y, z)$. At another instant t, the wavelet arrives at a point $B(x', y', z')$. The totality of all wavelets originating on Σ_0 will now form a surface wave Σ', which is the envelope of all the wavelets. The distance from Σ_0 to Σ' is expressed by the characteristic function (point) $V(x, y, z, x', y', z') = v'(t' - t)$, where v is the velocity of the wave in the medium. The transformation of Σ_0 to Σ', or the rays issuing from points on Σ_0 to the corresponding rays intersecting Σ', describes a finite contact transformation, and the directions (optical) (p_0, q_0) on Σ_0 and (p', q') on Σ' are given by the equations

$$p_0 = -\frac{\partial v}{\partial x_0}, \qquad p' = -\frac{\partial v}{\partial x'}$$

$$q_0 = -\frac{\partial v}{\partial y_0}, \qquad q' = -\frac{\partial v}{\partial y'}$$

$$r_0 = -\frac{\partial v}{\partial z_0}, \qquad r' = -\frac{\partial v}{\partial z'}$$

where $r_0^2 = \mu_0^2 - p_0^2 - q_0^2$, etc., and $r = \sqrt{\mu^2 - p^2 - q^2}$ is the so-called Geometrical Optics Hamiltonian.

2. Aberrations A light ray originating at a point $P_0 = (x_0, y_0, z_0)$ on the object plane $z = z_0$, is imaged by the optical system at a point $P_1 = (x_1, y_1, z_1)$, which we assume to be on the Gaussian plane $z_1 = z_g$ of the system, and let the point $P_g = (x_g, y_g, z_g)$ be the Gaussian image of P_0. The two planes, $z = z_0$ and $z = z_g$ are conjugate planes.

We select in the image space a wave surface (front) Σ' which crosses the axis of the system at $O_a = (o, o, o_a)$. Let the ray intersect the surface Σ' at $P' = (x', y', z')$ as shown in Fig. 1. Now draw a spherical reference surface S of radius R equal to the distance $P_1 O_a$,. (Fig. 1).

The displacement vector $\overrightarrow{P_g P_1}$ measures the deviation of the actual image of P_0 from the corresponding (aberration free) Gaussian image. This deviation is called the *geometrical aberration of the ray*, or the *ray aberration*. On the other hand, the optical distance measured along the ray, namely, $\overrightarrow{P' P_g}$ is called the *aberration of the wave front*, or simply the *wave aberration*, which is positive if the reference surface is between the wave surface Σ' and the image plane $z = z_1$, negative otherwise.

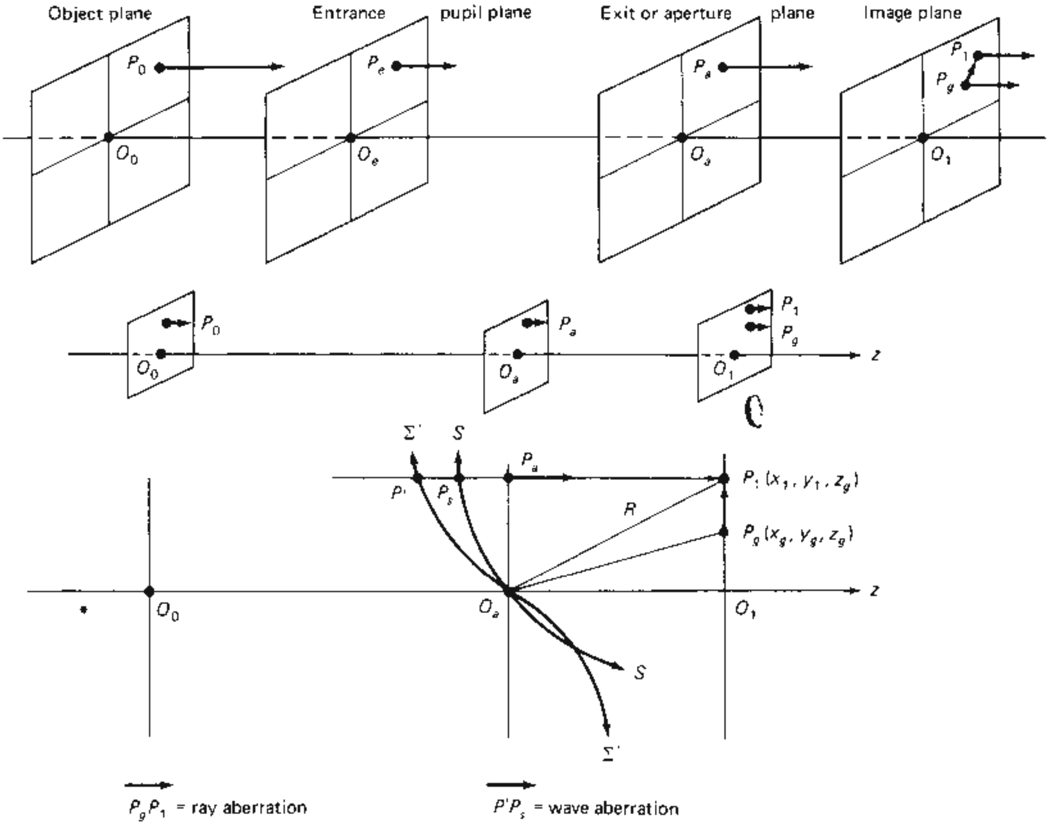

FIG. 1.

This wave aberration is expressed by the Hamilton characteristic function $V(x_0, y_0, z_0; x_1, y_1, z_1)$ or the difference of the characteristics at P_S and P', namely,

$$V(x_0, y_0, z_0; x_S, y_S, z_S) - V(x_0, y_0, z_0; x', y', z'). \quad (2.1)$$

Consequently, we can say that any ray, or bundle of rays emerging from the object plane (space) will reappear as another (unique) ray or bundle crossing the image* plane (space). The latter are characterized by the coordinates and directions in the image space, which will depend on the corresponding quantities of the object ray or bundle and the nature of the optical medium. Mathematically, this is called a mapping of the object space into the image space by the optical system; the intervening medium thus determines the type of mapping or transformation function.†

Let $P_0 = (x_0, y_0, z_0)$ and $P_1 = (x_1, y_1, z_1)$ be the coordinates of the object ray and the image ray, respectively. We write this change of the object ray into the image ray in the form of a transformation or mapping given by the relations

$$\begin{aligned} x_1 &= x_1(x_0, y_0, p_0, q_0, z_0, z_1) \\ y_1 &= y_1(x_0, y_0, p_0, q_0, z_0, z_1) \end{aligned} \quad (2.1a)$$

$$\begin{aligned} p_1 &= p_1(x_0, y_0, p_0, q_0, z_0, z_1) \\ q_1 &= q_1(x_0, y_0, p_0, q_0, z_0, z_1) \end{aligned} \quad (2.1b)$$

Eliminating p_0, q_0 from the first of set equations (2.1a) with the aid of the second set (2.1b) (assuming the Jacobians do not vanish), say

$$\begin{aligned} p_0 &= p_0(x_0, y_0, p_1, q_1, z_0, z_1) \\ q_0 &= q_0(x_0, y_0, p_1, q_1, z_0, z_1) \end{aligned} \quad (2.2)$$

we rewrite equations (2.1a, b) as follows:

$$\begin{aligned} x_1 &= x_{1i}(x_0, y_0, p_1, q_1, z_0, z_1) \\ y_1 &= y_1(x_0, y_0, p_1, q_1, z_0, z_1) \\ p_0 &= p_{0i}(x_0, y_0, p_1, q_1, z_0, z_1) \\ q_0 &= q_0(x_0, y_0, p_1, q_1, z_0, z_1) \end{aligned} \quad (2.3)$$

*This is true except at singular points of the mapping function, i.e., at focal points, caustics, etc.

†The type of transformation determining the image ray from the object ray in terms of the characteristic function V is called *contact transformation*, which changes any surface in object space into any new surface in the image space.

By separating the linear terms in the arguments, (2.1a) becomes

$$x_{1i} = \sum_i a_{ij} x_{0j} + \sum_j b_{ij} p_{0j} + f_i(x_{0j}, p_{0j})$$

$$p_{ij} = \sum_i e_{ij} x_{0j} + \sum_j d_{ij} p_{0j} + g_i(x_{0j}, p_{0j})$$

$$(ij = 1, 2) \quad (2.4)$$

where $f_i(x_{0j}, p_{1i})$, $g_i(x_{0i}, p_{0j})$ are the deviations from an aberration-free image point. The latter is represented by the linear forms. The four functions f_i, g_i are called the *ray aberrations* of geometrical optics. Knowledge of them will determine the deviation of the image from the object produced by the optical system.

The constants a_{ij} etc. will depend also on the positions of the object and image planes. However, by properly choosing their positions and making the principal ray coincide with the optic axis of the instrument, the linear forms may be reduced to

$$\begin{aligned} x_{1i} &= M x_{0i} \\ p_i &= N x_{0i} + L p_{0i} \end{aligned} \qquad (i = 1, 2) \quad (2.4')$$

where M is the magnification factor, N is the reciprocal of the focal distance, and $L = M^{-1}$. If $f_i = g_i = 0$ (no aberration), (2.4) defines an *ideal* optical system.

Consequently, the main task in any optical imaging problem is to calculate the position x_i and the directions (optical) p_i in image space, usually on a fixed plane $z = z_i$ and most often on a Gaussian image plane, from the knowledge of the functions f_i, g_i. In practice, one determines x_i, p_i by tracing individual rays through the system, applying the laws of refraction or reflection (mirrors) or, in the case of isotropic media, one employs numerical integration. The labor of obtaining fairly good approximate values of f_i, g_i is long, but with modern computers one is able to reduce the time by several orders of magnitude, so that now it is possible to calculate the image position function to a high degree of accuracy, at least for moderate orders of aberration.

Theoretically, the image functions can also be derived if one of the characteristic functions of the optical system is known, for instance, the point characteristic V or the mixed characteristic W. They are found from the relations

$$p_i = +\frac{\partial V}{\partial x_i}, \qquad x_i = -\frac{\partial W}{\partial p_i} \qquad (i = 1, 2) \quad (2.5)$$

where $W = V - (x_1 p_1 + y_1 q_1)$, exception being made for telescopic systems, where the angular characteristic applies.

We have already mentioned the difficulties encountered in finding V or W in explicit form, except in a few optical systems. However, for theoretical discussions an analysis of aberrations and, in a number of practical cases; the characteristic functions are overall better suited for classifying aberrations.[3,4,5,6]

3. General Theory of Aberrations In the design and construction of image forming systems, one tries to minimize the effects of aberrations on the image quality,* or at least remove some of the harmful aberrations by compensating different aberrations of various orders.[4,5]

In general, the balancing of aberrations is a difficult problem. However, a general (formal) analysis of aberrations without specifying the characteristic properties of the optical system—except for geometric configurations (symmetry etc.) based on the wavefront concept of light propagation—will facilitate the discussion of characterizing and classifying the aberrations.

The fundamental functions needed to make a formal analysis of the image forming properties of an optical system are the characteristic functions of Hamilton: the *point characteristic*, or *eiconal*, $V(x_{0i}, x_i)$; two *mixed characteristics*,† $W(x_{0i}, p_i)$, $\bar{W}(x_{1i}, p_{0i})$;‡ and the *angular characteristic* $T(p_{0i}, p_{1i})$. These functions are related to each other through a so-called Legendre transformation. For instance, if the point characteristic $V(x_{0i}, x_i)$ is known, then the mixed characteristic $W(x_{0i}, p_i)$ is obtained by subtracting a term $x_1 p_1 + y_1 q_1$ from V, i.e.,

$$W(x_{0i}, p_i) = V(x_{0i}, x_i) - (x_1 p_1 + y_1 q_1) \quad (3.1)$$

where x_1, y_1 are expressed in terms of $(x_0, y_0; p_1, q_1)$.§ We then obtain the image coordinates on the image plane $z = z_1 = 0$ and the directions p_0, q_0 on the object plane $z = z_0 = 0$ from

$$\begin{aligned} x_1 &= -\frac{\partial W}{\partial p_1}, & p_0 &= -\frac{\partial W}{\partial x_0} \\ y_1 &= -\frac{\partial W}{\partial q_1}, & q_0 &= -\frac{\partial W}{\partial y_0}. \end{aligned} \qquad (3.2)$$

The above relations, together with the relations $x_0 = \partial V/\partial p_0$, $x_1 = \partial V/\partial p_1$, given by the point characteristic, and the expression $V - W = x_1 p_1 + y_1 q_1$, constitute a Legendre transformation; the inverse of this transformation, i.e., W, is obtained from V by subjecting $x_1 p_1 + y_1 q_1$ (the image coordinates) to a Legendre transformation.

The other mixed characteristic (object characteristic) is simply $\bar{W}(x_1, y_1, z_1, p_0, q_0, z_0)$.

The angular characteristic, often used in telescopic reflecting systems, etc., is related to V

*In electrical terminology, "noise."

†The *image* and the *object* characteristics, respectively.

‡We have assumed the object and image planes to be conjugate planes in the Gaussian sense. In general, W will depend on the six parameters, and for the case where the image plane is in a homogeneous medium it will depend on five parameters: x_0, y_0, p_1, q_1, z_1.

§$\bar{W} = v + y_0 p_0 + y_0 q_0$.

as follows. The coordinates of the object and image planes are given by the expressions

$$x_0 = \frac{\partial T}{\partial p_0}, \quad x_1 = -\frac{\partial T}{\partial p_1}$$
$$y_0 = \frac{\partial T}{\partial q_0}, \quad y_1 = -\frac{\partial T}{\partial q_1}. \tag{3.4}$$

The relations above, together with those corresponding to V, also constitute a Legendre transformation between T and V, and $T = V + x_0p_0 + y_0p_0 - x_1p_1 + y_1p_1$.

In the analysis of wave or ray aberrations, it is more convenient to deal with the mixed characteristic $W(x_0, y_0, p_1, q_1; z_0, z_1)$, especially in the diffraction theory of optical systems, since it enters in the phase function of the solution of the wave equation discussed in section 1. Now we see that apart from the linear terms, the ray aberration functions $f_i(x_{0i}, p_i)$, $g_i(x_{0i}, p_i)$ are derived by simple differentiation of W or V or T, whichever is appropriate to the problem.

We have already mentioned the difficulties of obtaining explicit (closed form) expressions for V or W, therefore we express W in a series of homogeneous polynomials of various degrees (orders) in the four variables, say (x_0, y_0, p_1, q_1) for fixed object $(z = z_0)$ and image $(z = z_1)$ planes:*

$$W = W_0 + W_1 + W_2 + W_3 + W_4 + \cdots + W_N + \cdots \tag{3.5}$$

where W_N is a homogeneous polynomial of degree N in the arguments. The leading term W_0 does not play any role, and W_1 represents free space. The quadratic polynomial W_2 may be written as

$$W_2 = \sum_{i,j=1}^{4} a_{ij}u_iu_j \tag{3.6}$$

where $u_1 = x_0$, $u_2 = y_0$, $u_3 = p_1$, $u_4 = q_1$. We write in full

$$\begin{aligned} W_2 = {} & a_{11}x_0^2 + a_{12}x_0y_0 + a_{22}y_0^2 + a_{13}x_0p_1 \\ & + a_{23}y_0p_1 + a_{14}x_0q_1 + a_{24}y_0q_1 \\ & + a_{33}p_1^2 + a_{34}p_1q_1 + a_{44}q_1^2. \end{aligned} \tag{3.7}$$

Therefore, from (3.2) the image coordinates are

$$\begin{aligned} x_1 &= \frac{\partial W_2}{\partial p_1} = a_{13}x_0 + a_{23}y_0 + 2a_{33}p_1 + a_{34}q_1 \\ y_1 &= \frac{\partial W_2}{\partial q_1} = a_{14}x_0 + a_{24}y_0 + a_{34}p_1 + 2a_{44}q_1. \end{aligned} \tag{3.8}$$

We do not write the directions (p_0, q_0) of the ray at the object point (x_0, y_0). Equations (3.8) are the same linear terms we discussed in section 2. Therefore, W_2 represents what is known as the paraxial approximation of the characteristic function and of the image functions (x_1, y_1). In certain arrangements (special optical systems) mentioned in section 2, the coefficients a_{23}, a_{34}, and a_{14}, and even a_{33}, a_{44}, may be eliminated so that one obtains an ideal system. Consequently, one does not consider this approximation to W as an aberration.

The next approximation is the homogeneous polynomial of degree 3, W_3. Its expansion is given by

$$W_3 = \sum_{i,j,k=1}^{4} a_{ijk}u_iu_ju_k. \tag{3.9}$$

Further, W_4 is expanded as

$$W_4 = \sum_{i,j,k,l=1}^{4} a_{ijkl}u_iu_ju_ku_l. \tag{3.10}$$

There are altogether 20 terms in W_3. If we fix the object plane, $z = z_0$, then the homogeneous terms in x_0y_0 (alone) are omitted, since they do not account for any displacement in the image plane. There are four such terms in W_3,

$$x_0^3, x_0^2y_0, x_0y_0^2, y_0^3$$

so the number of independent wavefront aberrations reduces to 16.

In W_4 there are altogether 35 terms, but by discarding the terms in x_0, y_0 alone, the number of independent wave aberrations diminishes to 30.† On the other hand, if the system has a plane of symmetry, say, either the x-z or y-z plane, i.e., rays lie on a meridian plane, then the number reduces further to 16 terms. Identifying $u_1 = x_0$, $u_2 = y_0$, $u_3 = p_1$, $u_4 = q_1$, the terms with the following coefficients a_{ijkl} vanish:‡

$$\begin{aligned} a_{0031} = a_{0013} = a_{1003} = a_{0130} = a_{1021} \\ = a_{2011} = a_{1120} = a_{1102} = a_{3001} \\ = a_{2110} = a_{0310} = a_{1201}. \end{aligned}$$

The number of wave aberration terms in W_N increases considerably with N. Therefore we shall limit the analysis to W_4, i.e., to third-order (ray) aberrations for optical systems possessing rotational symmetry, since in most if not all

*The W_k depend on z_0, z_1. However, being fixed quantities, they are absorbed by the constant coefficients: A_{ij}, etc.

†The number of individual terms in W_N is given by

$$N = \frac{(n+1)(n+2)(n+5)}{3!}.$$

‡The numbers appearing in the subscripts indicate the exponents of the variables associated with the indices. For example, a_{1030} corresponds to the term $a_{1030}x_0p^3$, a_{1111} to $a_{1111}x_0y_0pq$, etc.

practical cases the instruments possess geometrical symmetry. The wave aberration function W then depends only on three parameters,

$$u_1 = x_0^2 + y_0^2, \qquad u_2 = p_1^2 + q_1^2,$$
$$u_3 = 2(x_0 p_1 + y_0 q_1), \qquad (3.11)$$

known as the three optical invariants of the system. In the expansion of W, the odd polynomials disappear, and we have

$$W = W_0 + W_2 + W_4 + \cdots.$$

The image functions are

$$x_1 = \frac{\partial W_2}{\partial p_1} = 2(a_3 x_0 + a_2 p_1),$$
$$y_1 = \frac{\partial W_2}{\partial q_1} = 2(a_3 y_0 + a_2 q_1). \qquad (3.12)$$

These expressions give an image free of aberration.

The W_4 term contribution is given by

$$W_4 = a_{11}u_1^2 + a_{22}u_2^2 + a_{33}u_3^2 + a_{12}u_1u_2$$
$$+ a_{13}u_1u_3 + a_{23}u_2u_3. \quad (3.13)$$

The image functions (deviations from the ideal or Gaussian image) are derived from the expressions

$$\delta x_{1i} = \frac{\partial W_4}{\partial p_{1i}} = \frac{\partial W_4}{\partial u_j}\frac{\partial u_j}{\partial p_{1i}},$$
$$\delta p_{0i} = -\frac{\partial W_4}{\partial x_{0i}} = -\frac{\partial W_4}{\partial u_j}\frac{\partial u_j}{\partial x_{0i}}$$
$$(i = 1, 2; j = 1, 2, 3) \quad (3.14)$$

In (3.13) one notices the presence of only six aberration coefficients, $a_{11}, a_{22}, \ldots, a_{23}$. Of these a_{11} is associated with the object coordinates $x_{0i} = (x_0, y_0)$. It is not considered an aberration per se. To obtain the five types of third-order aberrations from (3.13) we assume without loss of generality rays restricted to points $(x_0, 0)$ on the object plane and, after differentiation, letting $p_1 = \rho \cos \varphi, q_1 = \rho \sin \varphi$, we arrange the right-hand side of (3.13) in descending powers of ρ. The x_{1i} will now depend on five aberration coefficients, excluding a_{11}, whereas p_{0i} will be free of a_{22}. This arrangement for δx_{1i} will determine the five geometrical "Seidel" aberrations of third order. The terms in $(\delta x_1, \delta y_1)$ depending on ρ^3 alone give the *spherical* or *aperture* aberration; the terms in ρ^2 give the *primary coma*; the linear terms in ρ are known as *astigmatism* and *curvature of field*; and the term independent of ρ produces *distortion* of the *pincushion* or *barrel* type.

For a detailed discussion, we refer the reader to the treatises in Refs. 3 and 5, and for electron optical systems to those listed in Ref. 4. However, in diffraction problems[2,5] the expansion of the wave aberration functions for rotational symmetric systems is usually given in terms of three new parameters σ, ρ, φ, which are related to the ray functions x_0, y_0, p_1, q_1 in object and image space (planes) as follows:

$$\sigma^2 = u_1 = x_0^2 + y_0^2, \qquad \rho^2 = u_2 = p_1^2 + q_1^2,$$
$$\sigma\rho \cos \varphi = u_3 = 2(x_0 p_1 + y_0 q_1). \quad (3.15)$$

The wave aberration function is written in the form

$$W(x_0, y_0, p_1, q_1, z_1) = \sum_{l,n,m} b_{lnm}\sigma^{2l+m} \cos^m \varphi \qquad (3.16)$$

where $l, m = 0, 1, \ldots, n = 0, 1, 2$, and $n - m > 0$ and even. This expansion is the *standard* or *classical* expansion used by earlier investigators before the Zernike–Nijboer papers on diffraction theory of aberrations. The degree of the polynomial W_K is equal to the sum of the exponents of σ and ρ in the term $b_{lnm}\sigma^{2l+m}\rho^n \cos^m \varphi$.

For instance, if we let $2l + n + m = 2$, i.e., W_2, then the three terms of W_2 are obtained by letting $m = 0$, $l = 1$, $n = 0$; $m = 0$, $l = 0$, $n = 2$; $m = 1, l = 0, n = 1$.

A more convenient expansion of W is a Fourier-like expansion*

$$W = \sum_{l,n,m} b_{lnm}\sigma^{2l+m}\rho^n \cos m\varphi. \quad (3.17)$$

Here, a single term $b_{lnm}\sigma^{2l+m}\rho^n \cos m\varphi$ represents any of the homogeneous polynomials discussed above. For example, W_2 is obtained by letting $l = 1$, $n = m = 0$; $l = m = 0$, $n = 2$; and $l = 0$, $m = n = 1$. The W_2 polynomial is given by the expressions

$$W_2 = b_{100}\sigma^2 + b_{020}\rho^2 + b_{011}\sigma\rho \cos \varphi \quad (3.18)$$

which is the same as in the standard expansion. However, the Fourier form has the advantage of being an orthogonal function in φ, so it facilitates the integration over φ in the diffraction integrals.

On the other hand these expansions are superseded in their application to the diffraction theory of aberrations by the Zernike–Nijboer form of expansion, i.e.,

$$W = \sum_{l,n,m} b_{lnm}\sigma^{2l+m} Z_n^m(\rho) \cos m\varphi \quad (3.19)$$

where l, n, m have the same meaning as in the earlier expansions, but here $Z_n^m(\rho)$ is a polynominal of degree n in ρ and not a single term ρ^n as in the other expansions. Furthermore, the Zernike polynomials, Z_n^m are orthogonal over a circular plane region. In the next sections we shall discuss the advantage of this expansion

*For nonsymmetric systems one introduces another sum in $\sin m\varphi$, i.e., a complete Fourier-series expansion.

over the other two, the standard and the Fourier developments.

In (3.20) below and in Tables 1 and 2 are listed the expansions of W_2, W_4, and W_6 in the three expansion forms[5] and the Zernike polynomials $Z_n{}^m$ up to $n = 6$, $m = 6$.

In each of them the order for a single aberration member is $N = 2l + n + m - 1$, and the number of types in a single aberration is $M = (1/\gamma)(N + 1)(N + 8)$. The degree of the polynomial W_K representing the wavefront function is $K = N + 1 = 2l + n + m$.

$$\begin{aligned}
W_2 &= a_1\sigma^2 + a_2\rho^2 + a_3\sigma\rho\cos\varphi \\
W_4 &= a_{11}\sigma^4 + a_{12}\sigma^2\rho^2 + a_{22}\rho^4 \\
&\quad + a_{13}\sigma^3\rho\cos\varphi + a_{23}\sigma\rho^3\cos\varphi \\
&\quad + a_{33}\sigma^2\rho^2\cos\varphi^2 \\
W_6 &= a_{111}\sigma^6 + a_{112}\sigma^4\rho^2 + a_{122}\sigma^2\rho^4 \\
&\quad + a_{222}\rho^6 + a_{113}\sigma^5\rho\cos\varphi \\
&\quad + a_{123}\sigma^3\rho^3\cos\varphi + a_{133}\sigma^4\varphi^2\cos^2\varphi \\
&\quad + a_{223}\sigma\rho^5\cos\varphi + a_{233}\sigma^2\rho^4\cos^2\varphi \\
&\quad + a_{333}\sigma^3\rho^3\cos^3\varphi
\end{aligned} \tag{3.20}$$

$Z_0{}^0 = 1$	$Z_5{}^1 = 10\rho^5 - 12\rho^3 + 2\rho$
$Z_1{}^1 = \rho$	$Z_5{}^3 = 5\rho^5 - 4\rho^3$
	$Z_5{}^5 = \rho^5$
$Z_2{}^0 = 2\rho^2 - 1$	
$Z_2{}^2 = \rho^2$	$Z_6{}^0 = 20\rho^3 - 30\rho^4 + 12\rho^2 - 1$
	$Z_6{}^2 = 15\rho^6 - 20\rho^4 + 6\rho^2$
$Z_3{}^1 = 3\rho^3 - 2\rho$	$Z_6{}^4 = 6\rho^6 - 5\rho^4$
$Z_3{}^3 = \rho^3$	$Z_6{}^6 = \rho^6$
$Z_4{}^0 = 6\rho^4 - 6\rho^2 + 1$	
$Z_4{}^2 = 4\rho^4 - 3\rho^2$	
$Z_4{}^4 = \rho^4$	

4. Classifications of Aberration for Rotational Symmetric Systems[2,4,5] To classify the ordinary (ray) aberrations, we shall examine the different terms of the W_n of the wavefront aberration function W given by the three expansion forms u_1, u_2, u_3. Each W_n depends on the three optical invariants $u_1 = x_0{}^2 + y_0{}^2$, $u_2 = x_0p + y_0q$, $u_3 = p^2 + q^2$, or in σ, ρ, and φ given by the relations $\sigma^2 = u_1$, $\rho^2 = u_3$, and $\sigma\rho\cos\varphi = u_2$. The first three terms of W, i.e., W_2, W_4, W_6 are given in Tables 1 and 2, from which we can obtain the ordinary aberrations of first, third and fifth orders. A typical term of W_n is

Zernike–Nijboer development (new)

$$b_{lnm}\sigma^{2l+m}Z_n{}^m(\rho)\cos m\varphi \tag{4.1a}$$

Fourier development

$$b_{lnm}\sigma^{2l+m}\rho^n\cos m\varphi \tag{4.1b}$$

Standard (classical) development

$$a_{lnm}\sigma^{2l+m}\rho^n\cos^2 m\varphi \tag{4.1c}$$

The order N of a single aberration (geometrical or ray) is $N = 2l + n + m - 1$, and the number of terms or types of aberration is $M = \frac{1}{8}(N + 1)(N + 7)$. The degree L of the polynomial W_n giving the order of the wave aberrations is $L = N + 1 = 2l + n + m$, where $l = 0, 1, 2, \ldots, n = 1, 2, \ldots, m = 0, 1, 2, \ldots$, and $n - m$ is even, making L even and equal to the sum of the powers of σ and ρ which appear in each individual member of the wave aberration function.

Consider first-order aberrations, i.e., W_2. Since $N = 1$, there are actually three terms in W_2. From Tables I and II they are

Zernike–Nijboer

4	$\sigma^2\rho^4(140)$		$\sigma^4\rho^2\cos^2\varphi(042)$	
5		$\sigma\rho^5\cos\varphi(051)$		
6	$\rho^6(060)$			

$$b_{100}\sigma^2 Z_0{}^0(\rho), \qquad b_{011}\sigma Z_1{}^1(\rho)\cos\varphi, \qquad b_{020}Z_2{}^0(\rho) \qquad (4.2a)$$

Fourier

$$b_{100}\sigma^2, \qquad b_{011}\sigma\rho\cos\varphi, \qquad b_{020}\rho^2 \qquad (4.2b)$$

Standard

$$a_{100}\sigma^2, \qquad a_{011}\sigma\rho\cos\varphi, \qquad a_{020}\rho^2. \qquad (4.2c)$$

We shall ignore the term or terms which depend solely on σ. Therefore we have only two members, whose coefficients are b_{011} and b_{020}, etc. However, these two terms are not aberrations in the sense of representing a deformation of the image. They simply shift the focal point, the b_{020} term along the principal axis and the b_{011} in the image plane at $(x_1, 0, 0)$ from the origin $(0, 0, 0)$—the intersection of the principal ray with the image plane. Consequently, one does not consider the first-order terms as aberrations.

The next order aberrations come from W_4. These are called third-order aberrations, five in all according to the value of N (see above). Again we ignore terms solely in σ, since they do not influence the image pattern. The terms in W_4 are given below. From the tables, we have:

Zernike–Nijboer type

$$\underline{l = 0, n + m = 4}$$

$$b_{040}Z_4{}^0(\rho) = b_{040}(6\varphi^4 + 6\rho^2 + 1) \qquad m = 0, n = 4,$$

$$b_{031}\sigma Z_3{}^1(\rho)\cos\varphi = b_{031}\sigma(3\rho^3 - 2\varphi)\cos\varphi \qquad m = 1, n = 3,$$

$$b_{022}\sigma^2 Z_2{}^2(\rho)\cos 2\varphi = b_{022}\sigma^2\rho^2 \cos 2\varphi \qquad m = 2, n = 2, \quad (4.3a)$$

$$\underline{l = 1, n + m = 2}$$

$$b_{120}\sigma^2 Z_2{}^0(\rho) = b_{120}\sigma^2(2\rho^2 - 1) \qquad m = 0, n = 2,$$

$$b_{111}\sigma^3 Z_1{}^1(\rho)\cos\varphi = b_{111}\sigma^3\rho\cos\varphi \qquad m = 1, n = 1,$$

Fourier type

$$b_{040}\rho^4, \qquad b_{031}\sigma\rho^3\cos\varphi, \qquad b_{022}\sigma^2\varphi^2\cos 2\varphi, \qquad b_{120}\sigma^2\rho^2, \qquad b_{111}\sigma^3\rho\cos\varphi \qquad (4.3b)$$

Standard type

$$a_{040}\rho^4, \qquad a_{031}\sigma\rho^3\cos\varphi, \qquad a_{022}\sigma^2\rho^2\cos^2\varphi, \qquad a_{120}\sigma^2\rho^2, \qquad a_{111}\sigma^3\rho\cos\varphi. \qquad (4.3c)$$

From the tables we can write the individual members of W_6 from which we could obtain the individual fifth-order aberrations by differentiation.*

We can classify various types of aberrations from the subscripts appearing in the coefficients b_{lnm}. The aberrations associated with the coefficients $b_{0,2k,0}(k = 1, 2, \ldots)$ depend only on ρ. Such members produce spherical aberrations of order $2k - 1$; thus in W_4 the term of b_{040} is called spherical aberrations of third order. Terms whose coefficients are $b_{l,2k+1,1}$ produce *coma* of order k, where $l = 0, 1, 2, \ldots, k = 1, 2, \ldots$. For $l = 0$, $k = 0$ we have a simple distortion of the image and it is not considered an aberration. The term with coefficient b_{031} is the first-order coma or primary coma, with b_{051} secondary or second-order coma, with b_{071} third-order coma, etc. However, terms with coefficients $b_{l,2k+1,1}$ are also coma aberrations, where $l = 1, 2, \ldots, k = 1, 2, \ldots$. To distinguish those terms with $l = 0$ from the others with $l = 1, 2, \ldots$ we call the aberrations with $l = 0$ *pure*, so all terms with coefficients $b_{0,2k+1,1}$ are *pure* coma aberrations of order k, the others *mixed* comas. Terms of the wave aberration function W_n having for coefficients $m = 2$, $l = 0, 1, 2, \ldots$, $n = 2k$, $k = 1, 2, \ldots$, produce *astigmatism* of order k. For $l = 0$, $k = 1$, $m = 2$, the aberration term b_{022} produces first-order or primary astigmatism; for $m = 2$, $k = 2$ secondary astigmatism; etc. When we take $m = 3$, etc., no particular name is given this type of aberration. The special terms of the type $b_{022}\sigma^2\rho^2\cos^2\varphi$ is called *wing aberration*, and for $m = 3$, $n = 1$, $l = 0, 1$, etc., *arrow*-type aberrations. For $m = 0$ and $l > 0$, the aberration wave function produces a curvature of the field, thus all the terms associated with $b_{l,2k,0}$ produce a *curvature of field* of order k, producing a change of focus depending on the field given by σ^{2l}.

In comparing the three expansions of W_4, the Z–N development contains additional terms of lower power in ρ. The additional terms displace the point (focal) to maximum illumination that is compensating (balancing) higher-order aberrations with the lower orders. This is an important advance over the standard expansion of the wave aberration functions, especially when the Z–N expansion is introduced in the phase function of the diffraction integral, not to mention the advantage of employing orthogonal functions over the domain of integration for evaluating the diffraction integrals; in most optical situations, the domain is circular.

5. Diffraction Theory The starting point of

$$*\delta x_1 = \alpha\left[W_\rho\cos\varphi - W_\varphi\frac{\sin\varphi}{\rho}\right] \qquad \delta y_1 = \alpha\left[W_\rho\sin\varphi + W_\varphi\frac{\cos\varphi}{\rho}\right] \Bigg\} \quad w = W(x_{0i}, \rho, \varphi).$$

α depends on the distance from the reference surface to (x_1, y_1) and the maximum value of ρ.

the modern theory of diffraction of optical imaging systems may be traced to the famous paper on the diffraction theory of the phase contrast method by Zernike.[1] He and his students made significant advances in the theory of diffraction. Nijboer[2] was able to calculate to an unprecedented degree of accuracy the intensity distribution of the field (contours) produced by an optical system affected by several types of aberration of various orders. Moreover, experiments were performed in Zernike's laboratory by another of his pupils, Nienhuis, to verify the theory. The laboratory results agreed to a high degree with Nijboer's calculations. Likewise, experiments with microwaves were carried out at McGill University by Bachynski and Bekefi[2] using lenses made of dielectric materials; the results were compared with calculations based on Nijboer's formulation of diffraction of aberrations. Again, comparison of calculations with experimental observations surprisingly shows a great likeness to the contours of the intensity distribution on the Gaussian plane. Further investigations have shown the usefulness and the advantages of the Zernike-Nijboer formulation of the diffraction of aberrations over the earlier formulations in other fields than optics.

The Zernike-Nijboer formulation of diffraction of aberrations rests on the expansions of the wave aberrations function in a series of orthogonal functions, known as Zernike polynomials, which are orthogonal over a circular region. Since the geometrical shapes of apertures or stops in lens systems, microscopes, cameras, or telescopes, are circular, this form of expansion is the most appropriate one for treating diffraction, scattering and other problems including problems of vibrating elastic systems. The advantage of introducing this kind of expansion in the diffraction integrals lies in the simplification achieved not only in the evaluation of the integrals, but also on account of the orthogonality of the polynomials over the domain of integration; the coefficients of the expansion do not mix with each other when the aberrations are small. The extension to large aberration was carried out by van Kampen.[2]

Since then, great advances have been made, both in theory and experimental observations leading to important applications in the improvement of optical instruments. This success has been paralleled in other fields of science such as in electron optical image formation, in microwave optics, and in the design of image formation apparatus employing high- or low-frequency waves (radio, infrared, ultraviolet, X-rays, and even acoustic waves). Significant contributions have been made in the design of microwave lenses (dielectric), microwave imaging instruments such as satellite cameras, mirrors for collecting (exploring) information on sources of electromagnetic radiation of different frequencies from distant objects such as planets, stars, and galaxies, as well as in the development of the new branch of optics named *holography*.[7]* In holography, the theory of diffraction of aberrations plays an important role in the design of optical and other image forming systems to obtain faithful images of objects emitting or illuminated by different kinds of radiation—coherent, incoherent, or mixed. The vast usefulness of the diffraction theory of aberrations is accounted for in the similarity of the mathematical differential equations governing wave phenomena and the analogous solutions, which, subject to certain appropriate conditions, resemble each other in mathematical form.

We would like to refer also to some of the earlier significant contributions to the theory of diffraction of aberrations by Ignatowski, Fischer, Steward, Picht and more recently by Luneburg and others.[3]

The basis of the diffraction theory of aberrations of optical systems is founded on Kirchhoff's integral or a modified form of it, namely,

$$U(P) = -\frac{ikn}{2\pi}\iint_S \sqrt{K}\, U_0(Q) \cdot \exp ik[W + (\mathbf{r}\cdot\mathbf{s})]\, dS \qquad (5.1)$$

where $U_0(Q)$ is the value of the field on the wave surface (front) S after passing through the optical system, usually located in the image space; n, K, and $\mathbf{r}$ are, respectively, the refractive index of the medium in image space, the Gaussian curvature of the wavefront, and the distance vector from the point Q, located on S, to the image point (observation point) P. The function W is Hamilton's mixed characteristic of the optical system which depends on the coordinate of the object and the optical direction of the ray at Q, namely the vector $\mathbf{s}$. Here the field represented by $U_0(Q)$ is the geometrical optics wave solution of the harmonic scalar equation or a component of the vector wave equation derived from Maxwell equations. Here U_0 is considered a scalar quantity, or a component of the vector field.

A more convenient form of (5.1) used frequently in actual problem is [3,4]†

$$u(P) = -\frac{ik}{2\pi}\iint_{D=p^2+q^2\leqslant n^2} g(p\cdot q) \cdot e^{ik[W+(\mathbf{r}\cdot\mathbf{s})]}\, dp\, dq, \qquad (5.2)$$

where

$$g(p, q) = \sqrt{n^2|\Delta|}\; U_0(p, q). \qquad (5.3)$$

The symbol Δ denotes the discriminant of the second differential form of S, i.e., $\Delta = LN - M^2$, with L, M, N given by the expressions

$$nL = W_{pp} - \frac{p^2 + r_0^2}{n^2 r_0^2} Z$$

*Recently acoustic waves have been used for wavefront reconstruction imaging.[9]

†$(\mathbf{r}\cdot\mathbf{s}) = xp + yq + z\sqrt{n^2 - p^2 - q^2}$.

$$nM = W_{pq} - \frac{pq}{n^2 r_0^3} Z \qquad (Z = pW_p + qW_q - W),$$

$$nN = W_{qq} - \frac{q^2 + r_0^2}{n^2 r_0^2} Z. \qquad (5.4)$$

where $\mathbf{s} = (p, q, r_0)$ are the optical direction cosines of a ray on Σ with $r_0^2 = \sqrt{n^2 - p^2 - q^2}$. A point $P(x, y, z)$ of Σ is given by the equations

$$x = -W_p + \lambda(p, q)p, \qquad y = -W_q + \lambda(p, q)q,$$
$$z = -\lambda(p, q)r_0 \qquad (5.5)$$

where $\lambda(p, q)$ is the distance from P to the image point.

In practice one takes as the surface of integration the aperture of the exit pupil. The integrals (5.1) and (5.2) form the basis of the diffraction theory of aberrations. They give all the information about the image field or the intensity distribution at any point in image space. They are known as *Debye-Picht-Luneburg Integrals*.

Evaluation of the integrals (5.1) or (5.2) is difficult even for simple imaging systems, on account of the presence of W, which is not known explicitly except for simple optical instruments. In addition, the standard expansion of W makes the analysis of the field distribution or equal illumination contours on the image plane difficult. This is simplified when W is expanded according to the Zernike–Nijboer[2] or Fourier procedures.

The problem of spherical aberrations of any order has been treated exhaustively by Boivin, not only for circular apertures, but for annular apertures as well. The calculation of the diffracted field in the presence of higher-order aberrations, including the more general problem of nonsymmetric optical systems, is given in reference 3.

All the methods discussed above are valid only for small aberrations. For large or moderately large aberrations, one must resort to asymptotic methods, which at present are sufficiently developed to include most of the interesting cases occurring in the theory of diffraction of optical systems. When these analytical methods are combined with the present progress in computational methods, the intensity distribution produced by an optical system can be calculated to any desired degree of accuracy.

There are many branches of science in which aberrations play an essential, though "negative," role, wherever image forming systems are involved or stability of dynamic systems is studied. In the theory of reconstruction of wavefronts,[6] spherical aberration and astigmatism have to be controlled in order to reconstruct the object structure accurately. In high-energy accelerators (linear, circular), especially in toroidal accelerators for achieving thermonuclear fusion (deuterium–tritium plasma ignition), both the accelerating field and the magnetic field are used to confine the beam of particles within a tubular region close to the axis (optical) of the torus, which is circular. Since the fields are not only functions of space but of time as well (periodic in time), the electron-optical analysis of the system will involve aberrations both in space (geometrical) and in time (stability). In addition, as the charged particles are accelerated the energy varies, and this variation introduces a continuous variation in the de Broglie wavelength of the particles, which introduces an additional kind of aberration known in optics as *chromatic aberration*.[7] Therefore, the problem here involves not only geometrical aberrations (stability), but also chromatic aberrations, which interact with each other, making the analysis very complex.

In microwave focusing[8] (spectroscopy, microscopy) and especially in the construction of giant mirrors and telescopes for exploring the sources of radio, ultraviolet, and X-rays in outer space, care is taken in the design to minimize the aberrations, in particular spherical aberrations and astigmatism, caused by temperature variations on the surface of these instruments.

Recently, sound and ultrasound waves[9] have been used in studying structural defects in solid materials, and in the exploration and surveying of the ocean floor and land masses. In addition, the recent development of apparatus used for imaging biological matter, in particular the internal organs of the human body,[10] is a striking example of the advances which have been made in extending the optical ideas of imaging systems to the whole wave spectrum, including elastic and sound waves on the one hand and charged particles on the other, thanks to the dual nature of particles and waves.[11]

ABSORPTION SPECTRA

Spectroscopy is the measurement of the amount of light, or other radiant energy, transmitted, absorbed, or emitted by a sample of matter, as a function of the frequency, or wavelength, of the radiation. Absorption spectra provide information on individual atomic or molecular units and their immediate environment. Thus it is possible to determine what species are present in a sample and in what form they are present, including the sizes and shapes of individual molecules and often the environments of the molecules. The information obtained directly is the amount of absorption or emission, related to the quantity present and the probability of the radiative transition, and the frequencies absorbed or emitted, which are proportional to the separations of the energy levels in the sample. Spacings of energy levels are equal to Planck's constant times the frequency of the radiation, $\Delta E = h\nu$, and the frequency is related to the vacuum wavelength λ by $\lambda\nu = c$, where c is the speed of light in vacuum. In practice, energy information is often expressed as a vacuum wavenumber, σ(or $\tilde{\nu}$), which is the number of waves per unit of length, and hence the reciprocal of the wavelength; $\sigma = 1/\lambda = \nu/c$. Wavelengths are measured in meters or fractions of meters (e.g. nanometers, nm); wavenumbers are measured in waves per meter or, more often, in waves per centimeter, cm^{-1}.

Spectroscopic studies extend across the electromagnetic spectrum. Gamma rays and x-rays provide information about particles inside the nucleus and about inner-shell electrons of atoms. Ultraviolet and visible radiation interact primarily with electrons in the outer shells of atoms and molecules. Infrared and microwave frequencies produce molecular vibrations and rotations. Radio-frequency spectroscopy measures energies of reorientation of nuclear spin angular momenta in magnetic fields. The present article will consider only absorption of infrared, visible, and ultraviolet radiation by molecules, omitting Mössbauer and atomic absorption, fluorescence, and spin resonance techniques, as well as microwave and Raman spectroscopy.

Experimental Methods Conventional spectroscopy relies upon dispersion of radiation, or separation according to frequency, by a prism or grating monochromator. Most current instruments follow similar principles of design. In a Littrow mount, radiation passing through the entrance slit is collimated, or converted to approximately parallel rays, by a spherical or paraboloidal mirror. The collimated beam is passed through a prism and returned by a reflecting surface through the same prism, or is reflected by a plane grating, returning to the collimating mirror and from there to the exit slit, from which it is focused by an ellipsoidal mirror onto a small detector. The Czerny–Turner mount employs two spherical mirrors in place of the single collimating mirror. These are side by side, with the grating lying along the bisector of the line between them so that, except for the angular position of the grating, the arrangement resembles a Littrow system and its mirror image, sharing a common grating. An Ebert monochromator substitutes a single large spherical mirror for the two mirrors of the Czerny–Turner design. If a concave grating is substituted for the plane grating, no other lenses or mirrors are required. The slit, grating, and image point will lie on a large circle called the *Rowland circle.* Some instruments incorporate a large part of the circle; others include little more than the three critical points inside the case, shifting the circle with respect to the instrument, by rotating the grating, instead of moving components around the circle.

Prisms offer good dispersion properties for the visible and ultraviolet regions, but are generally inferior to gratings for the infrared region and for highest resolution spectra. Most gratings have been made by ruling an aluminum surface with a diamond tip, then casting replicas of the ruled surface in plastic. Gratings with lower levels of scattered light may now be produced holographically, both plane and concave. For very high resolution, a coarse grating can be employed in a very high order (an echelle grating) with cross dispersion by another element to separate the orders. Low resolution infrared spectra may be obtained with a wedge interference filter.

Some research instruments employ only a single beam passing through the sample and monochromator to the detector, but nearly all commercial instruments are now of double-beam design, with a reference beam serving to correct for solvent and atmospheric absorption and, especially, for variations in source intensity with frequency. These may be compared by an optical null system that automatically attenuates the reference beam to match the sample beam, or by an electronic comparison of beam intensities. This is increasingly being accomplished with digital electronics under microcomputer control. To avoid sample decomposition, ultraviolet spectrometers disperse the beam before the sample, whereas infrared spectrometers usually place the sample before the monochromator to avoid displacements of the image of the exit slit on the small detector surface.

A very different design concept employs interferometry to provide the coding by which frequency information is extracted. The beam is not dispersed, but the movement of a mirror with time superimposes an interference pattern on the beam that is different for each frequency. Taking the Fourier transform of the signal, with a computer, generates the spectrum as intensity vs. frequency. When applied to infrared spectroscopy the technique is commonly called FTIR. Interferometers have a substantial energy advantage over dispersive instruments. They can accept radiation from a larger aperture, and because the entire spectrum is examined at once, rather than measuring small frequency increments sequentially, there is an energy gain for thermal detectors that increases with the number of resolved frequency intervals in the spectrum. This second factor, often called *Fellget's advantage*, disappears for photon detectors because the noise increases with total radiation striking the detector surface.

The newest experimental approach takes advantage of tunable sources, eliminating the need for a monochromator or interferometer. First applied in microwave spectroscopy, the technique has now been extended to the infrared and visible regions with tunable dye lasers and diode lasers. Photoacoustic spectroscopy is a variation in which the absorption of radiation produces expansion of the absorber, and thus an acoustic signal.

Conventional sources for the ultraviolet region are hydrogen, deuterium, or xenon discharge lamps. For the visible and near infrared regions, tungsten filament lamps are satisfactory. Common infrared sources include a hollow cylinder of refractory oxides (Nernst glower), a rod of silicon carbide (Globar), alumina tubes, Nichrome wires, and, for the far infrared, silica jacketed mercury arcs.

The standard detector for the visible and ultraviolet region is the photomultiplier, which has almost entirely replaced photographic emulsions. For the near and medium infrared, solid state photoconductors (PbS, PbSe, Au-doped Ge, etc.) provide high sensitivity, especially if cooled. Triglycine sulfate, a pyroelectric detector, and the Golay pneumatic cell, a thermal detector, have advantages for the far infrared. Thermal detectors, including thermocouples and bolometers, are less sensitive than photon detectors, such as cooled photoconductors, for high frequencies but are usable over the entire spectrum.

Solid samples and strongly absorbing liquids are usually dissolved in a solvent. Water is transparent in the ultraviolet (to beyond 200 nm, or 50,000 cm^{-1}). Other suitable solvents, in order of decreasing range, include ethanol and ether, saturated hydrocarbons (e.g. isooctane and cyclohexane), methylene chloride, chloroform, and carbon tetrachloride. Absorption cells usually have a path length of 1 cm. There are no good transparent solvents in the infrared, but carbon tetrachloride is clear over a large region and carbon disulfide is transparent in most regions where carbon tetrachloride is not, for cells less than 1 mm thick. The thin spacings required, coupled with lack of durability of most infrared cell windows, makes maintenance of infrared cells a significant problem.

Sample cells for the visible region may be of glass or any other transparent material, but special glasses or, especially, quartz or fused silica are required for the ultraviolet. (CaF_2, NaCl, and other materials are also transparent but are not competitive because of price, workability, and durability disadvantages.) Infrared cells are typically made with NaCl windows (transparent to about 625 cm^{-1}) or other alkali halides (KBr, CsBr, CsI). For selected regions, quartz or silica, calcium fluoride, magnesium fluoride, and certain special glasses (e.g., arsenic compounds) are advantageous. Polyethylene and silica are transparent in the very far infrared. Rolled AgCl and KRS-5, a mixed thallium bromide–iodide, are impervious to water and transparent over a large part of the infrared.

Solid samples that cannot be dissolved or prepared in thin enough sections for transmission measurements may be immersed in a medium of similar refractive index (e.g., mulled in mineral oil or pressed in KBr or other soft material into a pellet) or examined by attenuated total internal reflectance. A half-rod or prism of transparent material with a refractive index greater than that of the sample is placed against the sample and the beam is totally internally reflected at the interface. As the sample index changes with frequency, because of absorption bands, the total reflectance is modified, giving a spectrum that resembles the absorption spectrum. The method shows high sensitivity, especially for thin films where the prism acts as a light pipe to give multiple internal reflections from the surface.

Structure Determinations To a good approximation, the electronic energy of a molecule may be found by ignoring the motions of nuclei; the energy obtained by solving the Schröedinger equation then contains an error, as a function of positions of nuclei, that is just the vibrational potential function. Similarly, the vibrational energy may be evaluated by ignoring rotations. This separation of the wave function is called the *Born–Oppenheimer approximation.* It allows first-order interpretation of spectra in different regions as if they were solely electronic, vibrational, or rotational in origin.

The primary theoretical tool of the molecular spectroscopist is group theory, applied to the symmetry properties of the system under study. Absorption of radiation normally requires a change in dipole moment of the absorber during the transition. The intensity of absorption is determined by the transition moment, $\Psi_f{}^* M \Psi_i \, d\tau$, the integral over initial and final state wave functions and the dipole moment operator. From symmetry arguments it can be shown that certain transitions must have zero transition moment (at least in the usual approximations, such as isolated harmonic oscillators or one-electron wave functions.) These conditions provide selection rules, that predict which transitions may be active in absorption for various possible structures. Comparison of observed with predicted spectra then usually allows a determination of the actual structure of the molecule.

Prediction of intensities is much more difficult, depending more strongly on detailed models for the absorber, but successful correlation of intensities and structure can therefore provide significant additional information.

Analysis of low-frequency spectra of crystals relies on the symmetry of the unit cell. Vibrational motions, called *phonons*, travel through the crystal and may be analyzed according to the theory of transmission lines with discrete elements. The shapes of absorption bands are determined primarily by the densities of states. If phonon energy is plotted against phonon wavenumber in the crystal, the curves are flat for certain wavenumber values (often near the boundaries of the Brillouin zones), so the probability of absorption at these energy values is significantly increased. The energy determines the frequency of the external radiation that will be absorbed. Symmetry arguments in crystals are modifications of those for isolated molecules, involving lattice groups as well as point groups.

Selection rules may also be derived on the basis of conservation of angular momentum. A photon carries one unit ($\hbar$) of angular momentum, and thus adds this unit to the molecule upon absorption. Depending upon the nature of the molecular transition, this angular momentum will change the rotational state, or a degenerate vibrational state, or the orbital momentum of an electron. Spin angular momentum is seldom affected, except insofar as it is coupled with other motions. Because angular momentum follows vector addition rules, the angular momentum of the molecule can change in magnitude by ±1 or 0 units, unless it is initially zero. Group theory provides additional insight into the axis along which the angular momentum can change.

Models of the electronic structures of molecules are usually based upon one-electron wave functions, called *orbitals.* Some examples include the united-atom and separated-atom models for diatomic molecules and their extension to polyatomics, the free-electron model for unsaturated and aromatic structures, and Hückel calculations for aromatics. In addition, theoretically based rules have been given by Walsh and by Woodward and Hoffman that predict which orbitals will be occupied and the effects on molecular shapes and reactivities. Ab initio calculations, employing self-consistent field approximations, have been carried out for small molecules, providing a theoretical basis for extrapolations to larger systems.

Qualitative Analysis Molecular vibrations can be described as superpositions of normal, or independent, modes of vibration. Each normal mode involves the entire molecule and has the symmetry of one of the symmetry species, or irreducible representations, of the point group that describes the ground-state symmetry of the molecule. Nevertheless, certain normal modes are affected primarily by specific functional groups within the molecule. For example, C—H stretching modes appear at a wavenumber near 3000 cm^{-1}, somewhat higher if the hydrogen is near an electron-rich group such as an aromatic ring, an oxygen, or a chlorine, and generally a little lower for aliphatic C—H. Stiffer bonds absorb at higher frequencies. N—H and O—H are near 3300-3700 and S—H around 2500 cm^{-1}; C=O is near 1650-1750, compared with C—O, closer to 1000-1200 cm^{-1}. Larger mass moves the vibration to lower frequencies; C—Cl stretching bands appear near 600-900 cm^{-1} and C—I lower yet. Vibrational absorptions that always tend to appear in the same place are called *characteristic frequencies.* By contrast, low-frequency vibrations, including modes involving primarily bending motions, and stretches that may couple with adjacent bonds, such as C—C in aliphatic chains, are much more variable in position, depending on the particular molecule in which they occur. Thus the low-frequency end of the spectrum is called the *fingerprint region.* Often the nature of a compound can be determined from the characteristic frequencies and the exact compound then identified by comparing the fingerprint region with spectra of known compounds.

One must be particularly careful in identifying spectra of gases and solids. Rotational structure can appear in the gas phase, especially for small molecules, that depends to some extent on the gas pressure. Spectacular misinterpretations of spectra have been reported when different rotational branches of a single absorption band have been assigned to different molecular absorbers. Often solids will give spectra very similar to solution spectra, but the spectrum may also vary markedly depending upon crystal structure and orientation of crystallites with respect to the beam. The halide pellet technique tends to introduce spurious hydroxyl bands and the high pressure or chemical reactions sometimes alter the spectrum significantly.

A first approximation to explanation of electronic absorption spectra, in the visible and ultraviolet, was provided by the model of *chromophores* and *auxochromes.* Certain structural fragments (chromophores) were recognized that cause absorption. For example, a single aromatic ring (benzene) absorbs weakly around 250 nm (40,000 cm^{-1}), as does a carbonyl or nitro group. Substituents (auxochromes) on the molecule shift the absorption, most often to lower frequencies. For example, methyl, chloro, hydroxy, methoxy, amine, and acetyl substituents on the benzene ring produce shifts, increasing in the order given, of the strong absorption band initially near 200 nm (49,000 cm^{-1}). Although the chromophore–auxochrome model was initially empirical, theoretical justifications of many of the absorption bands and frequency shifts are now possible.

Despite advances in theory underlying absorption spectra, most qualitative identifications rely on empirical correlation of observed spectra with the spectra of known compounds. In the ultraviolet and visible, relatively few bands are observed and these are often broad and sometimes featureless. Nevertheless, the positions offer significant information on possible absorbers, which can be supplemented by changing sample conditions. For example, a nonpolar molecule such as benzene will show little frequency shift with change of solvents; a polar compound such as a ketone will show an appreciable shift; and addition of acid to an amine will produce the amine hydrochloride, which has a totally different absorption spectrum. Extensive compilations of electronic spectra for comparison are now available.

Quantitative Measurements Except for beams of unusually great intensity, the absorption is determined by the Lambert–Bouguer law or Beer's law. The fractional intensity lost in any small increment of sample thickness is the same, and is proportional to the thickness increment and to the concentration of the absorbing species. This leads to the idealized law, for monochromatic radiation,

$$I = I_0\ 10^{-abc}$$

where a is the absorptivity of the absorbing species, present at concentration c, in a cell of length b. In practice, however, deviations are often observed. If the absorptivity varies over the frequency spread of the beam, the more strongly absorbed frequencies will be depleted, and the absorptivity will therefore decrease with sample path length. Chemical and physical interactions in the sample may modify the nature of the absorbing species, causing the absorptivity to vary with concentration. Thus it is necessary to check each sample to determine whether Beer's law is obeyed before attempting a quantitative analysis. So long as the absorbance, $A = abc = -\log$ (transmittance), is additive for all absorbing species present, nonlinearities in the calibration curve of measured absorbance vs. concentration can be accommodated by graphical techniques or successive approximations.

Any number of components may be determined simultaneously by making measurements at the same number of frequencies, but accuracy will suffer unless several conditions can be satisfied. There should be significant differences of absorptivity of the various species at the frequencies selected. No absorptivity should change rapidly with frequency at any of the analytical frequencies. If an absolute background (I_0, or $A = 0$) line is not available, the reference background line must be drawn between fixed frequencies, rather than between similar features (e.g., transmittance maxima) of the curves.

Greater accuracy in a multicomponent analysis is achievable by making measurements at more frequencies than the number of unknowns. The analytical equations may be expressed in matrix form, $\mathbf{A} = \mathbf{KC}$, where $\mathbf{A}$ is a column matrix of measured absorbance values at the several analytical frequencies, $\mathbf{C}$ is a column matrix of the (unknown) concentrations of the species present, and $\mathbf{K}$ is a rectangular matrix of calibration values, one measured value (ab) at each analytical frequency for each species. Multiplication of each side on the left by the transpose of $\mathbf{K}$ gives $\tilde{\mathbf{K}}\mathbf{A} = \mathbf{A}' = \tilde{\mathbf{K}}\mathbf{KC} = \mathbf{K}'\mathbf{C}$, where $\mathbf{A}'$ has the same dimension as $\mathbf{C}$ and $\mathbf{K}'$ is a square matrix. Solution of $\mathbf{A}' = \mathbf{K}'\mathbf{C}$ gives the best values of the concentrations to a least squares approximation.

Quantitative analysis is usually much more difficult for solid and gaseous samples than for solutions. Solid samples are generally not spatially homogeneous, so Beer's law cannot be expected to apply. However, if the sample has been very finely divided before mulling in oil or pressing in a transparent matrix, the deviations may be small enough. It is often necessary to resort to some form of internal standard, a compound of known absorptivity added in known concentration to the sample, so that the amount of sample in the beam can be determined.

Gases are spatially homogeneous but because of rotational fine structure may appear inhomogeneous with respect to frequency. The beam typically averages transmittance over several narrow absorption bands and the gaps between, so the observed absorbance depends strongly on the widths of the absorption bands, which depend, in turn, on the pressures of the gases in the sample. The apparent absorptivity increases as the gas pressure increases (i.e., absorbance increases faster than pressure, for given cell length) because pressure broadening makes the sample more nearly homogeneous with respect to frequency over the spectrometer bandwidth.

Stray radiation, scattered within the monochromator and reaching the detector mixed with the signal at another frequency, also may cause quantitative errors. The problems are most severe near the ends of the spectrometer range, where the signal intensity is low.

ACCELERATOR, PARTICLE

Particle accelerators are electromagnetic devices used to generate energetic beams of charged particles—electrons, protons or other ions. They are widely used in research in many fields of physical science and they have many practical applications in medicine, manufacturing, and engineering.

The earliest forerunners of particle accelerators were the gas discharge tubes and x-ray tubes of the late 1800s. They provided some of the early technological base for accelerator development, but they were special in purpose, very limited in voltage, and did not provide the motivation for accelerator development.

The need for particle accelerators became apparent in the 1920s after Rutherford had demonstrated the existence (1911) and the disintegration (1919) of the atomic nucleus using alpha particles from a radioactive substance to probe the structure of the atom. Clearly these experiments gave promise of a radical new understanding of the nature of matter. But just as clearly, particles from radioactive substances were not adequate for the task of exploring atomic and nuclear structure. Beams from such sources were very limited in intensity, poor in collimation, lacked control of energy, and were limited to β-rays (electrons) and α-particles (helium nuclei). Reviewing the need for particle accelerators and the technological base for developing them, Rutherford stated in a famous address in 1927:

> It would be of great scientific interest if it were possible in laboratory experiments to have a supply of electrons and atoms of matter in general, of which the individual energy of motion is greater even than that of the α-particle. This would open up an extraordinarily interesting field of investigation which could not fail to give us information of great value, not only on the constitution and stability of atomic nuclei but in many other directions. . . . .[B]ut it is obvious that many experimental difficulties will have to be surmounted before this can be realised.

Inventors and experimenters were already at work to overcome the difficulties with a variety of approaches: electrostatic devices, Tesla coils,

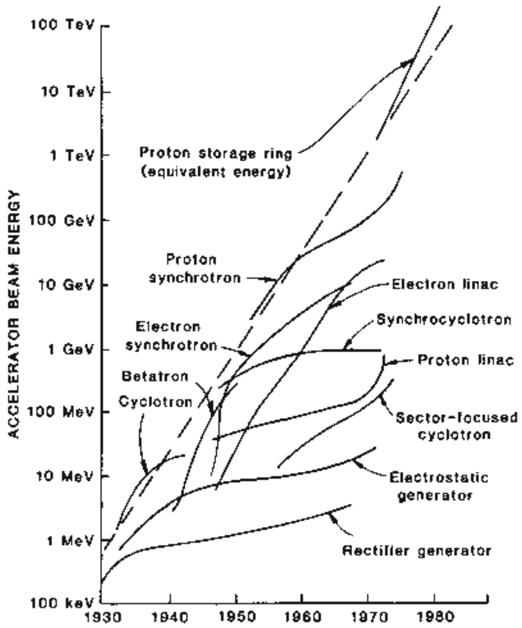

FIG. 1. The maximum energy of each type of accelerator is plotted against the year it was achieved. For colliding beams, the energy of an equivalent fixed target accelerator is plotted. Maximum energy has increased by about 8 orders of magnitude in 5 decades.

transformers, voltage multipliers, radio-frequency resonance acceleration, even atmospheric electricity. By the early 1930s several types of particle accelerators had been invented and successfully used in nuclear experiments.

The electric force is the only macroscopic force strong enough to accelerate particles. The magnetic force, while also strong, is exerted perpendicular to a line of motion, and thus may be used to change the direction of, but not to accelerate, particles. Applying these forces, many kinds of accelerators have been developed, but all are based on a few physical concepts. The emergence of these concepts will be used as a framework to discuss the principal types of accelerators.

Direct-Potential-Drop Accelerators The simplest particle accelerator concept entails a source of charged particles at one end of an insulating evacuated tube and a source of high voltage placed across the ends of the tube. The particles are accelerated from the source end of the tube to the target end by the electric field and gain kinetic energy. The energy of accelerated particles is universally expressed in electron-volts, eV, the energy gained by a particle bearing a charge equal to that of an electron accelerated through a potential difference of one volt. The energies that are of interest in nuclear studies are several hundred kiloelectron-volts, keV, and upwards without a presently preceived limit. The technological difficulties encountered in the realization of this concept are connected with generating the high voltage and with electrical breakdown both internally and externally in the accelerating tube.

J. D. Cockcroft and E. T. S. Walton, who were the first to achieve nuclear disintegration by electrically accelerated particles in 1932, used a voltage-multiplying rectifier circuit of four stages which effectively charged capacitors in parallel and discharged them in series to reach about 400 kV. They used a glass accelerating tube which was divided into two segments with an intermediate electrode at mid-potential. The ion source was a low-voltage discharge in hydrogen yielding a supply of protons. This type of accelerator has been continuously improved by increasing the number of power supply stages and the segments of the accelerating tube, increasing the frequency of the charging circuit, immersing the voltage supply and the accelerating tube in insulating fluid or pressurized gas to reduce breakdown and other variations and refinements. The *Cockroft–Walton accelerator* remains in use today in many applications up to a few MeV and as a preaccelerator typically operating at 750 keV to inject a beam into a higher-energy accelerator.

The other application of the simple concept of direct application of voltage to an accelerating tube that has had enduring success is the *Van de Graaff* or *electrostatic accelerator*. In this accelerator the potential is supplied electrostatically by an insulating belt transporting charges between ground and a large, usually spherical, high-voltage terminal. R. J. Van de Graaff demonstrated an electrostatic generator of this type in 1931 and the first application to nuclear studies was made by a group headed by M. A. Tuve at the Carnegie Institution in Washington in 1933 with a beam of 600 kV protons. This type of accelerator has also been subject to many improvements and variations. The charging belt and the accelerating tube may be vertical or horizontal. After the earliest examples these accelerators were invariably housed in pressure tanks to exploit the superior voltage holding properties of various gases at high pressures. Refinements in the design of segmented accelerating tubes and the use of shells at intermediate potentials between the grounded pressure tank and the high voltage terminal have been the main factors leading to reliable operation of Van de Graaff accelerators at over 10 MeV. More than twice that voltage is achieved in the tandem design in which negative ions are accelerated from ground potential to a positive terminal where they are stripped of electrons to form positive ions and then further accelerated to ground potential.

Both the Cockcroft–Walton and the Van de Graaff accelerators are characterized by good regulation, easy control of voltage, and excellent beam collimation. They also work with either sign of charged particle and a comparatively simple change of ion source may permit acceleration of partially or completely stripped nuclei of any element.

Resonance Acceleration The concept of resonance acceleration, that is, repeated acceleration by radio-frequency power at relatively low voltages to produce high-energy particles, made it possible to avoid the severe technological problem of electrical breakdown at high voltage. R. Wideroe in 1928 demonstrated the principle with a single tubular electrode supplied with radio-frequency power mounted between two grounded electrodes. Sodium ions, Na^+, were accelerated into the electrode while it was negative, passed through, and further accelerated at the other end when the potential of the tube became positive, thus attaining an energy corresponding to twice the applied radio-frequency voltage. In 1929 E. O. Lawrence elaborated the concept to include the effect of a magnetic field and invented the *cyclotron*. If, in a uniform magnetic field, ions are accelerated perpendicular to the field by a radio-frequency voltage applied to a reentrant electrode, then for appropriate values of the field and frequency the ions will pursue a circular path and return to the opening of the electrode when the voltage has reversed and the ions will again be accelerated. Continuing, the ions will describe a spiral path increasing in radius and energy as they enter and leave the accelerating electrode in resonance with the applied radio-frequency voltage, making it possible to reach energies corresponding to hundreds of times the applied voltage. An additional requirement is that the ions remain in the mid-plane of the cyclotron; that requirement, focusing, is met by a slight decrease of the magnetic field with radius. The great advantage of achieving high energies without the necessity of generating high voltages led to the rapid development of the cyclotron as an accelerator of protons, deuterons, and alpha particles of energies of several tens of MeV. It was the leading type of accelerator until the end of World War II and over a hundred were in operation in laboratories all over the world. As the requirements of research called for increasing energy the limitation of the classical cyclotron became apparent. The cyclotron resonance condition specifies a frequency of the accelerating voltage equal to the rotational frequency and proportional to the magnetic field and the charge to mass ratio of the ions, but as the energy of the ion increases the mass of the ion increases (relativistic effect), decreasing the rotational frequency and violating the resonance condition. This limits the number of turns that the ions will stay in phase with the accelerating voltage and limits the energy of the cyclotron to some tens of MeV.

The Induction Accelerator There were many attempts in the 1920s and 30s to devise an accelerator using the electric field induced by a changing magnetic flux (transformer action) to accelerate ions. The requirements of a magnetic field to hold ions in a circular orbit and to provide a changing flux linking the orbit to accelerate the ions were demanding, and success was not achieved until 1941 when D. Kerst demonstrated electron acceleration in his *betatron*. The betatron was immediately recognized as being very well adapted to accelerate electrons for high-energy x-ray production, and it was commercially developed and extensively used for that purpose. A typical energy was about 25 MeV. It was also developed as a research tool to an energy of about 300 MeV but was soon rendered obsolete by other developments.

More recently, special purpose *linear induction accelerators* have been developed to provide very intense, short bursts of electrons at energies of a few MeV.

The Principle of Phase Stability In 1944 and 1945 V. Veksler and E. McMillan, seeking a means of circumventing the energy limitation of the cyclotron, independently formulated the principle of phase stability. They pointed out that in the acceleration of charged particles by a radio-frequency field, particles in a certain phase band were stable; that is, if they had small errors of phase with respect to the accelerating field or of energy, the acceleration itself automatically tended to correct the error. This principle had far-reaching consequences; it effectively removed the energy limitation (except the economic one) of accelerators and it led to the development of several new designs.

In the *synchrocyclotron*, as the ions are accelerated and their mass increases, the frequency of the accelerating voltage is slowly decreased. The ions automatically remain in the proper phase and increase in energy to the limit imposed by the size of the magnet. Synchrocyclotrons were rapidly developed for protons, deuterons, and alpha particles to energies of hundreds of MeV. The magnets weighed several thousand tons and had pole diameters up to about 5 meters. The size and cost of the magnet became the limiting factor as the need for higher energies in nuclear research continued.

The principle of phase stability coupled with the cyclotron resonance condition provided the means around the limitation of the synchrocyclotron also. In the *proton synchrotron*, low-energy ions are injected into a ring-shaped magnet. Both the frequency of the accelerating voltage and the magnetic field are increased, holding the ions in a nearly constant radius orbit as they are accelerated. The weight and cost of a magnet for constant-radius orbits are very much less than those of one spiral orbits. As in the cyclotron, the ions are focused by a small decrease of field with radius. Proton synchrotrons of this type extended the practical energy limit to over 10 GeV (10,000 MeV).

Electron synchrotrons or just *synchrotrons* are based on the same principles, with one simplifying feature but a new limitation. The simplification is that since an electron attains nearly the constant velocity, *c*, at an energy of a few MeV, only the magnetic field need be varied if the electrons are introduced into the synchrotron with a few MeV energy. The limitation compared with the proton synchrotron is an energy limitation and is due to the radiative loss of energy of charged particles in circular orbits. This is called *synchrotron radiation* and is a special case of bremsstrahlung. This effect, which placed a practical energy limit of about 1 GeV on the first generation of synchrotrons, is not significant in proton accelerators because the energy loss varies inversely as the square of the mass of the particle.

Linear Accelerators The concept of the *linear accelerator*, that is the acceleration of charged particles along a linear path by radiofrequency fields, goes back to the 1920s, and early development was carried out in the 1930s. However, the necessary rf power technology was not available at that time and the cyclotron and the Van de Graaff accelerators were so successful that linear accelerator development languished. Radar and communications developments during World War II resulted in great advances in rf technology and specifically in the availability of high-power high-frequency tubes of several kinds. This led to the development of two kinds of linear accelerator in the immediate post-war years.

The first was the *electron linear accelerator* or *electron linac* by W. Hansen in 1947. In this accelerator a traveling rf wave is introduced into a waveguide which has been loaded with a series of washer-shaped irises to reduce the phase velocity of the wave to *c*. Electrons preaccelerated to about 2 MeV, where their velocity is 0.98*c*, ride the crest of the advancing wave as, in analogy, a surfer rides a water wave. Typically the frequency is about 3000 MHz and the diameter of the waveguide accelerating tube is 8 cm. The maximum energy achieved with accelerators of this type has been 24 GeV at the SLAC 2-mile accelerator. In the lower energy range, about 100 MeV, hundreds of these accelerators have been built commercially and are used as x-ray sources both for therapy and radiography.

The second was the *proton linac* developed by L. Alvarez in 1948. In this accelerator, a standing rf wave is set up in a resonant tank in a mode in which the maximum electric field is along the axis of the tank. A series of "drift tubes" of appropriate length, shape, and spacing are distributed along the axis so that charged particles are accelerated by the rf field when they are between drift tubes, but are shielded from the field during the reverse half cycle. An initial energy at injection is necessary; in the modern proton linac this is typically a Cockcroft–Walton accelerator operating at 750 KeV. Proton linacs themselves are used as injectors into proton synchrotrons. For this purpose their energy may be 50 or 200 MeV. The highest-energy proton linac is an 800 MeV accelerator designed to exploit the high current capability of linacs.

Linear accelerators similar in principle to proton linacs may also be used to accelerate nuclei of any atom, including Uranium. Such heavy-ion linear accelerators (*hilacs*) are more complicated because they must provide for acceleration of particles of various charge-to-mass ratios corresponding to different charge states and different nuclei.

Sector-Focused Cyclotrons We have seen that the energy of the classical cyclotron is limited by violation of the resonance condition as the mass of the particle increases with energy. The synchrocyclotron provided a way around this difficulty but only at the expense of intensity because the magnets are pulsed. If the magnetic field of a cyclotron increased with radius, the resonance condition could be matched to the increasing particle mass; however, an increasing field defocuses and all the particles would be lost. L. H. Thomas in 1938 pointed out that a focusing force could be restored if the magnet poles were sectored, producing alternate regions of high field and low field even if the average field increased to match the resonance condition. This idea was not immediately exploited, but developments beginning in 1949 resulted in numerous variations of cyclotrons characterized by azimuthally varying magnetic fields and constant rotational frequency. Accelerators of this type have been built for protons to energies of about 600 MeV with currents of 150 μA, a factor of 100 greater than can be achieved with a synchrocyclotron. The sector focusing idea introduced a flexibility into design, making it possible also to build cyclotrons which could accelerate ions of different species and with variable energy. These developments have rendered both the classical cyclotron and the synchrocyclotron obsolescent.

Alternating-Gradient Focusing The principle of phase stability removed the energy limitation of the classical cyclotron and it made possible the design of accelerators using annular magnets, but the focusing requirement was still met as in the case of the cyclotron by introducing a negative gradient of the magnetic field with radius which gives a force restoring ions to the median plane of the magnet (vertical focusing in the usual orientation). This focusing force, which is relatively weak, determines the space required by the beam, hence the size and cost of the magnet. The focusing force cannot be increased simply by increasing the gradient of the magnetic field, because then the ions would not be confined in the radial direction (horizontal defocusing).

N. C. Christophilos in 1950 and E. D. Courant, M. S. Livingston, and H. S. Snyder in 1952 independently devised a new focusing scheme called *alternating-gradient* or *strong focusing*. If a magnet is divided into segments, alternating segments with vertical focusing and radial defocusing forces with segments having vertical defocusing forces and radial focusing forces the net effect will be focusing in both directions.

Strong focusing incorporated into proton synchrotron design reduced magnet aperture cross sections by a factor of ten or more, making it economically possible to design proton accelerators up to several hundred GeV. The largest of these at the Fermi National Accelerator Laboratory (1972) and at the European Organization for Nuclear Research, CERN, (1976) have annular magnet systems of 2 km major diameter and aperture cross sections of about 5 by 15 cm. The maximum proton energies of these accelerators are 500 and 450 GeV, respectively. The energy of electron synchrotrons incorporating strong focusing is still limited by radiative energy loss, but the advantage of small magnet cross section has made it possible to achieve energies of more than 10 GeV.

Colliding Beams In a collision between a particle and a stationary target nucleus, not all the kinetic energy is available to induce a reaction. Part of the energy, as required to conserve momentum, goes to the motion of both particles after the collision. For accelerated and target particles of equal mass and for energies where relativistic effects are small, the available energy is approximately one-half the energy of the accelerated particle. This is not a serious loss; however, for particles accelerated to higher energies, an increasing fraction goes to the energy of motion. For protons at relativistic energies striking target protons, the available center-of-mass energy is approximately $\sqrt{2E}$ GeV, where E is the energy of the incident particle in GeV. Thus the largest proton synchrotrons of about 500 GeV energy can deliver only about 30 GeV to a reaction. If two beams of particles of energy E traveling in opposite directions could be made to collide head on, an energy 2E would be available for reactions. The possibility that this obvious, but very difficult to achieve, objective might be realized was derived from suggestions made independently by D. W. Kerst, G. K. O'Neill and others in 1956. Because even the most intense accelerator beams are not adequate to give a useful interaction rate if two accelerator beams are simply pointed at each other, it is necessary to collect, store and recycle the accelerated particles. This is done by injecting the beam from an accelerator into an annular magnet with a constant magnetic field. If the magnetic field is very precise and if the pressure in the vacuum chamber very low ($<10^{-9}$ Torr), the beam may be made to circulate for many hours, even days. Such *storage rings* may be constructed in intersecting pairs with provisions for loading them in opposite directions with particles from an accelerator. At the beam intersections a small fraction of the particles interact and the noninteracting ones continue around for repeated chances to interact.

The ISR (Intersecting Storage Rings) at CERN provides for collisions of proton beams at 30 GeV, giving a total energy of 60 GeV. A single beam of 30 GeV on a target would give only about 7.75 GeV. A single storage ring may also be used to store two counter-rotating beams of particles of opposite sign. Thus PETRA at Hamburg and PEP at Stanford are single storage rings designed for electrons and positrons at about 20 GeV each. At CERN the 450 GeV proton synchrotron has been reconfigured with a complicated set of auxiliary rings to accelerate, store, and collide protons and antiprotons at 270 GeV, giving collisions of 540 GeV. To produce this collision energy with a single accelerator and a fixed target would require an energy of about 15 TeV (15×10^{12} eV)!

Uses of Accelerators While the demands of nuclear and particle physics research have been the strongest driving force in the development of new accelerators and the achievement of high energies, the applications of accelerators in other sciences and in industry has been widespread and the contributions very important. Usually the accelerators designed for practical applications operate at less than the maximum energy for their type, but they may often be required to meet other demands at the limit of technology—intensity, reliability, compact size, etc.

In medicine, accelerator-produced radioisotopes are routinely used to image internal structures and to monitor functions. Thousands of small compact electron linear accelerators are used in hospitals to generate penetrating x-rays for cancer therapy. Accelerated particles ranging from protons to silicon nuclei and secondary beams of neutrons and pions are also used for cancer therapy but on an experimental basis. In engineering and manufacturing, electron accelerators are used to generate penetrating x-rays to examine large structures; small ion accelerators are used to implant controlled impurities in the fabrication of semiconductor devices. Radioisotope tracers are used to study and monitor chemical reactions, wear, and other processes. Small accelerators are used to log oil wells and other bore holes by analysis of the characteristic radiation from various elements when excited by neutrons. Plastics with superior electrical and chemical properties are produced by curing organic polymers with electron beams. Extremely sensitive and nondestructive analysis can be accomplished by inducing characteristic x-ray emission by proton or alpha-particle beams from cyclotrons or electrostatic accelerators. Synchrotron radiation, electromagnetic radiation from energetic electrons confined to orbits by magnetic fields, a limiting factor in energy of electron accelerators, is an extremely useful source of intense, highly collimated radiation extending from the infra-red to x-rays. There are many applications of this radiation in chemistry, metallurgy, and biology.

The Future of Accelerators The course of accelerator development may be displayed in an interesting way in a plot first due to M. S. Livingston. The maximum energy achieved with each type of acclerator is plotted against the year it was achieved, see Fig. 1. It will be noted that, as each type of accelerator reaches or approaches a limiting energy, a new type appears. A linear envelope of these curves shows that maximum accelerator energy has increased by a factor of about 8 each decade for 50 years. There appears to be no letup in the demand for higher energies for research directed towards the ultimate structure of matter; yet the sizes of the largest accelerators are measured in kilometers and the cost in hundreds of millions of dollars. It seems likely then that further advances in accelerator performance will depend upon the emergence of new concepts to circumvent the limits of size and cost. Superconductivity is already coming into use to provide higher magnetic fields at lower power costs and will be exploited more fully. Strong electric fields are associated with intense laser beams; a way may be found to apply these fields to accelerate particles. The very strong magnetic fields associated with an intense electron beam may be useful to confine other particles. The collective effects of a swarm of particles may be used to transfer energy to other particles. Invention and development are continuing and there will be new concepts almost surely leading to new types of accelerators with performance going well beyond the present large accelerators.

ACCELERATORS, LINEAR

Linear accelerators (often abbreviated to "linacs") are used for acceleration of electrons, protons, and heavy ions. Electron linear accelerators have yielded electrons at energies above 20 GeV; proton linear accelerators have not yet reached energies above 800 MeV.

Although the term "linear accelerator" is occasionally used to describe systems in which particles are accelerated by electrostatic fields (Cockcroft-Walton or electrostatic accelerators), the term is generally used to apply to systems in which particles are accelerated along a linear path by application of rf fields. Only accelerators of this type will be discussed in this article.

The linear accelerator has the advantage that the accelerated beam is easily extracted for experimental use. In principle it is capable of producing well-focused beams of higher intensity than are available from circular machines of the synchrotron or synchrocyclotron type. It does, however, require very high power levels at frequencies where conversion equipment is relatively expensive. For a given final energy, a linear accelerator will usually be materially more expensive than a synchrotron. (For a general discussion of accelerators see ACCELERATORS, PARTICLE.)

Field Patterns Used in Linear Accelerators The rf fields used for acceleration are set up in a long cylindrical cavity whose axis is to be the axis of the accelerated beam. Hence for acceleration the field pattern must have a major electric field component parallel to the axis. This requirement is satisfied by the TM_{010} waveguide mode in which a paraxial electric field has its maximum strength at the axis and falls to zero at the cavity wall. Azimuthal magnetic fields lie in planes normal to the axis, have small values near the axis and increase to maximum values at the cavity walls. Usually the field pattern is maintained by coupling to these magnetic fields by loops or apertures excited by external power sources. Corresponding to the high rf magnetic field at the wall, paraxial currents flow in the walls and are responsible for a major fraction of the power loss in the system. When high electric fields are required on the axis to accelerate to high energy in reasonable distances, the wall currents are correspondingly high. For acceleration rates of 2 MeV/m, power losses in copper walls will be of the order of 50 kW/m.

Both standing wave and traveling wave patterns are used in linear accelerators. If traveling waves are used, as is the case in most *electron* machines, the phase velocity of the waves must be made equal to the velocity of the particles accelerated; as the particle velocity increases, the phase velocity also must increase. But phase velocities in simple waveguides always are greater than the velocity of light, and loading must be introduced to reduce the phase velocity to the desired value. This is accomplished by introduc-

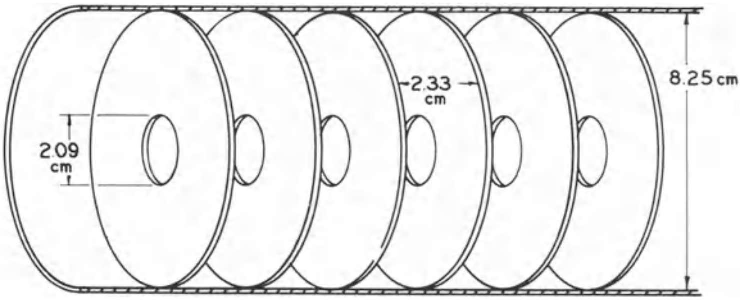

FIG. 1. Cutaway of iris-loaded waveguide for electron linear accelerator.

tion at intervals of washer-shaped irises, as shown in Fig. 1.

Standing wave patterns are used in *proton* linear accelerators. Cavities many meters in length are excited in the TM_{010} mode in which the axial field is uniform from one end of the cavity to the other. Protons which enter the cavity at a low injection velocity may arrive at a phase of the rf field at which they are immediately accelerated, but before they have traveled more than a few centimeters, the field will reverse and become decelerating. To protect the particles from the field in its decelerating phase, "drift tubes" are introduced, as shown in Fig. 2. These are pipes coaxial with the cavity and of such length that the particle is protected from the field during its reverse phase and emerges only after a complete rf cycle when the field again is accelerating. As the particles gain energy, the drift tubes are increased in length.

It would appear that the rather complicated drift-tube structure is conceptually and mechanically inferior to the rather simple iris-loaded traveling-wave system. It is adopted at the relatively low phase velocities required for protons in the range below about 200 MeV because the extreme loading required to reduce the phase velocity of the iris-loaded system to velocities below one-half of the velocity of light results in very high losses. From the point of view of rf power consumption, the drift-tube structure is much superior at low phase velocities.

Electron Linear Accelerators Electrons very rapidly approach the velocity of light (c) as they are accelerated. At 1 MeV an electron already has reached 94 per cent of its ultimate velocity. At energies higher than this satisfactory acceleration will be achieved if all sections of the accelerator are made to have phase velocities equal to c. This makes much easier the tasks of construction and of operation. For example, rf excitation of a section of the accelerator may fail and the whole machine will still be operative, although at a slightly lower final energy.

Losses per unit length in waveguides generally decrease as the square root of the rf wavelength for equal axial fields. Hence, where possible, it is desirable to operate at as high a frequency as possible. But, as wavelength is decreased the diameter of the structure and of the beam aperture decrease correspondingly. The highest frequency that gives convenient beam apertures and at which adequate power sources are available is in the 3000-MHz range. For reasons that are primarily historic, most electron linear accelerators in the United States are operated at a frequency of 2856 MHz.

Both the phase velocity and the group velocity in the guide are determined by the dimensions of the guide and the loading irises. The group velocity is fixed also by the capabilities of the rf power sources. Klystrons with outputs of the order of 20 MW have become standard; each klystron can excite a section of waveguide 3 m long to axial fields of 10 MV/m. The group velocity suitable for this operation is 1 per cent of the velocity of light. The dimensions indicated in Fig. 1 result in a phase velocity of c and a group velocity of $0.01c$ when the guide is excited at 2856 MHz.

Injection is from a conventional electron gun. In some cases a short "bunching section" pregroups the electrons around the peak of the accelerating wave. In this section, the phase velocity is matched to the electron velocity by suitable choices of dimensions.

The power levels required are so high as to preclude continuous operation. Typical operation is with two-microsecond (2-μsec) pulses repeated several hundred times per second. Of the 2-μsec pulse, the first half is required to build up the accelerating field.

Electron linear accelerators in the energy range below 100 MeV are widely used for x-ray production and are commercially available. Most of the pioneer work on electron linear accelerators was done at Stanford where a machine two miles long is in operation at over 20 GeV. At Orsay, France, a 1.3-GeV electron machine is in operation, and in Kharkov in the USSR a 2-GeV accelerator is also in operation.

Proton Linear Accelerators Because of the lower velocities of protons at million-electron-volt energies, proton linear accelerators suffer from several limitations from which the electron machines are free. Injectors for protons usually are Cockcroft-Walton voltage multiplier sets giving energies of 500 to 750 keV. At 750 keV the velocity of a proton is only 0.04*c*. The accelerating field component at such low phase velocities varies strongly with radius at a rate that is approximately proportional to the square of the frequency. This effect sets an upper limit of about 200 MHz for the frequency of the accelerating field, and most proton linear accelerators are operated in the neighborhood of 200 MHz. A cavity resonant in the TM_{010} mode at that frequency will be about 90 cm in diameter.

Figure 2 is a schematic cross section through a 50-MeV proton linac formerly used at the Brookhaven National Laboratory as the injector for the 33-GeV synchrotron. Sections are shown at the injector end, at the region where the protons have an energy of about 10 MeV, and at the high-energy end. The over-all length of the machine is about 33 m. The drift tube shapes indicated have the purpose of keeping each section of the machine resonant to give a uniform accelerating field pattern and, at the same time, of holding the resistive losses in the walls of the drift tubes to levels as low as possible.

The principle of phase stability is operative in proton linacs whereas, at the extreme relativistic velocities of multi-MeV electrons, electron linacs do not enjoy phase stability and require extreme precision in axial dimensions. In the proton linac, the drift tube lengths increase at a rate corresponding to acceleration at a phase displaced 20° or 30° from the peak of the wave. The phenomenon of phase stability (see ACCELERATORS, PARTICLE) results in continual restoration to the correct phase of protons which enter the machine at phases in the neighborhood of the correct phase. Often prebunchers are used to collect a large fraction of the injected beam around the accelerating phase. These prebunchers have the same design as the modulating gap in a klystron and function in the same fashion.

At the stable phase the field across an accelerating gap is rising as the proton crosses the gap. As the proton enters the gap, the accelerating field has a focusing component, but as it enters the next drift tube it feels a larger defocusing field and the net effect is a strong defocusing. In early proton linacs this effect was overcome by the introduction of rudimentary grids at the downstream end of each gap. These grids give unsatisfactory performance because they intercept a large fraction of the beam and because their poor optical quality results in loss of many protons. With the advent of alternating gradient focusing, grids in linacs were largely abandoned and focusing is now accomplished by quadrupole magnets imbedded in the drift tubes. This has resulted in an increase in output current by two orders of magnitude to levels of the order of 100 mA.

As in electron machines, the high rf power level required forces operation at a relatively low duty cycle. Since, at this frequency, the time required to build up the field in the linac cavity is about 200 μsec, pulse lengths for research use are chosen to be several hundred microseconds. Duty cycles are rarely larger than 1 per cent.

The first proton linac was the 40-ft machine at the Lawrence Radiation Laboratory in which protons were accelerated to 32 MeV. This machine was made possible by the development during World War II of powerful rf sources for radar applications. It was a pulsed machine

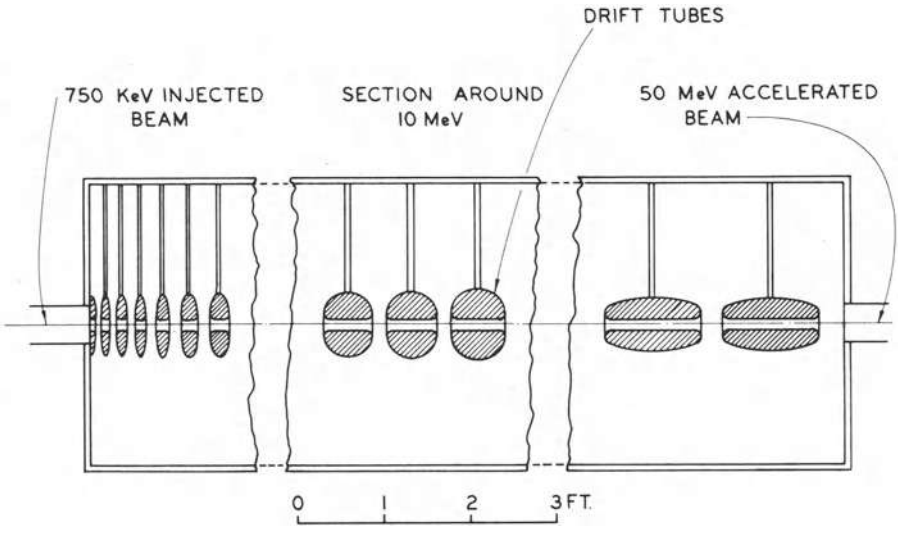

FIG. 2. Cross section through proton linac.

operating at peak currents in the microampere range.

In the early 1950s a daring attempt was made at Livermore to build a continuously operating prototype for a very-high-energy linear accelerator to accelerate protons to energies of hundreds of MeV where they could be used in production of fuels for reactors and weapons. The prototype was built and operated. In those days the highest frequency practical for continuous operation was 12 MHz and as a consequence the resonant cavity was 60 ft in diameter, so big that a railroad spur was run into the resonator to deliver heavy parts. The prototype was 60 ft long. Focusing was by solenoids inside the drift tubes—alternating gradient focusing had not yet been invented. After about two years of work it was discovered that there was considerably more natural reactor fuel than had been suspected and the project was abandoned. The project, called the MTA, was highly classified at the time but was declassified in 1957.

In the late 1950s, 50-MeV pulsed linacs operated at 200 MHz were built to serve as injectors for the proton synchrotrons at the Argonne National Laboratory (ANL), the Brookhaven National Laboratory (BNL) and the CERN International Laboratory in Geneva. These were in operation by 1961. In a few years the BNL linac was replaced by an updated 200-MeV machine which is still in operation in 1982. A similar linac was built at the newly formed Fermi National Laboratory in Batavia, Illinois to be the injector for the second stage of the 200–500-GeV proton synchrotron.

A 20-MeV proton linac is in operation at the KeK Laboratory in Japan where it is the injector for the 12 GeV synchrotron. This machine's KeK Laboratory in Japan where it is the injector for the 12 GeV synchrotron. This machine's structure has some valuable innovations that serve as protection against damage by earthquakes.

The first proton linac to be built by industry for industrial use (production of radiopharmaceuticals) came into operation in 1981 at 40 MeV. It was built by the New England Nuclear Corporation near Boston.

The highest energy reached in a proton linac by 1982 was achieved at Los Alamos where an 800-MeV "meson factory" has been in operation for about a decade. This interesting machine combines a 100-MeV drift-tube linac with a 100–800 MeV iris-loaded section. The iris-loaded structure is not as simple as were the early electron linacs; coupling down the linac is via a cavity on the side of the structure which is coupled to the cavities on each side of an iris. This is reported to improve stability and to decrease rf losses. At 100 MeV the proton velocity is approaching half of the velocity of light and the iris-loaded structure becomes as efficient as the drift-tube system.

Heavy-Ion Linear Accelerators Heavy ions such as C, N, O and Ne and higher masses can be accelerated in a structure similar to a proton linac but usually operated at a lower frequency. Multiply charged ions are injected at a few hundred electron volts and accelerated to energies of the order of 1 MeV per nucleon. The earliest heavy-ion machines resulted from a joint design study between Berkeley and Yale. Machines were built at both centers and proved very valuable in research on nuclear physics and nuclear chemistry. The Yale machine has been shut down but the Berkeley accelerator has undergone massive improvements. In 1982 the Berkeley "Superhilac" had its beam transported a considerable distance across the campus and then injected into the Bevatron, a large synchrotron where much higher energies are achieved.

Heavy-ion accelerators have been particularly valuable in production of transuranium elements. Their energies are continually being pushed to higher levels in the hope of production of elements in the predicted "islands of stability" far beyond the end of the presently collected periodic table of the elements.

A very ambitious heavy-ion accelerator was built during the 1970s at a new laboratory in Darmstadt. It combines several linear accelerator types in sequence, each peculiarly suitable for use in the energy range in question. In 1981 this machine—the UNILAC—was undergoing major rebuilding and modernization. When this is complete the machine's output can include heavy ions with energies of 14 MeV per nucleon.

New Developments Three new developments during the decade of the 1970s merit attention.

First is the "radio-frequency quadrupole" or RFQ. It was proposed in the Soviet Union during the years after 1971 that a structure could be designed in which the rf accelerating fields would not defocus the beam but could provide focusing as well as acceleration. The structure would consist mainly of four bars parallel to the particle orbits, one above, one below, and one on each side of the orbit. The surfaces of these bars facing the orbits would be lightly corrugated, the corrugations above and below facing each other, and the rising part of the side corrugations facing the low part of the upper and lower ones. There was considerable skepticism in the United States about this scheme, and it was not tested in the US until 1978. The tests were at Los Alamos where it was shown that the Russian predictions were completely correct and that the RFQ system has notable advantages at low energies over conventional drift-tube systems. These include possible injection at much lower energies than the conventional 750 keV—the Los Alamos system used 100-keV injection. Possible applications of the RFQ will be mentioned below.

Another step forward, applicable to the linac as well as in many other places is the evolution of rare earth permanent magnets. Pioneering work on these materials has been carried on in many places, mainly industrial, in the United States, Japan, and elsewhere. These materials would be used primarily in linacs in the form of quadrupoles. Permanent magnet quadrupoles for linac focusing were proposed and studied at Brookhaven in the 1950s, but the barium ferrite permanent magnet materials did not have sufficient remanent fields. The new materials have remanent fields a factor of ten higher—of the order of 1 Tesla. The problem of how to construct these materials into a powerful quadrupole was first solved in LBL; since then contributions have been made in a number of laboratories. The first working application of rare earth quadrupoles is in the New England Nuclear accelerator mentioned above.

Sporadic work has been in progress for twenty-five years on development of superconducting rf cavities. Early work in the High Energy Physics Laboratory at Stanford led to optimism that rf fields could be increased and losses drastically reduced in superconducting niobium cavities. But difficulties intervened. There have been few applications; notable has been the superconducting cavity in the Cornell synchrotron. More recently a superconducting heavy-ion linac is almost completed at Argonne. In 1981 most of the linac was assembled and in operation. Eventually it will accelerate heavy ions to energies of 25 MeV per nucleon.

Design Studies and Proposals *FMIT.* A major problem in the design of fusion reactors will be the choice of materials for the "first wall," the wall closest to the reaction area. This wall will be subjected to bombardment by about 10^{14} 15-MeV neutrons per second. Various projects using the D–T reaction have been undertaken but generally they produce neutron fluxes too low by two orders of magnitude. Finally it became evident that the only way to meet the parameters required was by use of a 30-MeV deuteron linac operating continuously with currents of the order of 100 milliamperes. With a liquid metal target this device could yield as much as 10^{16} neutrons per second. The original design was done at Brookhaven; later, the effort was joined by several other laboratories. Eventually the detailed design study was awarded to the Hanford Engineering organization, later to be joined by Los Alamos. This team has made important progress in the design effort. In 1982 it is not clear if or when construction will be approved.

SNQ. At Karlsruhe, a design study is in progress on a linac to serve as a spallation source. A 1.1-GeV proton linac with a current of 100 mA will yield neutron fluxes comparable with those from high-flux reactors. The Karlsruhe linac would have a 5–10% duty cycle. There is some optimism that this project may be approved.

Breeders. The basic idea behind the MTA project mentioned above has been revived. Advances in linac technology make it possible to build a much more reasonable machine than was the MTA. The parameters of such an accelerator, for use in production of plutonium from U^{238} or production of tritium, would be similar to those just described for the SNQ except that it would have a 100% duty cycle. Its energy and current might be higher than those of the SNQ by, perhaps, a factor of two. The design and use of such an accelerator have been discussed for some time at several centers, particularly at Brookhaven and at the Chalk River Laboratory of Atomic Energy of Canada, Ltd.

Medical Applications Electron linacs have been used for several decades in hospitals for radiography and for treatment of tumors. A favorite energy is around 50 MeV. They are produced commercially. Medical and industrial applications involve over 1000 electron linacs in the United States alone.

Neutrons produced by disintegration of deuterons accelerated in cyclotrons have been used for tumor irradiation since the 1930s. More recently protons accelerated in linacs have been used in neutron production. Most notable is the neutron beam generated at the Fermilab in Illinois by an extracted 67 MeV beam from the injector for the Fermilab synchrotron.

Proton beams from linacs and synchrotrons have proved useful in radiography; they appear, for example, to yield more sensitive detections of breast cancers than do the conventional X-ray beams.

Perhaps the most spectacular medical accelerator application involves the use of negative pions. These are unstable antiparticles. They can penetrate human flesh without doing much damage; then, at the end of their orbits they join with a stable particle in an explosive annihilation. Since the orbits have well defined ranges this is evidently a very desirable particle for tumor irradiation. During the late 1970s a design study was done at the Stanford University Hospital. One conclusion of the study was that the facility would be very expensive. A linac with four rooms for patient irradiation would cost some tens of millions of dollars. Hence construction has been postponed pending results from a pion study at Los Alamos. A pion beam has been derived from the Los Alamos "meson factory" and a number of patients have been treated. In the meantime the Los Alamos group has been attempting to design a facility that can be materially less expensive. Part of the Los Alamos enthusiasm for development of the RFQ has been for inclusion in a pion irradiation facility.

Theory Since linear currents have been brought to high levels—hundreds of milliamperes—a number of mysterious phenomena have been observed. In electron linacs spurious field modes have deflected beams into the accelerator walls. In proton linacs the beam "emittance"—its size and angular distribution—has increased for no immediately visible reason in the low-energy part of the machine.

In 1982 it can be said that intensive work using modern computers has resolved these mysteries. This comes as a result of studies in the United States, Europe, and the USSR. Consequently it is now possible to design linacs with confidence that the machine performance will be as predicted by the linac theory groups.

ACCELERATORS, VAN DE GRAAFF

The electrostatic particle accelerator originated by American physicist Robert Jemison Van de Graaff is widely used for nuclear structure research. These constant-potential accelerators make use of the electrostatic belt generator invented by Van de Graaff about 1930. They belong to the *direct* accelerator family in which the high voltage power is applied directly across the terminals of a highly evacuated multi-electrode tube. Electrified atoms or electrons from a source within the high-voltage terminal gain velocity and energy as they move along the tube axis to ground under the action of the applied electric field. As each particle emerges from the accelerator, it is moving with a kinetic energy equal to qV where q is the particle charge and V the generator voltage.

While a Rhodes Scholar at Oxford during 1927 and 1928, Van de Graaff selected the electrostatic approach to fulfill the need, much emphasized by Rutherford, for more copious sources of atomic particles comparable in energy to those spontaneously emitted from naturally radioactive materials (see ELECTROSTATICS). Subsequently, at Princeton University, Van de Graaff produced over one million volts between the spherical terminals of two small electrostatic belt generators of a new and surprisingly simple design; in 1931, he described the electrostatic belt generator principles, and their suitability for the bombardment of atomic nuclei, before the American Physical Society. The method was first applied to nuclear investigations at the Carnegie Institution of Washington in 1932. The early machines, insulated in atmospheric air, produced streams of light positive ions such as protons and deuterons homogeneous in energy and with smooth control over the voltagê range of the machine. General acceptance of the Van de Graaff accelerator as the precision instrument for experimental nuclear research followed rapidly, and its further development for this purpose has been continuous since that time. Greater compactness and higher voltage were attained by insulating the belt generator and tube with compressed gas; greater beam intensity came through improved ion source and acceleration tube technology. About 300 such accelerators were in use by 1960, producing particles and radiation with energies from 400 keV to 10 MeV. At that time, Van de Graaff accelerators for nuclear science incorporated the "tandem acceleration" principle described below. It opened the way to far higher particle energies by applying the tandem principles to multiply charged heavy atoms.

Van de Graaff accelerators can accelerate any electrified particle, including any of the 92 elements, electrons, and clumps of matter simulating micrometerorites. In addition to use in experimental nuclear physics with high-energy positive ions, Van de Graaff electron accelerators designed for voltages in the 1 to 5 MeV range are used to produce megavolt x-rays for the treatment of malignant disease and for the radiographic inspection of heavy opaque structures such as metal forgings, weldments, and rocket engines. Streams of electrons from such accelerators are also used for radiobiological and radiochemical research and for the treatment of skin malignancies. Radiation processing studies for such purposes as the sterilization of surgical materials, the cross-linking of polyethylene and other plastics, the deinfestation of grains, and increased shelf life of foods have often made use of Van de Graaff accelerators.

Van de Graaff Generator Operating Principles Although a variety of electrostatic machines had been developed since the first frictionally excited generator of Otto von Guericke in the middle of the seventeenth century, all have been superseded by the Van de Graaff generator because of its greater voltage capability and comparative simplicity. The essential components of the generator, outlined in Fig. 1, include a well-rounded metal terminal supported by an insulating column and an endless insulating belt system which physically conveys electric charge from ground to the high voltage terminal.

Electric charge of the desired polarity is deposited on the moving belt surface by corona from a row of metal points at a controllable voltage with respect to the lower pulley toward which they are directed. In addition to overcoming friction and windage, the motor-driven belt does work in carrying this charge from ground to the terminal potential. Transfèr of the charge from belt to terminal is accomplished by again presenting a row of points toward the electrified belt. This time the electric field of the surface-bound charge produces the gaseous ionization needed for conduction across

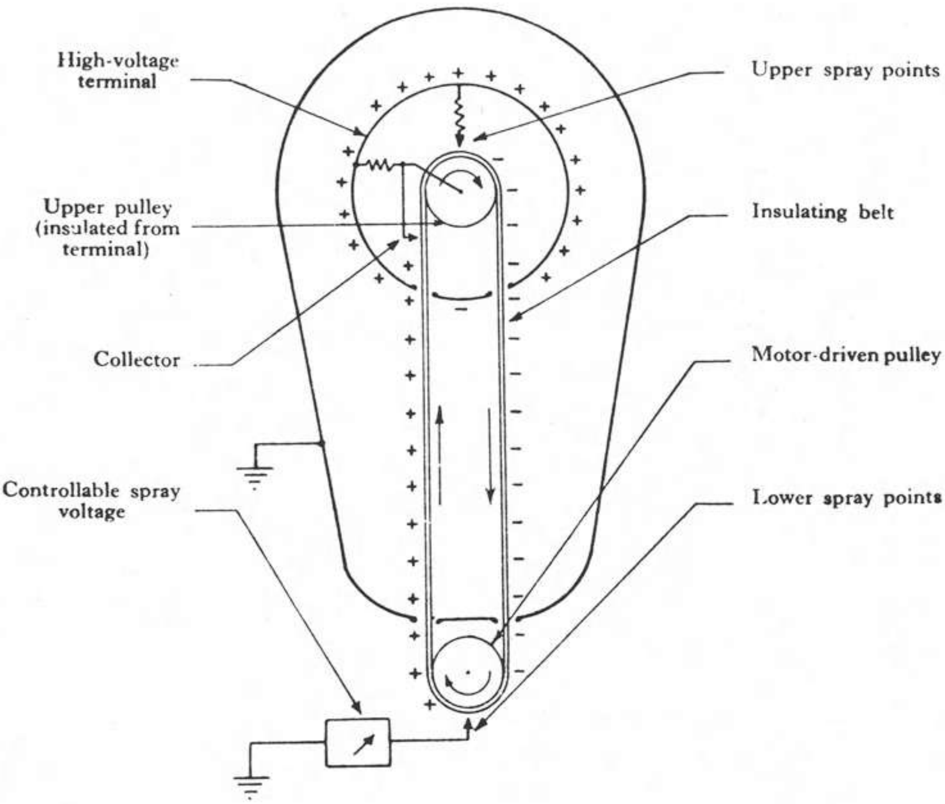

FIG. 1. Diagram of Van de Graaff electrostatic belt generator. Reproduced by permission of The Institute of Physics and The Physical Society from the article by R. J. Van de Graaff, J. G. Trump, and W. A. Buechner, *Reports on Progress in Physics*, **11**, 1 (1948).

the point-to-belt gap. Van de Graaff pointed out that these ionized charge-transfer processes remain independent of the terminal voltage if they are located in the field-free space within the hollow terminal or below the ground plane. The current of such an electrostatic generator is limited by the maximum charge density which can be insulated in the gaseous medium surrounding the belt and by the total area per second of charge-laden surface entering or leaving the terminal. To increase the current capability of the system, the return run of belt may be charged within the terminal in a similar manner but with the opposite polarity.

The potential, V, of the high voltage terminal of a Van de Graaff generator is determined by the amount and polarity of the accumulated charge on its insulated terminal. At any instant $V = Q/C$ where Q is the net positive or negative charge on the terminal and C is the capacitance of the terminal system to ground. Although the Van de Graaff generator is inherently a constant-current machine, it can be maintained steadily at the desired voltage by balancing the current arriving at the terminal against the total current delivered to the load. The load usually includes the particle current through the accelerating tube, the current through resistors which divide the terminal voltage uniformly along the supporting column, and any corona from the terminal itself arising from the high electric field at its surface. By adjusting either the belt current or the load current, the terminal voltage may be maintained at any desired value up to the maximum which can be insulated. This maximum voltage depends only on the physical size and geometry of the terminal and on the electrical strength of dielectric medium surrounding it. An isolated metallic sphere would be the ideal terminal, but modifications are necessitated by the supporting column, belt, and tube.

The pair of generators built by Van de Graaff at Princeton in 1930 each had an aluminum spherical terminal 2 ft in diameter supported in air by a slender glass rod 7 ft long. A silk ribbon was employed as the insulating charge conveyor. The voltage insulated in atmospheric air between these two generators, one accumulating positive and the other negative charge, was more than twice any previously attained constant voltage.

About 5.5 million volts were insulated in air between two larger generators constructed by Van de Graaff in the early 1930s for nuclear research. This voltage required spherical terminals 15 ft in diameter supported on insulating tubular columns 25 ft high. This historic equipment, shown in an early sparking demonstration in Fig. 2, was used in a modified form for precision nuclear research at Massachuesetts Institute of Technology for nearly 20 years. It is now impressively installed at Boston's Museum of Science for daily demonstrations of high-voltage phenomena before large audiences and explanation of the underlying electrical principles.

The need for still higher constant voltages for nuclear investigations, and the desire for more compact apparatus, led to the use of high-pressure gases for the insulation of electrostatic accelerators. Today nearly all Van de Graaff accelerators operating at potentials in excess of one-half million volts are within a steel pressure tank and insulated in gases compressed to 10 to 25 atmospheres. Electronegative gases such as sulfur hexafluoride (SF_6) and "Freon" ($CCl_2 \cdot F_2$) are now increasingly used instead of mixtures of nitrogen and CO_2, since they insulate approximately the same voltages at one-third gas pressure.

Acceleration System The evacuated acceleration tube, the source of positive ions or electrons, and the target to which the energized particles are directed, constitute the particle accelerating system of the Van de Graaff accelerator. The insulating length of the evacuated acceleration tube is divided into many sections by metal disk-like electrodes, each with an axial opening for the passage of the particle beam. Each disk is mounted between annular rings of glass or porcelain to form a slender vacuum-tight accelerating column. The tube electrodes take their potential from the metallic members in the generator column along which the terminal voltage is divided by resistors. The charged particles, acted upon by the electric field be-

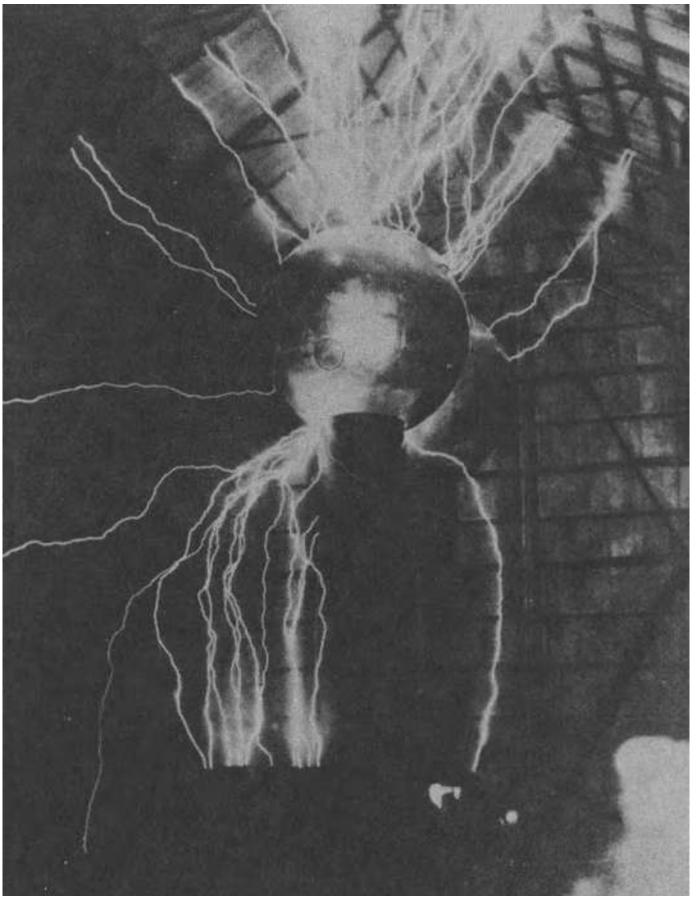

FIG. 2. 5.5-million volt Van de Graaff generator in sparking demonstration.

tween these electrodes, are progressively accelerated and focused as they mọve through the electric fields between the electrodes. At the remote end, the beam emerges as a collimated and directed stream of energetic particles.

Tandem Acceleration and Multiply Charged Ions Van de Graaff accelerators for nuclear science now reach higher particle energies with a given terminal voltage by switching the polarity of the accelerated particles. In the two-stage tandem diagramed in Fig. 3, negatively charged ions are produced at ground and then accelerated toward a high-voltage positive terminal. Within this terminal, the swiftly moving negative ions are stripped of electrons by passing through a thin gaseous region. The resultant positive ions continue through the tube under the second accelerating action of the positive terminal. A singly charged particle, such as a proton, thus arrives at the ground end of the system with an energy of $2qV$.

At sufficiently high energy, atoms of higher atomic number may be stripped of several or even of all their satellite electrons. An ion which lacks N electric charges during the second acceleration stage gains a total energy of $(N + 1)V$ in a two-stage tandem accelerator. Three-stage acceleration is secured by adding an additional inline two-stage accelerator with a central negative terminal and using it to produce one stage of negative ion acceleration for injection into the second tandem. In 1967 the first three-stage tandem Van de Graaff, developed by the High Voltage Engineering Corporation and using terminals at 6 MV, was brought into use for nuclear research at the University of Pittsburgh. This was shortly followed by a three-stage tandem 7.5-MV terminal at the University of Washington in Seattle and in 1970 by two in-line 10-MV "Emperor" tandem Van de Graaffs at the Brookhaven National Laboratory.

Although the light elements, hydrogen and helium, were almost exclusively used as atomic projectiles in nuclear structure physics until 1960, interest in heavier nuclei developed rapidly as higher energies became possible. It is estimated that, by applying tandem acceleration principles, a two-stage Van de Graaff accelerator with a 15-MV positive terminal can produce a beam of uranium ions with energies up to 400 MeV. In large part because of the more complete electron stripping attained at higher energies, three-stage acceleration could produce uranium ions with energies over 1000 MeV.

During the 1970s a number of two-stage Van de Graaff accelerators for national physics research became operational at university and national laboratories in several countries at controllable terminal voltages up to 16 MV. In England at Daresbury an SF_6-insulated, vertically mounted two-stage Van de Graaff designed for terminal voltages up to 30 MV reached the testing stage in 1981.

Medical Applications of Van de Graaff Accelerators Since x-rays are the form of electromagnetic energy, similar to light, produced by the sudden stopping of high-energy electrons, Van de Graaff accelerators are often used as x-ray sources for the treatment of malignant disease and for radiography. In this application, the high-voltage terminal is operated at negative polarity, the electrons are emitted from a tungsten source at the terminal end of the acceleration tube, and they are suddenly stopped after traversing the length of the tube by striking a water-cooled metal target, usually of tungsten or gold.

A 2 million volt x-ray generator of this type,

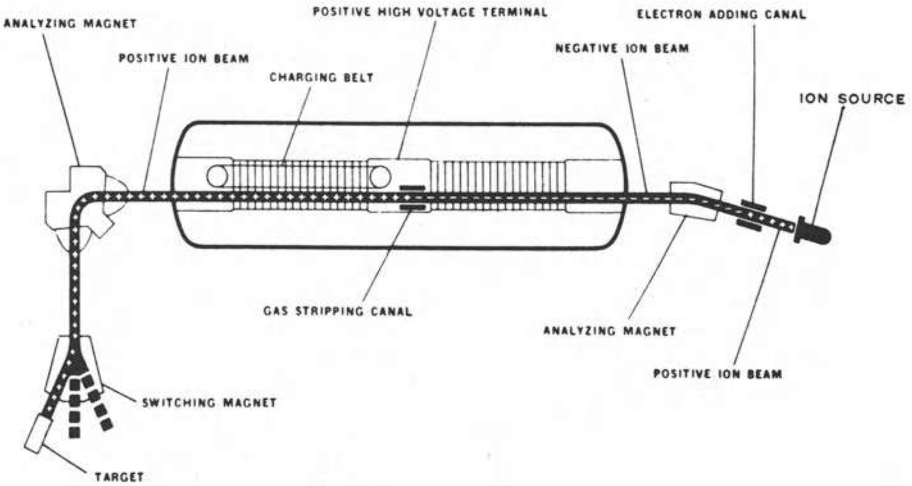

FIG. 3. Diagram of two-stage tandem Van de Graaff accelerator. Reproduced from the article by R. J. Van de Graaff in *Nuclear Instruments and Methods*, 8, 195–202 (1960), by permission of the North-Holland Publishing Co.

in which a gold target is bombarded with 300 μA of electrons, yields an x-ray intensity of 100 r/min measured 1 meter from the target in the electron direction. The quality of this radiation is closely similar in its physical properties to that of the gamma rays from radium or from the radioactive isotope cobalt 60. To equal this x-ray intensity would require over 4000 curies of cobalt 60 or 6000 grams of radium. This Van de Graaff accelerator for therapy is housed in a steel tank 3 ft in diameter and 6 ft long and is insulated by a mixture of nitrogen and CO_2 at 300 psi.

ACOUSTICS

The word *sound* is used to describe two different things: (1) an auditory sensation in the ear; (2) the disturbance in a medium, which can cause this sensation. (Making this distinction answers the age-old question, "If a tree falls in a forest and no one is there to hear it, does it make a sound?")

The science of sound, which is called *acoustics*, has become a broad interdisciplinary field encompassing many academic disciplines—physics, engineering, psychology, speech, audiology, music, architecture, physiology, and others. Among the branches of acoustics are physical acoustics, architectural acoustics, psychoacoustics, musical acoustics, electroacoustics, noise control, shock and vibration, underwater acoustics, speech, physiological acoustics, and bioacoustics.

Physical acoustics deals with the production, propagation, and detection of mechanical waves in continuous media. Of particular interest are the radiation, reflection, refraction, diffraction, attenuation, and scattering of longitudinal waves. Much attention has been given to acoustic waves of high intensity (nonlinear acoustics) and those of high frequency (ultrasonics).

Two interesting acoustical effects, whose understanding requires the use of quantum mechanics, are the propagation of *phonons* (lattice vibrations of very short wavelength) in solids and sound propagation in liquid helium. At least five different kinds of sound have been identified in liquid helium at very low temperatures, where it becomes a superfluid. Acoustic signals generated by high-energy particles in water appear to be promising as a means for detecting high-energy protons, muons, and neutrinos.

Architectural acoustics deals with sound in buildings, and in particular the efficient distribution of desirable sound and the exclusion or reduction of undesirable sound. It is usually this branch of acoustics which comes to mind when the layperson hears mention of the term acoustics.

In most auditoriums, the intensity of the reflected sound exceeds the intensity of the direct sound reaching most listeners. Thus the character of the perceived sound is very much dependent on the nature of the reflected sounds and especially their temporal and spatial distributions. The reflected sound which reaches the listener within about 50 milliseconds of the direct sound is often called the *early* sound. Later-arriving reflections make up the *reverberant* sound. One of the parameters characterizing an auditorium is the *reverberation time*, usually defined as the time required for the reverberant level to decrease 60 dB after the sound source ceases.

Psychoacoustics deals with the perception of sound. Loudness, pitch, timbre, and duration are attributes used to describe sound. These attributes depend in a rather complex way on measurable quantities such as sound pressure, frequency, spectrum of partials, duration, and envelope. The relationship of the subjective attributes of sound to physical quantities is the central problem of psychoacoustics.

Musical acoustics considers special problems connected with the production, transmission, and perception of musical sound. Of considerable interest is the physics of musical instruments, including studies of modes of vibration and feedback processes which sustain oscillations in wind instruments.

Musical acoustics overlaps several other branches of acoustics, such as architectural acoustics (concert halls and music listening rooms), psychoacoustics (perception of loudness, pitch, and timbre), speech communication (singing), and electroacoustics (reproduction of music).

Electroacoustics deals mainly with transducers, such as microphones and loudspeakers that convert sound to electrical signals and vice versa. Sometimes the amplification, recording, and reproduction of sound are included as well. The multi-billion dollar audio and entertainment industries depend upon and apply the principles of electroacoustics, and so it is familiar to the consumer.

Unwanted sound or *noise* has been receiving increasing recognition as one of our critical environmental pollution problems. Like air and water pollution, noise pollution increases with population density; in our urban areas it is a serious threat to our quality of life. Noise-induced hearing loss is a serious health problem for millions of people employed in noisy environments. Finding technical solutions to many of our environmental noise problems is central to the branch of acoustics called *noise control*.

Vibration is a term that describes oscillation in a mechanical system. *Shock* is a rather loosely defined aspect of vibration wherein the excitation is sudden, severe, and nonperiodic. The branch of acoustics referred to as *shock and vibration* includes theoretical and experimental studies of both deterministic and random vibration. Methods of measuring shock and vibration have received considerable attention, as have methods for predicting their effects on physical structures.

Underwater acoustics deals with the propagation of sound in water, especially in sea water. The special interest in this field results from two important applications: underwater communication and sonar (SOund NAvigation and Ranging). Slight changes in sound velocity due to temperature gradients in the oceans result in refraction of sound, the creation of special channels and shadow zones, and other effects of importance to nautical and naval personnel.

Acoustical studies of *speech communication* constitute an important branch of acoustics. The production, analysis, and synthesis of speech have been popular areas of research for acousticians, and their work has been greatly facilitated by the availability of the digital computer.

Physiological acoustics is mainly concerned with the auditory system, how it responds to sound, and evoked responses to sound. New insight into the mechanics of the ear have resulted from probing with laser light and the Mössbauer effect, and this has contributed to some new mathematical models of how the cochlea or inner ear functions.

Bioacoustics deals with the interaction of sound waves with biological tissues in humans and animals. Much recent research in this area is concerned with the use of high-frequency *ultrasound* in medical diagnosis and treatment.

The human auditory system responds to sounds with frequencies ranging from about 20 to 20,000 Hz. Below this audible range is *infrasound* and above it is *ultrasound*. It is possible to generate sound waves in air with frequencies of hundreds of megahertz, and in solids frequencies up to 2.5 THz (2.5×10^{12} Hz) have been generated.

The strength of a sound field is measured by its mean square pressure p expressed as a *sound pressure level* L_p in decibels. Decibels are logarithmic units that compare a sound pressure to a reference pressure, usually 20 micropascals or 2×10^{-5} N/m^2, which is near the threshold of hearing for a healthy young person with normal hearing. Prolonged exposure to sound levels above 85 dB can damage the hearing mechanism, and at levels of 130 dB damage can occur almost instantaneously.

The *loudness* of a sound is a subjective quality that depends mainly upon the sound pressure, but to a lesser extent on the frequency, spectrum, and duration of a sound as well. In an effort to obtain a quantity proportional to the loudness sensation, a loudness scale was developed in which the unit is called the *sone*. One sone is defined as the loudness of a 1000-Hz tone at a sound pressure level of 40 dB. The ear shows a marked decrease in sensitivity at frequencies below 200 Hz, and this decrease is most pronounced at low levels.

Various methods are available for expressing the loudness of complex sounds from their sound pressure levels in octave or third-octave bands. Environmental noise levels are usually measured with a sound level meter using the A-weighting network, and these A-weighted levels correlate reasonably well with subjective loudness. For some types of noise, such as that of a jet aircraft, a scale of perceived noise level may be preferable.

Acoustic disturbances can usually be regarded as small perturbations to an ambient state (which in a fluid may be described by the pressure, density, and fluid velocity). The linear approximation (sometimes called the acoustic approximation) considers only first-order changes in these variables, and assumes that their time averages are zero. In a sufficiently intense sound field, however, the time average of one or more of these variables may differ from its ambient value. This is an example of *nonlinear* behavior. Steepening of wavefronts in intense sound waves is another.

ADSORPTION AND ABSORPTION

When a porous solid such as charcoal is exposed, in a closed space, to a gas such as ammonia, the pressure of the gas diminishes and the weight of the solid increases; this is an example of the adsorption of a gas by a solid. It is termed physical adsorption because the forces bringing it about are the "van der Waals" forces of attraction which act between the molecules of the gas and the atoms or ions comprising the solid. It is now known that all solids, whether porous or nonporous, will adsorb all gases physically, whereas the phenomenon of *chemisorption* is specific in nature. Thus hydrogen is chemisorbed by transition metals such as nickel or iron but not by oxides such as alumina.

In physical adsorption the amount of gas taken up per gram of solid depends on the temperature T, the pressure p, and the nature of both the gas and the solid: $n = f(p, T, \text{gas, solid})$. For a given gas (the "adsorbate") adsorbed on a particular solid (the "adsorbent") at a fixed temperature, the amount adsorbed depends only on the pressure of the gas, and the relationship between n and p, viz., $n = f(p)_{T,\text{gas, solid}}$, is termed the *adsorption isotherm*. For vapors, the alternative form $n = f(p/p^0)_{T,\text{gas, solid}}$ is preferable (p^0 = saturation vapor of the adsorbate at temperature T).

Adsorption isotherms may be classified into the five types of the Brunauer-Emmett-Teller (BET) classification. The basic isotherm, the Type II, is concave to the p/p^0 axis at low relative pressures, then passes through a point of inflection (situated usually between ~0.05 and ~$0.30p^0$) to become convex to the p/p^0 axis at higher relative pressures; the point of inflection corresponds to the *monolayer capacity* n_m of the adsorbent, i.e., the amount of adsorbate which can be accommodated in a completed single molecular layer ("monolayer") on the surface of the solid; the convex branch corresponds to the building up of a multimolecular layer ("multilayer"). From n_m it is possible in principle to calculate the specific surface A (= surface area per gram) of the solid, by assigning a value to a_m, the area occupied per molecule of adsorbate in the monolayer. In practice, however, very few adsorbates other than nitrogen (at its b.p., 77 K) are found to be suitable, and the "BET-nitrogen" method is now the standard procedure for estimation of the specific surface of finely divided or porous solids. (When $A <$ ~$1 \text{ m}^2\text{g}^{-1}$, krypton, though less reliable, has to be used).

If the solid contains mesopores (pores having a width between tens and hundreds of Å) the isotherm is similar to Type II except that the convex branch is replaced by a hysteresis loop in which the curve for desorption lies above that for adsorption, (Type IV isotherm); frequently, with xerogels for example, the isotherm bends over to become effectively horizontal as saturation pressure is approached. By application of the Kelvin equation to points on the loop (usually the desorption branch) it is possible to calculate the pore size distribution of the adsorbent, but owing to the arbitrary nature of the assumptions that have to be made, including oversimplified pore models, the detailed interpretation of the results is uncertain. Even so, the method (again with nitrogen as adsorbate) is valuable for comparative purposes, and is indeed virtually the only method available for the lower end of the mesopore range.

Since adsorption is exothermic, the amount adsorbed at a given pressure must fall as temperature increases. The differential molar heat of adsorption $\dot{q}$—i.e., the limit of the ratio ($\delta Q/\delta n$), where δQ = heat evolved for an increment δn in the amount adsorbed—is a function of the amount adsorbed. In general, $\dot{q}$ decreases gradually from an initial high value (e.g., ~$2q_L$) as n increases over most of the monolayer range, then rises to a low maximum (e.g., ~$1.3q_L$) as n approaches n_m, and finally falls to a nearly constant value close to q_L in the multilayer region (q_L = molar heat of condensation). The initial fall is ascribed to surface heterogeneity (adsorption occurring preferentially on the high-energy sites), and the low maximum is explained in terms of the attractive interaction between adsorbed molecules in the monolayer as they become closely packed together.

The *net heat of absorption* ($\dot{q} - q_L$) determines the shape of the isotherm in the monolayer region: the greater the value of ($\dot{q} - q_L$) the sharper is the "knee" of the isotherm; and if $(\dot{q} - q_L) \approx 0$, the isotherm actually becomes convex to the p/p^0 axis, giving a Type III or a Type V isotherm. (The latter, like the Type IV, bends over as p/p^0 approaches unity).

In micropores (i.e., pores of width ⩽15 Å), the attractive fields from neighboring walls overlap so that the net heat of adsorption, and with it the adsorption at a given relative pressure, is enhanced; consequently the isotherm rises steeply from the origin. Thus a solid containing micropores plus mesopores will give a Type IV, and one with micropores plus a large external surface will yield a Type II isotherm, but with a much sharpened knee in each case. With a wholly microporous solid, where mesopores are absent and the external surface is negligible, the point of inflection vanishes and the isotherm soon reaches a plateau and remains horizontal for the rest of its course (Type I isotherm). The mechanism of adsorption in micropores is still a matter of controversy and reliable methods for the estimation of micropore size distribution are still lacking.

The detailed course of the isotherms of all types, and of the corresponding curves of $\dot{q}$ against n, vary considerably with the mode of preparation and subsequent treatment of the solid, which influence both the porosity of the solid and the structure of its surface. However, in recent years some success has been achieved in preparing standardized samples of a few substances, notably silica, γ-alumina, and graphitized carbon blacks.

Since physical adsorption results from van der Waals forces, the greater the condensability of the gas or vapor as measured by its boiling point or its critical temperature, the greater is the amount of gas or vapor adsorbed at a given pressure. Thus at room temperature and atmospheric pressure, the "permanent gases" such as hydrogen or nitrogen are only slightly adsorbed even on a good adsorbent such as charcoal, while carbon dioxide is more adsorbed, and benzene and carbon tetrachloride are strongly adsorbed. At very low temperatures the adsorption is correspondingly greater, so that nitrogen at its boiling point of −195°C has an adsorption, on a given solid, comparable with that of benzene at 25°C. For the adsorption to be readily measurable, however, the solid needs to have a relatively large area—a completed monolayer of nitrogen, 1 square meter in extent, weighs only 0.3 mg, for example—so that adsorption phenomena may escape notice unless the solid is "highly disperse," i.e., has an area exceeding several square meters per gram.

Chemisorption results from valency forces—from the sharing of electrons between the adsorbate molecule and the adsorbent—so that, in effect, a surface chemical compound is formed. Chemisorption is characterized by a high heat of adsorption (of the order of many tens of kilojoules per mole, in contrast to the 20–30 kJ mol^{-1} of physical adsorption) and by difficulty of reversal: to desorb a chemisorbed gas in a reasonable time requires a temperature much higher than that at which the chemisorption occurred. Even so the adsorbate may be released in a chemically changed form; thus carbon monoxide chemisorbed on zinc oxide at room temperature is desorbed as carbon *dioxide* at 300°C.

Chemisorption is an essential primary step in heterogeneous catalysis. At least one of the reactants must be chemisorbed on the surface of the catalyst, and each of its molecules then forms, on the surface, a "transition complex" with a chemisorbed molecule of the second reactant B, or with a molecule of B which hits it directly from the gas phase.

Physical adsorption is an extremely widespread phenomenon, frequently unwanted. The adsorption of water vapor by chemicals, by textiles, by building materials and by glass is frequently troublesome and can only be avoided by taking extreme precautions; sometimes, however, the adsorption of water may be beneficial, and it plays an important role, for instance, in the hygiene of clothing.

Adsorption, whether physical or chemical, also reduces the adhesion, and therefore the friction, between solids; gases can accordingly act as lubricants. In addition, adsorption diminishes the tensile strength of brittle solids; the breaking stress of glass when exposed to nearly saturated water vapor is four times less than when exposed to a vacuum. The mechanism is a matter of controversy, but it is probably connected with the fact that adsorption reduces the free surface energy (in the thermodynamic sense) of the solid. Adsorption also causes a small (a fraction of 1 per cent) expansion of the solid, but the swelling pressure set up—i.e., the pressure which would have to be exerted on the solid to prevent expansion—is very high and may reach many atmospheres. Stresses set up in structures made up of porous solids, such as cement and mortar, when they take up or lose vapors, particularly water, may be so great as to cause cracking.

Absorption is said to occur when the molecules of the gas or vapor actually penetrate into the solid phase itself, so that a solid solution is formed; hydrogen is absorbed by iron at elevated temperature in this way, and many synthetic polymers absorb water vapor; benzene vapor is extensively taken up by rubber and water vapor by gelatin. Extensive swelling occurs and if the solid is mechanically weak, the absorption may continue until the system acquires the consistency of a jelly, or even the fluidity of a sol. An absorption isotherm (analogous to the *adsorption* isotherm discussed earlier) can be determined, but is generally complicated and is best handled theoretically as a branch of solution thermodynamics.

In *adsorption from solution*, when a solid having appreciable surface area (say ~1 square meter per gram) is shaken up with a solution of substance A in solvent B, both A *and* B are adsorbed, but to different relative extents. This manifests itself in a change in the composition, e.g., a change Δx_A in the mole fraction of A in the solution. The problem is thus more complicated than in the adsorption of gases, and the measured isotherm—the curve of Δx_A against x_A —is not susceptible to any simple theoretical treatment. In a *dilute* solution of A, however, A is always relatively more adsorbed than the solvent B; and if A is colored, the resulting diminution in the concentration of A in the solution will be readily detected by eye or colorimetrically.

AERODYNAMICS

Aerodynamics is the science of the flow of air and/or of the motion of bodies through air. It is usually directed at achieving flow or flight with the maximum efficiency. Aerodynamics is a branch of aeromechanics; the other main branch is *aerostatics* (lift of balloons, etc.). In popular usage aerodynamics differs from *Gasdynamics* in that the latter considers other gases and products of combustion (and combustion); from *aerophysics*, which implies substantial molecular changes in the gas; and from *hydrodynamics*, which implies employing a medium of density approximating that of useful bodies in it, and not infrequently a sharp limit to its extent (i.e., a water surface).

Aerodynamics is conveniently divided into low and high speed regimes. (The latter is in the articles on COMPRESSIBILITY, FLUID DYNAMICS, and SHOCK WAVES; here low-speed aerodynamics is discussed.)

The many facets of aerodynamics include: (1) aerodynamic performance, (2) aerodynamic design, (3) aerodynamic loads, (4) aerodynamic structures, (5) aero-elasticity, (6) aerodynamic heating, (7) aerodynamic compressibility, and (8) aerodynamic research for all of the above.

The computation of aerodynamic effects is based on four laws (given as adapted for fluids):

(1) *Newton's Second Law*: "A force applied to a fluid results in an equal but opposite reaction which in turn causes a rate of change of momentum in the fluid."

(2) *The Equation of State*: (also called the Gas Law): "The product of pressure and volume of a gas, divided by its absolute temperature, is a constant."

(3) *The Continuity Equation*: "The mass that passes a station in a duct, or in a natural tube bounded by streamlines in a given time, must equal that passing a second station in the same time."

(4) *The Energy Equation*: "The total energy in a mass of air remains constant unless heat or work is added or subtracted."

The above relations, written algebraically and limited or combined, yield a vast array of equations used to calculate the practical problems of aerodynamics. One of the *equations* thus derived is due to Bernoulli and is widely used in low speed aerodynamics. It states that in free flow the sum of the static and dynamic pressures is a constant. Static pressure is that pressure which is equal in all directions; dynamic pressure is the pressure rise realized by bringing the fluid to rest. Bernoulli's equation states that as air speeds up, its pressure falls, thus explaining the "lifting suction" as the airstream traverses the curved upper surface of a wing.

The overwhelmingly important *law* of low speed aerodynamics is that due to Newton (1, above). Thus a helicopter gets a lifting force by giving air a downward momentum. The wing of a flying airplane is always at an angle such that it deflects air downward. Birds fly by pushing air downward. Propellers and jet engines make a forward force ("thrust") by giving air a rearward momentum. For some aircraft in some flight modes, *both* the engine *and* the wing are used to provide downward momentum. In the above statements, it is much more accurate to use the expression "downward (or rearward) momentum," rather than "downward (or rearward) velocity," since less dense air at high altitudes produces smaller forces for comparable velocity changes. Forcing the air downward does not occur instantaneously; it takes place over the lifting surface. Indeed, the motion reaches ahead of the airplane so that some downward velocity occurs before the airplane arrives. Thus, airplanes (helicopters, birds, etc.) are always "flying uphill" which is another way of saying it takes a force to fly even when the air is considered frictionless. This force is used to push air *forward*, and is called "drag due to lift." It *increases* as an airplane *slows down* or *flies higher*, and it may be reduced (for low-speed aircraft) by *increasing* the wing span. Supersonic aircraft, operating under the same laws, but in a different manner, still have a drag due to lift which increases as above, but is reduced designwise by *reducing* the span; hence the new airplanes whose wings crank back for high-speed flight. (The "uphill" concept has an analogy in the rolling resistance of a wheel. The weight a wheel carries deflects the surface on which it rests so that it sits in a "gully." Either way it rolls, the path is uphill).

A second important phenomenon (but not a "law" in the sense that it cannot be circumvented) is the manner in which air flows over say, an airplane surface. Away from the surface some free-stream velocity exists. As the surface is approached the local velocity becomes less than freestream and finally becomes zero at the surface. The zone in which the air is appreciably slower is called the *boundary layer*. Slowing the air reduces its momentum, and by Newton's law (above), a force is produced which acts in a direction to slow the airplane. Like forward force needed to produce lift, this *frictional drag* force must have a forward force supplied from somewhere to balance it. For high-speed aircraft a heating occurs in the boundary layer which requires additional force. Skin friction drag is *decreased* by reducing the amount of surface the air scrapes against (i.e., making the aircraft smaller) and by *flying slower* or *higher*—essentially the opposite of the actions which reduce the drag due to lift. Thus the science of aerodynamics seeks the most efficacious melding of the two types of losses. Factors which must be added include providing space for fuel and people, and enough wing to yield a reasonable landing speed. The drag due to lift and the drag due to friction are balanced by the forward thrust provided by the propeller or jet engine (which also operates by Newton's law). However, this is not enough. The distribution of lift on wing and tail must be so located that the aircraft is aerodynamically balanced. Like a child's swing, upon being disturbed it should tend to return to its original ("trimmed") condition.

In the above paragraphs the concern has been for aerodynamic efficiency through optimum design for optimum performance. After these have been achieved (by studies of previous designs and tests in *wind tunnels*) the aerodynamicist provides aerodynamic loads to which an aero-structural engineer must design. Aerostructural design is one of the most challenging of all design problems as the loads must be carried by minimum weight. Aeroplanes carry no "factor of safety" (sometimes called "factor of ignorance"). The aerodynamic-loads engineer furnishes the maximum air loads the aircraft is ever expected to see; the structure is designed to withstand these loads without being permanently bent. If it ever sees a greater load it will be bent or destroyed; there is about a 50 per cent difference between maximum no-permanent set load and catastrophic destruction, depending on the material of which the aircraft is constructed.

In an effort to keep aerodynamic structures light, they often become flexible, and, in turn, become susceptible to flutter, a motion similar to that of a flag in a wind. The motion gets worse with speed. It is the job of the aeroelasticity engineer to assure that flutter will not occur, usually through a redistribution of internal weights (fuel, etc.) and, rarely, through strengthening the structure.

At the higher speeds, the performance, loads, structures and elasticity problems are greatly worsened by the aerodynamic heating which occurs. This is discussed in the article on COMPRESSIBILITY.

Aerodynamics is not only concerned with aircraft. The wind loads on signs, buildings, trees; the aerodynamics drag of autos, boats, trains; the air pollution from smoke stacks of factories and ships; the evaporation of open water; the blowing of sand and snow; and the internal losses of air-conditioning ducts—all deserve and are getting scrutiny by aerodynamicists. The forces on all are proportional to the rate of change of momentum they give, or is given by the air; and all have friction drag in their boundary layers. Aerodynamic research scientists seek to further understand and improve the air flow involved in each.

Aerostatics Aerostatics is the science of making things (balloons, zeppelins, etc.) statically buoyant in the air.

The basic principle of aerostatics is due to Archimedes. "A body immersed in a fluid [or gas] is buoyed up by a force equal to the weight of the fluid [or gas] displaced." Thus for buoyancy the weight of structure plus the weight of the contained gas must equal the weight of the air displaced.

Wind Tunnels Wind tunnels are devices which provide an airstream of known and steady conditions in which models requiring aerodynamic study are tested. The essential elements of a tunnel are:

(1) A drive system consisting of either a compressor for continuous operation or a tank of compressed air for intermittent operation;

(2) a test section in which models are held and their orientation is changed.

(3) instrumentation capable of reading force, pressure, temperature, and optical effects produced by the model;

(4) an air efflux system consisting of free exit to the atmosphere or to a vacuum tank, or a tunnel returning the air to the compressor.

There are approximately 500 wind tunnels in the country, ranging in test section size from 1 in. X 1 in. to 80 X 120 ft, with speeds from 50 to 7000 mph.

AIRGLOW

The aurora has been known to mankind since antiquity (see AURORA). The intensity, color, and motion of an active auroral display invariably create a vivid and memorable impression upon those fortunate enough to observe it. The aurora is a luminescence of air at high altitude which results from the penetration of energetic charged particles (principally electrons) into the atmosphere. The existence of the Earth's magnetic field restricts the entry of these particles to high latitudes; thus only those living in the far North or South enjoy regular entertainment by this magnificent natural phenomenon.

There is another way by which the upper atmosphere becomes luminescent; this arises from the release of chemical energy stored up during the day by the absorption of sunlight. This luminescence is known simply as the *airglow*, although in earlier times it was rather ponderously dubbed "the light of the night sky." The sequence of events which lead to airglow may be understood by the following example.

Over the range of wavelength (or colors) to which the eye is sensitive the atmosphere is highly transparent. This is of course no accident but a natural result of evolution, as is the further fact that the human eye is most sensitive in the yellow-green (~5500 Å) just where the sun radiates light most strongly. But deep in the ultraviolet (below 1800 Å) oxygen molecules cease to be transparent and absorb light strongly; in this process the molecule is broken up into two oxygen atoms. Most of the sunlight which thus dissociates molecular oxygen is absorbed between 100 and 150 km above the Earth's surface. At such altitudes an atom makes a collision with another atom relatively infrequently, perhaps 100 times per second. At the surface of the Earth collisions occur at a rate of about a billion per second. But even if one oxygen atom encounters another they will not recombine to reform a molecule unless a third particle is also present to satisfy laws requiring that energy and momentum be conserved. The frequency of such triple collisions is of course much less than the frequency of simple two-body collisions. Thus it is that above 100 km a newly released oxygen atom could expect to live for months before it joins up with another in a triple collision to reform a molecule. But at lower altitudes the lifetime is shorter. So the oxygen atoms created by sunlight above 100 km drift downward until they arrive at the region between 90 and 100 km where their lifetime is short enough that they there recombine to form molecules rather than continue their downward drift. The recombination releases just the amount of energy originally required to split the molecule and so, in principle, this energy can appear in the form of light emission at any wavelength longer than about 1800 Å. In most cases the energy actually goes into heating the atmosphere but when it does come out as light one has a component of the airglow. In effect, what has happened is that a small fraction of the incoming sunlight has been trapped in the atmosphere and later released as longer wavelength light. One may think of this as a phosphorescence with a time delay imposed both by the need for oxygen atoms to drift downward to altitudes where they can recombine and by the recombination lifetime of many days even at this latter altitude.

This sort of airglow process includes not only dissociation and recombination of neutral molecules but also the case in which a molecule or atom is ionized by very short solar wavelength; here the neutral particle is stripped of one of its electrons, leaving a heavy positively charged ion behind. Eventually the free electron will meet and recombine with an ion, and in this process there also can be emission of light. It is the cloud of temporarily liberated electrons which reflect radio waves back to Earth (see IONOSPHERE).

Not all of the airglow comes from such recombination processes, although they are the principal source of the night airglow. During the daytime atoms and molecules in the upper atmosphere can absorb sunlight at wavelengths too long to dissociate or ionize. This energy is almost instantaneously re-emitted either at the same wavelength or at a longer wavelength; it can be considered as a fluorescent component in the day airglow. Yet another type of day airglow comes from the process in which a fast moving electron, newly formed by ionization, collides with an atom or molecule and transfers energy to it; the excited atom or molecule can then emit light.

From the Earth's surface one can only determine the total airglow intensity coming from above. To find out the altitude from which the glow arises one must measure either by using a rocket which passes through the emission layer or by viewing the horizon from a satellite. Such measurements show that nearly all of the airglow comes from the altitude region from about 50 km to 400 km. There is also a powerful means by which one can, in some cases, determine the emission altitude of airglow from the ground. This is to make measurements during the twilight period after sunset or before sunrise when the upper atmosphere is still illuminated by the sun even though it is dark at the surface. After sunset the dayglow emissions will persist until the Earth's shadow reaches the altitude from which the glow arises. The time at which the glow fades away will indicate what this altitude is.

Despite all this furious chemical activity in the upper atmosphere the net result is only a rather feeble glow, particularly at night. All the various recombination processes together produce a night airglow which is not immediately obvious even far from cities. One way to see that there *is* such a glow is to notice that one's hand looks dark against the night sky in some direction where there are very few stars, on a moonless night far from cities. Another way is to look from a jet aircraft just above the horizon at night (if the cabin lights are out). A faint greenish glow can be seen near the horizon; this is airglow from about 95 km altitude which appears brighter because one is looking nearly tangentially through the atmosphere. The green glow comes from oxygen atoms which have been excited by the energy released in the recombination of two other atoms. As it happens, it is this same radiation from oxygen atoms which gives aurora its yellow-green color, but in that case the atoms have been excited by an energetic stream of electrons injected into the atmosphere from above (see AURORA).

The day airglow is of course not detectable to the eye owing to the enormously more intense visible sunlight scattered in the lower atmosphere. It can be seen and photographed from above and astronauts have done just this.

Scientists have found that a great deal can be learned about the upper atmosphere by studying the airglow using sensitive devices (spectrometers) which isolate one or another of the many different wavelengths present in the airglow emission spectrum. Even the day airglow can be detected and measured from the Earth's surface with the help of special instruments although this is best done using spectrometers carried aboard satellites. One can identify the atom or molecule responsible for airglow emission at a certain wavelength. Then one can use the result of laboratory studies on how recombination processes lead to light emission to infer what particular atoms or ions must be recombining in order to produce that particular emission. It is even possible to use the airglow as a thermometer and find out the temperature of the atmosphere at the altitude from which a particular airglow emission arises. One way this is done is to use the Doppler effect; an atomic emission line in the airglow actually possesses a finite width in wavelength (about 1/100 Å) determined by the velocity of the emitting atoms. This velocity is a measure of the atmospheric temperature. Sometimes the temperature is seen to oscillate up and down over a period of an hour or less by as much as 50°C; when this happens one knows that waves are moving up in the atmosphere causing a periodic compression and heating. These waves generally start in the lower atmosphere, often from weather disturbances; they grow in amplitude as they rise through the atmosphere and so produce large oscillations in temperature when they arrive at, say, 100 km altitude. Their importance lies in the fact that they carry energy from the lower atmosphere to high altitudes. At the altitude where the wave dissipation occurs the character of the upper atmosphere is modified by the wave energy deposited there.

While much continues to be learned about our atmosphere using ground based studies of the airglow, there is today even more being done from space. An example is a study of the ozone layer using infrared airglow from the oxygen molecule. Dangerous ultraviolet light from the sun (just below 3000 Å) is blocked by the ozone layer and when it is absorbed the ozone is dissociated into an oxygen atom and an oxygen molecule. The molecule is excited and radiates near 13,000 Å; a measurement of this airglow radiation allows one to determine the density of the parent ozone molecules and to study how and why the ozone varies in both space and time.

ALTERNATING CURRENTS

Definition of Alternating Current An alternating current is a periodic function of the time, the function being such that the average value is zero. A special case of an alternating current is shown in Fig. 1. The square wave is clearly periodic, and in any one cycle, the area under the curve above the horizontal axis is equal to the area below the horizontal axis. If the two areas are not equal, the current may be described as an alternating current superposed on a direct current, provided the resultant current varies in a cyclic manner.

In general, any alternating current may be considered to be the sum of a Fourier series of sinusoidal waves. For example, the square wave shown in Fig. 1 may be written as

$$\frac{4A}{\pi}\left(\sin 2\pi ft + \tfrac{1}{3}\sin 6\pi ft + \tfrac{1}{5}\sin 10\pi ft + \cdots\right)$$

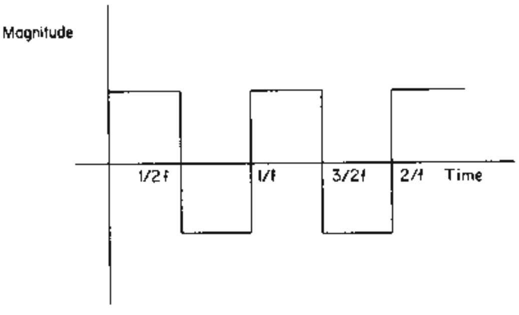

FIG. 1. A square wave alternating current.

where A is the amplitude of the square wave, f is the frequency in hertz (cycles per second), and t is the time in seconds. Since any alternating current may be expressed as the sum of a series of sinusoidal terms, the remainder of this article will be devoted to a discussion of sinusoidal voltages and currents.

Root-mean-square Value The equation for an alternating current i may be written as

$$i = I_m \sin(\omega t - \delta) \tag{1}$$

where I_m is the maximum or peak value of the current, ω is 2π times the frequency f in hertz (Hz), and δ is a phase angle. A graph of the current i is shown in Fig. 2. Since the positive and negative loops are mirror images, the average value of the current over a complete cycle is zero. The latter statement is valid for all alternating currents and, hence, gives no information about a particular alternating current.

A useful way of stating the magnitude of an alternating current is to give its effective or root-mean-square value. The term root-mean-square is derived from the idea of taking the square root of an average square of the current. Thus, by definition, the effective value I_e of the current i given by Eq. (1) is

$$I_e = \sqrt{\frac{\omega}{2\pi}\int_0^{2\pi/\omega} I_m^2 \sin^2(\omega t - \delta)\, dt} \tag{2}$$

where $2\pi/\omega$ is the time for one cycle. In effect, the quantity under the square root sign is the sum of the squares of the currents during one cycle divided by the time for one cycle. The value of I_e may be found by performing the integration. The result is

$$I_e = \frac{I_m}{\sqrt{2}} = 0.707 I_m \tag{3}$$

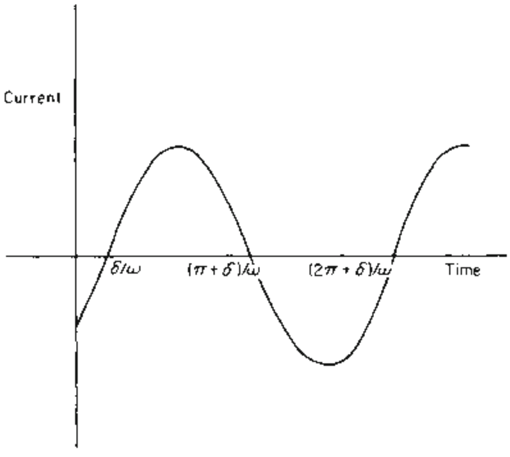

FIG. 2. A sinusoidal alternating current.

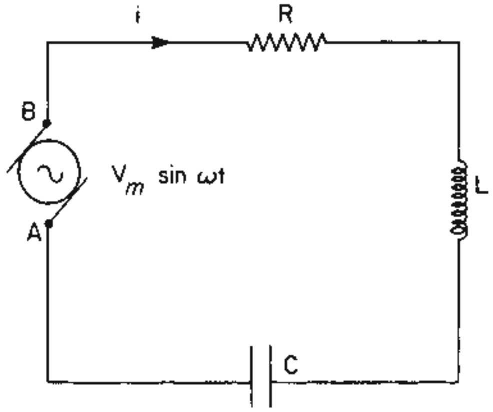

FIG. 3. An ac series circuit.

Clearly, the effective value of a sinusoidal alternating current is 70.7 per cent of the maximum or peak value. Similarly the effective value of a sinusoidal voltage is 70.7 per cent of the maximum or peak value.

Alternating-current Series Circuit A simple alternating-current series circuit is shown in Fig. 3. At the instant considered in the diagram, the current is in the direction shown. The circuit consists of a generator connected in series to a pure resistance R, a pure inductance L, and a capacitance C. It is important to understand the relationship of the current to the potential difference across each element. In each case, the best starting point is a basic definition. According to Ohm's law for a pure resistance,

$$R = \frac{V_R}{i} \tag{4}$$

where V_R is the voltage drop across the resistance. The inductance L of a coil is given by

$$L = \frac{N\phi}{i} \tag{5}$$

where N is the number of turns and ϕ is the magnetic flux passing through one of the turns of the coil as a result of the current i. Writing Eq. (5) as

$$Li = N\phi$$

and then differentiating both sides, we obtain

$$L\frac{di}{dt} = N\frac{d\phi}{dt} \tag{6}$$

According to Faraday's law, the right-hand side of Eq. (6) is the magnitude of the induced emf. The left-hand side, $L\, di/dt$, therefore, is the voltage drop V_L across the inductance L. Finally, the capacitance C is by definition

$$C = \frac{q}{V_C} \tag{7}$$

where q is the instantaneous charge on the positive plate and V_C is the drop in potential in going from the positive plate to the negative plate.

The relation between the impressed voltage $V_m \sin \omega t$ and the instantaneous current i follows from Kirchhoff's law that the sum of the differences in potential in going around a complete circuit must be zero. At the instant shown in Fig. 3, there is a potential rise $V_m \sin \omega t$ in going from A to B and there are potential drops, V_R, V_L, and V_C in traversing the rest of the circuit. According to Kirchhoff's law

$$V_m \sin \omega t - V_R - V_L - V_C = 0$$

$$V_m \sin \omega t - Ri - L\frac{di}{dt} - \frac{q}{C} = 0$$

Since the current is the rate of flow of charge

$$i = \frac{dq}{dt} \tag{8}$$

It is now possible to express the current i as a function of t. The result neglecting initial transient effects is

$$i = \frac{V_m \sin(\omega t - \delta)}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}} \tag{9}$$

where $\tan \delta = (\omega L - 1/\omega C)/R$. The phase angle δ is the angle by which the current i lags behind the impressed voltage.

The maximum or peak value of i is

$$I_m = \frac{V_m}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}}$$

If both sides of this equation are divided by $\sqrt{2}$, we obtain

$$\frac{I_m}{\sqrt{2}} = \frac{V_m/\sqrt{2}}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}}$$

$$I_e = \frac{V_e}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}} \tag{10}$$

Equation (10) states the relation between the effective value of the current and the effective value of the impressed voltage.

Impedance and Reactance The denominator of Eq. (10) may be defined as the impedance Z of the circuit. We may therefore write

$$I_e = \frac{V_e}{Z} \tag{11}$$

Equation (11) is similar in form to Ohm's law, Eq. (4). The impedance Z is the square root of the sum of the squares of two terms. The first is the resistance R, and the second is $\omega L - 1/\omega C$. The latter is called the reactance. The quantity ωL is the inductive reactance whereas $1/\omega C$ is capacitative reactance. If the inductive reactance is greater than the capacitative reactance, the phase angle δ is positive and the current lags behind the voltage. If the inductive reactance is less than the capacitative reactance, the current leads the voltage.

Vector Diagram The current and the various voltages may be related in a meaningful way by means of a vector diagram. Equation (10) may be rewritten as follows:

$$V_e = \sqrt{R^2 I_e^2 + (\omega L I_e - I_e/\omega C)^2} \tag{12}$$

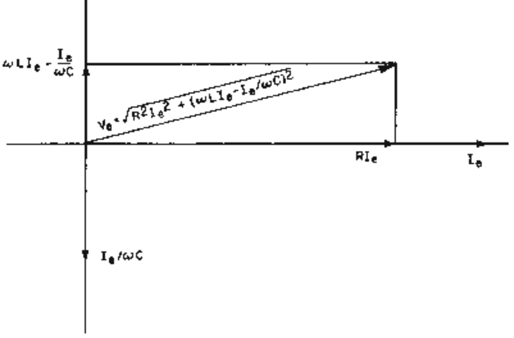
Equation (12) implies that V_e is the resultant of a vector RI_e at right angles to a vector $\omega L I_e - I_e/\omega C$. This is shown in Fig. 4. The current I_e is drawn along the horizontal axis, and the effective voltage drop across the resistance, RI_e, is also drawn along this axis. The effective voltage drop across the coil is $\omega L I_e$, and this potential difference is drawn along the positive vertical axis. Finally, the effective potential drop across the capacitor is $I_e/\omega C$, and this vector is drawn along the negative vertical axis. The resultant of the three vectors is V_e, in agreement with Eq. (12).

Resonance If the capacitance C can be varied, the current I_e will be a function of C in accordance with Eq. (10). When

$$\omega L = \frac{1}{\omega C} \tag{13}$$

the effective current will be a maximum. The circuit is then said to be in resonance. Actually, the inductance L or the angular frequency ω may be varied instead of the capacitance C. The circuit will be in resonance whenever Eq. (13) holds. At resonance, the impedance Z is equal to R, and the circuit, under such circumstances, acts as though it contains resistance only. The process of obtaining resonance is called tuning the circuit.

Average Power The potential difference V across an ac generator at any instant is the work required to transfer a unit charge from the



$\omega L I_e$
$\omega L I_e - \frac{I_e}{\omega C}$
$V_e = \sqrt{R^2 I_e^2 + (\omega L I_e - I_e/\omega C)^2}$
RI_e
I_e
$I_e/\omega C$

FIG. 4. A vector diagram for an ac series circuit.

negative to the positive terminal. The work done in transferring a charge dq is consequently $V\,dq$, and the work done per unit time is

$$P = \frac{V\,dq}{dt} \qquad (14)$$

where P is, by definition, the instantaneous power and dt is the time interval to transfer the charge dq. Since

$$i = \frac{dq}{dt}$$

Eq. (14) may be written

$$P = Vi$$

The instantaneous power is the product of the instantaneous voltage and current.

When alternating current circuits are considered, the average power $\overline{P}$ rather than the instantaneous power is of interest. By definition

$$\overline{P} = \frac{\omega}{2\pi}\int_0^{2\pi/\omega} Vi\,dt \qquad (15)$$

where, as before, $2\pi/\omega$ is the time for a complete cycle. The average power may be evaluated by making the following substitutions in Eq. (15):

$$V = V_\mathrm{m} \sin \omega t$$

$$i = I_\mathrm{m} \sin(\omega t - \delta)$$

The result is

$$\overline{P} = \tfrac{1}{2} V_\mathrm{m} I_\mathrm{m} \cos \delta \qquad (16)$$

Equation (16) may be rewritten

$$\overline{P} = \frac{V_\mathrm{m}}{\sqrt{2}} \frac{I}{\sqrt{2}} \cos \delta$$

$$\overline{P} = V_\mathrm{e} I_\mathrm{e} \cos \delta \qquad (17)$$

Evidently, the average power is the effective voltage times the effective current multiplied by the cosine of the phase angle. In this connection, $\cos \delta$ is called the power factor. Equation (17) may be interpreted to mean that only the component of V_e in phase with I_e contributes to the average power. The other component may be said to be wattless. Since

$$V_\mathrm{e} = I_\mathrm{e} Z$$

and

$$\cos \delta = \frac{R}{Z}$$

Eq. (17) may be written as follows:

$$\overline{P} = I_\mathrm{e}^2 R \qquad (18)$$

From the latter form, it may be concluded that the average power is the average rate at which heat is developed in the circuit. Equation (18) also shows that a direct current having a value I_e would produce the same heating effect as an alternating current having an effective value I_e.

The Complex-number Method In the foregoing, an alternating-current series circuit was discussed by representing voltages as vectors in the real plane. For more complicated circuits, this method is too clumsy. It is much more convenient to deal with vectors analytically by utilizing the j-operator. By definition,

$$j = \sqrt{-1}$$

When a real number is multiplied by j, it becomes an imaginary number. In other words, a point on the real axis is rotated through 90° so that it becomes a point on the imaginary axis. The "complex" impedance of a series circuit may thus be written

$$Z = R + j\left(\omega L - \frac{1}{\omega C}\right) \qquad (19)$$

since the reactance may be considered to be at right angles to the resistance. When several impedances are connected in series, the total complex impedance is

$$Z = Z_1 + Z_2 + Z_3 + \cdots \qquad (20)$$

and, when several impedances are connected in parallel, the total impedance is given by

$$\frac{1}{Z} = \frac{1}{Z_1} + \frac{1}{Z_2} + \frac{1}{Z_3} + \cdots \qquad (21)$$

The effective voltage V across the generator may be considered to be a vector along the real axis. The effective current I furnished by the generator is therefore

$$I = \frac{V}{Z} \qquad (22)$$

By solving Eq. (22), the magnitude of I and the phase relation between I and V may be found. Although new mathematical techniques are needed, the saving of time usually justifies the use of the complex number method of handling complicated ac circuits.

Transfer Function From a more advanced point of view, we may consider the voltage V in Eq. (22) as the source and the current I as the response. If we set $j\omega$ equal to a new variable s, called the complex frequency, then we may refer to $1/Z(j\omega) = 1/Z(s)$ as the transfer function. For a complicated network, the transfer function may generally be expressed as the ratio of two polynomials in s. Thus

$$\frac{1}{Z(s)} = \frac{N(s)}{D(s)}. \qquad (23)$$

The zeros of the transfer function are those values of s for which $N(s) = 0$, and the poles of the network are those values of s for which $D(s) = 0$. At a zero, the network does not respond to the source. At a pole, the network may oscillate at a natural frequency given by the imaginary part of s. For a sinusoidal input, the amplitude of the response may be very large at a pole. Network analysis is facilitated through the use of the transfer function. Basically, the transfer function expresses all the characteristics of the network.

AMORPHOUS METALS

Amorphous metals are materials with good electrical and thermal conductivity, with lustrous appearance, and with other common metallic properties, but with atomic arrangements which are not periodically ordered as in more familiar, crystalline metallic solids. *Noncrystalline, amorphous*, and *vitreous* are equivalent terms used to describe solids in which atoms are not periodically arranged and which in fact lack any sort of long-range order. The term *glass* has often been reserved for amorphous solids formed by continuous solidification of a liquid, but metallic glasses are now commonly considered to include amorphous metals produced in a variety of ways, including evaporation, sputtering, and electro- and chemical deposition, as well as cooling from the liquid state.

Widespread interest in metallic glasses has developed since 1960, when it was first demonstrated that metallic glasses could be formed by very rapidly cooling, or quenching, some molten metallic alloys. Liquid quenching techniques, illustrated in Fig. 1, have been developed for producing metallic glasses as continuous ribbons with widths of several centimeters and at speeds in excess of kilometers per minute.

Research on amorphous metals has resulted from both scientific and technological interest in these materials. They provide opportunities for investigating effects of structural disorder on the basic physical properties of metallic solids, and they offer promise for achieving new and useful combinations of properties for technological ends. Many of the unique properties of metallic glasses are thought to result from the remarkable isotropy and homogeneity of most of these materials on all scales greater than a few atom diameters.

Formation Metallic glasses, like other amorphous solids, are always unstable with respect to some crystalline phase or phase mixture. However, glasses can sometimes be formed from the liquid state because liquids become progressively more viscous and atomic mobility within the liquids becomes more limited as the temperature is reduced. If crystallization does not intercede, many liquids undergo large continuous changes in viscosity in a narrow temperature interval somewhere below their equilibrium freezing temperature T_m. The large increase in viscosity on cooling through this interval causes the supercooled liquid to become a rigid glass below a "glass transition" temperature T_g at which atomic mobility is severely reduced and crystallization is thereby suppressed. Although glasses are ultimately unstable against crystallization, they can be retained almost indefinitely at temperatures well below T_g.

The high fluidity of metallic liquids for temperatures greater than T_g, in contrast to more familiar glass formers like SiO_2, greatly facilitates crystallization as the liquids are cooled below T_m; but for temperatures less than T_g the high viscosity and very limited atomic mobility make formation of stable crystalline nuclei and growth of these nuclei very unlikely. Thus the critical temperature range in which rapid crystallization is liable to occur at appreciable rates is from T_m to T_g, and the less time spent in traversing this temperature interval, the

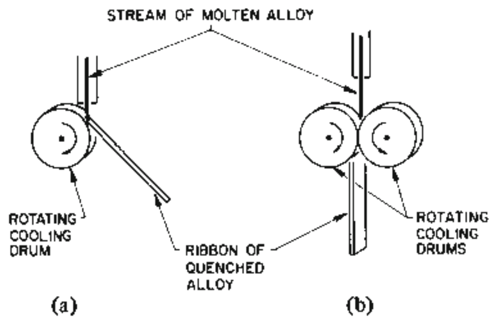

FIG. 1. Continuous quenching devices for making metallic glasses: (a) melt spinning and (b) roller quenching.

higher the probability of successful glass formation. The rate of crystallization R_c is expected to peak in this interval.

Many alloy systems and alloy compositions have been discovered which can be quenched to form a glass with cooling rates of 10^5–10^7°K/sec. These alloys involve compositions for which T_m is suppressed with respect to melting points of nearby crystalline phases, and compositions of high glass forming tendency are those with the lowest T_m values. Two devices used for preparing metallic glasses are illustrated in Fig. 1. Rapid quenching is accomplished by spreading the molten alloy on a metal surface which serves as a heat sink. This speeds the cooling by reducing the thickness across which heat must diffuse and by ensuring that the alloy remains in good thermal contact with the heat sink during the critical cooling period. Metallic glass ribbons produced in this way generally have thicknesses of less than 50 μm.

Several classes of metallic glasses which have been made by liquid quenching are listed in Table 1, and the list continues to grow. The most widely studied class consists of the transition metal–metalloid alloys with about 20 atomic percent metalloid. Electrodeposition and chemical or electroless deposition have also been used to produce several amorphous alloys of the transition metal–metalloid type.

An even larger range of materials has been prepared as amorphous solids by vapor quenching methods involving deposition by evaporation or sputtering onto a cooled substrate. Here the problem is to obtain metastable, noncrystalline atomic arrangements at sufficiently low temperatures to make spontaneous crystallization very improbable. Some nearly pure metals have been prepared as amorphous thin films on substrates cooled to 4°K. Nominally pure films of cobalt crystallize at about 50°K, and intentional addition of impurities, for example a few percent of silicon, greatly increases the crystallization temperature of such amorphous films. Amorphous metallic alloys which can be retained to temperatures well above room temperature have also been prepared by vapor quenching, including alloy systems and compositions for which glass formation by liquid quenching has been unsuccessful.

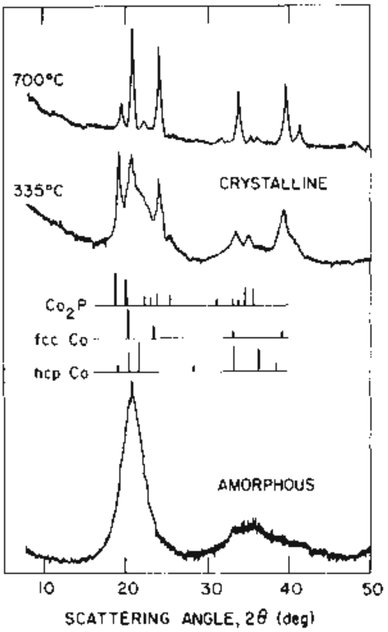

FIG. 2. X-ray scattering patterns for amorphous and polyphase, crystalline $Co_{80}P_{20}$.

Structure X-ray, electron, and neutron scattering experiments, together with electron microscopy, have provided evidence for nonperiodic atomic arrangements in the amorphous alloys discussed above. These materials produce diffuse diffraction patterns, with a few broad, overlapping peaks. Part of the diffraction pattern for an amorphous Co-P alloy with about 20 atomic percent phosphorus is shown in the lower section of Fig. 2. Heating this alloy changed the scattering pattern to that shown in the center of the figure. Appearance of sharp maxima indicates that the alloy began to crystallize to the expected crystalline phases of Co_2P and Co. Further heating to 700°C produced the sharper scattering pattern shown at the top of the figure, indicating improved perfection of the crystalline materials. Diffraction patterns of amorphous alloys look more like those of liquid metals than like diffraction patterns of crystalline materials. Electron micrographs of most amorphous alloys are featureless compared with those of crystalline solids.

The diffuse scattering patterns produced by amorphous solids can be used to calculate radial distribution functions, RDF(r), which describe correlations among atomic positions in the materials. The methods of analysis are the same as those used for liquid alloys. Examples for two amorphous metal–metalloid alloys are shown in Fig. 3. Maxima in RDF(r) occur for r-values corresponding to frequently occurring

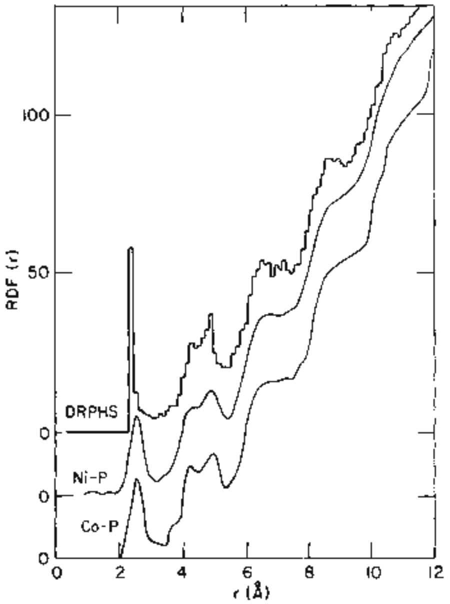

FIG. 3. Radial distribution function for amorphous transition metal–metalloid alloys $Ni_{76}P_{24}$ and $Co_{78}P_{22}$, and for a dense random packing of hard spheres (DRPHS) structural model. [From G. S. Cargill III, *AIP Conf. Proc.* **24** 138 (1975).]

interatomic separations in the amorphous alloys. RDFs illustrate several differences between atomic arrangements in amorphous and crystalline alloys. Long-range structural periodicity is absent in the amorphous alloys. There are only weak correlations between atomic positions separated by more than four or five atom diameters. There is no unique nearest neighbor distance in these amorphous alloys. Widths of the nearest neighbor maximum in the RDFs are typically between 0.4 Å and 0.5 Å full width at half maximum (FWHM). Radial distribution functions for crystalline Co or Ni would have much narrower nearest neighbor maxima, with widths less than 0.2 Å FWHM. Crystallization of these alloys increases their density by less than one percent. The RDFs and density measurements together provide statistical descriptions of atomic arrangements in amorphous alloys and serve as critical tests for three-dimensional structural models.

The most extensively studied models for atomic arrangements in metallic glasses are based on the nonperiodic "random" packing of spheres and are called *dense random packing of hard spheres models*. The RDF for a physically constructed dense random packing of several thousand single-sized steel spheres is shown in Fig. 3, together with the experimentally determined RDFs for two transition metal–metalloid alloys. The agreement is impressive, although the model takes no account of the alloy nature of the experimentally studied materials. Efforts to improve dense random packing models for binary alloys have used computers to generate dense random packings with two sizes of spheres, chosen to represent the two elements of the binary alloy. These structures have been relaxed by allowing those small displacements of atom sites which reduce the energy, calculated by assuming that the atoms interact with one another by pairwise forces. Although such models have been fairly successful in reproducing experimentally observed distribution functions for most metal–metalloid and rare earth metal–transition metal alloys, the more general applicability of dense random packing as a structural model for metallic glasses has not yet been established.

Electrical Resistivity Resistivities of amorphous metallic alloys are typically between 100 and 200 μΩ-cm, values which are higher than resistivities of most crystalline metals and alloys but are similar in magnitude to electrical resistivities of liquid metals. Although the reversible temperature dependence of electrical resistivity for amorphous alloys is less than for most crystalline metals, when the alloys crystallize, their resistivities decrease abruptly and irreversibly, as shown for example in Fig. 4.

The major features of the reversible resistivity behavior can be explained in terms of a model originally developed for liquid metals. The basic features of this model are that the electrical resistivity arises from scattering of conduction electrons by the amorphous structure and that the structure-dependent scattering can be evaluated from experimentally measured X-ray, electron, or neutron scattering patterns of the material.

A number of amorphous alloys become superconductors at sufficiently low temperatures. Much early work on vapor quenched amorphous alloys was stimulated by the discovery that amorphous bismuth was metallic and became superconducting at 6°K, although crystalline bismuth is a non-superconducting semimetal.

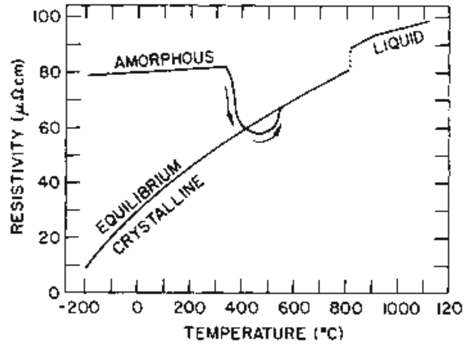

FIG. 4. Electrical resistivity for a $Pd_{80}Si_{20}$ alloy in amorphous, equilibrium crystalline, and liquid forms. [From P. Duwez, *Trans. Am. Soc. Metals* **60**, 607 (1967).]

However, subsequent research has failed to discover any amorphous superconductors with transition temperatures above 10°K.

Magnetic Properties Metallic glasses are as diverse in their magnetic behaviors as are crystalline metals and alloys, ranging from strong ferromagnetism to weak diamagnetism, including ferrimagnetism and spin glass type magnetism. The largest amount of research has been carried out on ferromagnetic transistion metal-metalloid (TM-M) alloys and on ferrimagnetic transition metal-rare earth metal (TM-RE) alloys. The magnetically ordered amorphous TM-M systems are well described as aligned ferromagnets, as illustrated schematically in Fig. 5(a), where metalloid atoms are not shown. Some TM-RE systems are ferrimagnets, with RE moments pointing opposite to the TM moments. For alloys with gadolinium as the rare earth element, the moments of TM atoms (small circles in Fig. 5(b)) are closely antiparallel to those of the RE atoms (large circles), but for other rare earths, notably terbium and dysprosium, the RE moments are strongly coupled to local easy directions, giving a canted ferrimagnetic arrangement like that shown in Fig. 5(c).

It is usual to think of glasses and amorphous solids as being macroscopically isotropic, and indeed these materials are isotropic with respect to most of their physical properties. Magnetic anisotropies for most amorphous transition metal-metalloid alloys are very small and their effects on coercivity and ease of magnetic saturation can be largely eliminated by suitable annealing treatments, which relax internal strains and allow some local rearrangements of atom positions. Coercivities for suitable annealed TM-M alloys can thus be as small as 10^{-2} Oe. Annealing in the presence of applied magnetic fields can also be used to induce macroscopic magnetic anisotropies in the amorphous TM-M alloys. Low coercivity and high permeability are very desirable properties for a variety of applications, including low-loss transformer cores, presently one of the most widely pursued applications for metallic glasses.

The behavior of magnetic domains in amorphous Gd-Co alloys is often dominated by large perpendicular easy axis magnetic anisotropies of 10^4-10^5 erg/cm^3 induced in the sputtered films by appropriate deposition conditions. This class of amorphous alloys has been of special interest because of its potential usefulness in magnetic memory devices, for which the magnetic anisotropy and ease of magnetic domain wall movement are essential.

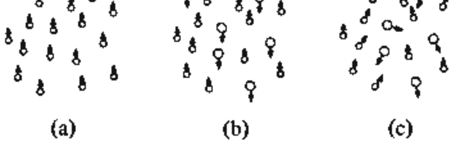

FIG. 5. Atomic magnetic moments in amorphous magnets: (a) ferromagnetic as in $Fe_{80}B_{20}$, (b) ferrimagnetic as in $Gd_{30}Co_{70}$, and (c) canted ferrimagnetic as in $Tb_{33}Fe_{67}$.

Other basic aspects of magnetic behavior of amorphous alloys which have been studied are the overall temperature dependence of magnetization, the characteristic magnetic excitations, including spin waves, and the effects of structural and chemical disorder on phase transition phenomena, including sharpness of the ferromagnetic-paramagnetic transition and the critical exponents associated with this transition.

Mechanical Properties Many mechanical properties of metallic glasses have been investigated, including elastic constants, yield and fracture strengths, modes of plastic deformation, the dependence of these properties on thermal history and measurement temperature. Most of these studies have employed quenched-from-the-liquid glasses.

Metallic glasses, like most polycrystalline solids, are mechanically isotropic, so only two constants, for example the bulk modulus and the shear modulus, are needed to characterize their elastic properties. Elastic stiffness constants of the glasses are generally smaller than those of the same materials in crystalline form, which are usually mixtures of crystalline phases. The bulk moduli differ only by 5-10%, but the shear modulus μ and Young's modulus E for glasses are lower by 30-50% than for corresponding polycrystalline solids. The lower resistance to shear deformation has been explained in terms of nonuniform atomic displacements which can occur in the glasses but which are restricted by symmetry constraints in the crystalline forms of these materials.

Metallic glasses are typically very strong, having observed yield strengths $\sigma_y \approx E/50$ as high as 370 kg/mm^2 (640×10^3 psi) for $Fe_{80}B_{20}$, similar to that of polycrystalline, cold drawn, high carbon steel. However, unlike high strength polycrystalline alloys, which are inherently brittle, most metallic glasses are microscopically ductile and can sustain appreciable local plastic deformation, particularly in compression or shear. Although there have been several proposals for using metallic glass wires or ribbons to form reinforced composites with plastic, ceramic, or metallic matrices, no commercially important applications of this sort have yet emerged.

Plastic deformation in metallic glasses for temperatures much lower than the glass temperature T_g is inhomogeneous, occurring in localized shear bands along directions of maximum resolved shear stress. In contrast to the usual work hardening which accompanies plastic deformation in crystalline solids, the localized shear bands of metallic glasses are manifestations of "work softening." The glassy material is weakened as a result of the local disruption of

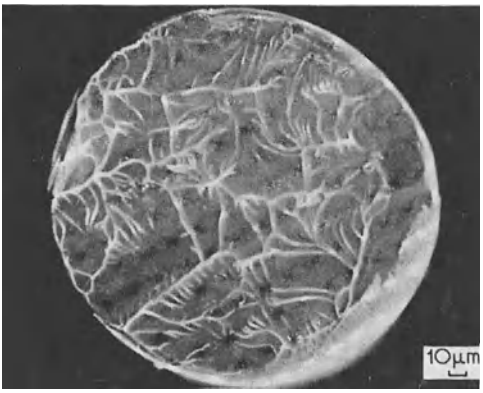

FIG. 6. Fracture surface of a glassy Pd-Cu-Si wire. [From L. A. Davis and S. Kavesh, *J. Mat. Sci.* **10**, 453 (1975).]

short-range order or the local creation of excess free volume by the previous plastic deformation. Tensile failure of metallic glass wires or ribbons occurs in the localized shear band, with characteristic veinlike fracture surface features like those shown in Fig. 6, which are suggestive of local melting. For temperatures closer to the glass transition temperature, deformation takes place by homogeneous viscous creep, with the strain rate proportional to the applied stress.

The ductility of many metallic glasses is lost through irreversible embrittlement when the alloys are annealed, even though the annealing temperatures are too low to cause any detectable crystallization. Most metal-metalloid alloys show this behavior, and those containing phosphorus are particularly susceptible. Some experiments suggest that the embrittlement is caused by fine-scale phase separation or segregation involving metalloid elements.

ANTENNAS

Communication systems characteristically consist of cascaded networks, each network designed to carry out some operation on the energy conveying the information. In radio communication, transmitting systems' antennas are the networks serving to transfer the signal energy from final circuit network to space. In receiving systems, on the other hand, antennas serve to transfer the signal energy from space to the input circuit networks. In circuits the flow of energy is restricted to one of two directions. The effectiveness of the transfer of energy between the antenna and its adjoining circuit is, therefore, determined solely by the terminal impedance of the antenna and that of the adjoining circuit network. The terminal impedance of a circuit network can generally be designed for operation over a relatively wide frequency band. On the other hand, the terminal impedance of an antenna may, in some cases, vary outside acceptable limits, thus limiting the useful frequency bandwidth of the antenna. The terminal impedance of an antenna and its variation with frequency is, therefore, one of the important parameters describing the performance of the antenna.

The relationship between an antenna and space, however, is more complex. The distribution of the radiated energy varies with direction in space, giving rise to the directive properties of the antenna. The energy radiated by the antenna is in the form of electric and magnetic fields. These are vector quantities which, at a distance from the antenna, are at right angles to each other and to the direction of propagation. The planes in which these vectors are located, and whether they are stationary or rotate with time, determine the polarization of the radiated field. The performance of an antenna can, therefore, be fully described only by specifying several parameters, such as radiation pattern, power gain,[1,2] directive gain, and polarization. In discussing antenna properties, it is convenient to consider the antenna as a radiating rather than as a receiving network. The antennas, however, are passive and linear networks and, therefore, subject to the law of reciprocity.[3] Therefore, the performance of an antenna, in terms of radiation pattern, gain, or polarization, is the same whether the antenna radiates or absorbs radiation.

Except for the region in the immediate vicinity of the antenna, termed the *near-field region* of the antenna, the radiated electromagnetic energy propagates radially away from the antenna, and the radiation intensity* varies inversely as the square of the distance from the antenna. This attenuation with distance is the *propagation loss.* In radio communication systems it is the principal component of the system's loss and must be compensated for by increasing the power of the transmitter, the gains of the transmitting and receiving antennas, and the sensitivity of the receiver. In describing antenna performance, it is customary to disregard the propagation loss and to represent the distribution of the radiated power as a function of the two direction angles only. Such distribution is commonly represented graphically in the form of a radiation pattern. Radiation patterns can take a variety of forms. One form is a polar diagram with radial displacement proportional to the field strength or to the radiation intensity in that direction. Another form is a rectangular diagram with abscissa representing one of the directional angles, and the ordinate representing the radiated field intensity. The intensity may be represented linearly as power or logarithmically in decibels.[4] For representing the directive properties of an antenna in all directions, contours of equal radiation intensity may be plotted, with the two direction angles as abscissas and ordinates, respectively.

The directive properties of an antenna also lead to the concept of antenna *gain.* The *directive gain* of an antenna in a specified direction is the radiation intensity in that direction compared to what it would be if the total radiated power were distributed equally in all directions. Besides the directive gain there is also the concept of *power gain.* The latter differs in that the total input power rather than the radiated power is used as the reference. The power gain for an antenna is always smaller than the directive gain by the factor of *radiation efficiency.* IEEE Standards Publications 145 and 149 (Refs 1 and 2) should be consulted for exact terminology. For some applications, such as point-to-point communication, high values of antenna gain are desired because such antennas concentrate the available power, thus effectively increasing it. Similarly, in receiving applications, such antennas are more responsive to radiation arriving from the desired direction and, at the same time, reduce the response to signals arriving from other (possibly interfering) directions. Conversely, for other applications such as broadcasting, broadly directional antennas with wide coverage may be desired.

The gain of an antenna is dependent principally upon the size of the antenna, expressed in wavelengths. The larger the antenna, the greater is likely to be the gain. The values of gain for different antennas range from 1.5 for an electrically small dipole to values hundreds and thousands of times greater. In practice, antenna gains are usually expressed logarithmically, in decibels. For the low-frequency end of the ratio spectrum (15 kHz to 3 MHz) antennas, although large physically, are relatively small in terms of wavelengths. Therefore, the directive gains of these antennas seldom exceed 3 (4.8 dB). The radiation efficiencies of low-frequency antennas are usually very low. As a result, their power gains are significantly lower than their directive gains and may be negative when expressed in decibels. In the high-frequency band (3–30 MHz), which is used principally for long-distance communication, antenna gains of 10–100 (10–20 dB) are frequently encountered. At microwave frequencies, where the wavelengths are a fraction of a meter, gains of several hundred and even thousand times (20 to over 30 dB), are common.

When an antenna has one or more of its dimensions significantly larger than a wavelength, its radiation pattern is likely to have more than one maximum. The radiation pattern in such cases is said to have a *lobe* structure. That part of the radiation pattern which encompasses the direction of the largest maximum and the radiation immediately to each side of it is referred to as the *main lobe.* The radiation about the minor maxima is referred to as the *secondary* or *side lobes.* One of the common goals in antenna design is the reduction in the levels of secondary lobes. These may, at times, be a source of interference to other transmissions.

In common with light, radio waves consist of electric and magnetic fields at right angles to each other and to the direction of propagation. The orientation of these fields, specifically the electric field, determines the polarization of the wave. Thus, if the electric field vector is parallel to the ground, the radio wave is termed *horizontally polarized.* Although the polarization of the energy radiated by an antenna, in general, varies with direction, an antenna is usually designated to be horizontally (or vertically, or circularly, etc.) polarized, depending on the polarization of its radiation in the direction of the main lobe maximum.

The importance of polarization in radio engineering lies principally in the different reflective properties of the ground for horizontally and vertically polarized waves. Different radio services are served best by different polarizations. Antennas for use in the low-frequency end of the radio spectrum, 15 kHz through about 3 MHz, are almost invariably vertically polarized. This includes the AM broadcast band (535–1605 kHz). In the high-frequency band, 3–30 MHz, both horizontal and vertical polarizations are employed. For television broadcast service

*In this discussion, radiation intensity has the dimensions of power flow per unit area, normally, watts per square meter. Electric field strength, on the other hand, is in volts per meter. Definitions of these and other terms can be found in Reference 1.

in the United States and many other countries (but not in the United Kingdom), horizontal polarization is in use. In the United States horizontal polarization is also standard for FM broadcasting service. However, to accommodate reception in private automobiles, FM broadcast stations are now permitted to add a vertically polarized component to the transmission, but it may not exceed the horizontally polarized component.

Recent years have witnessed a very rapid growth in the importance of communication using satellite relays. Since the antennas used in this service are highly directive, and the directions to satellites are significantly above the horizon, ground reflections play no part in such communications. For this reason various organizations involved in satellite relay communication make use of horizontal, vertical, and circular polarizations, depending on local considerations. One current practice is to use circular polarization in both directions: left-hand circular polarization for the up-link (ground-to-satellite) and right-hand circular polarization for the down-link. At the time of this writing (December 1981) a growing practice is to reuse frequencies. By this is meant the use of the same frequency for two channels in the same direction; one channel uses right-hand circular polarization, the other, left-hand circular polarization. Isolation of 27 dB (power ratio of 500:1) between the two channels is being reported using this practice.

The types and varieties of antennas encountered in practice are very numerous. Each type has some advantage over the others for some specific applications. Some of the more important and frequently encountered requirements are those for operating bandwidth, high radiation efficiency, a specified degree of directivity, whether high or low, polarization, etc. By no means the least of the requirements is that of economy; it is a poor engineering practice to overdesign the antenna system. Two fundamental types of antennas encountered in practice are illustrated in Figs. 1 and 2. Fig. 1 shows two of the electric radiators, a monopole and a dipole. A monopole, shown in Fig. 1(a), in one form or another, is used almost exclusively throughout the low-frequency end of the radio spectrum. It is vertically polarized. The dipole, shown in Fig. 1(b), is more versatile since it can be oriented to give either horizontal or vertical polarization. It is frequently used as an elemen-

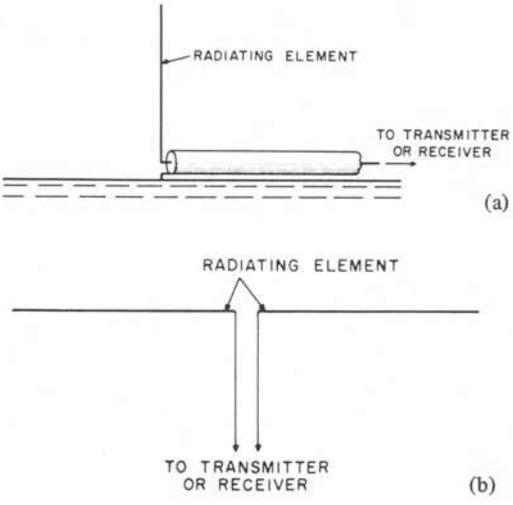

FIG. 1. Two types of elementary radiators: (a) Monopole over ground; (b) dipole.

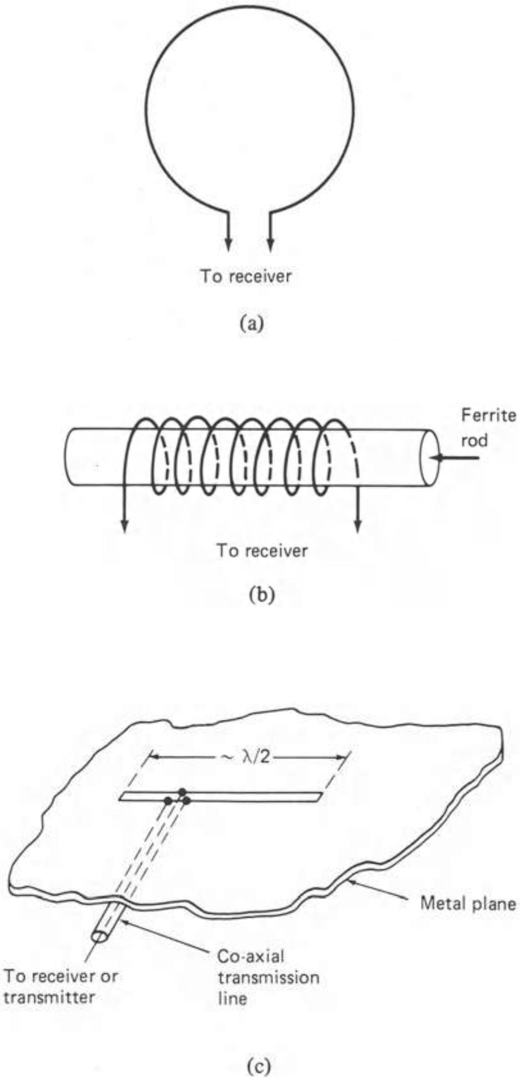

FIG. 2. Some examples of elementary magnetic radiators: (a) single-turn loop antenna; (b) ferrite rod antenna; (c) half-wavelength slot antenna.

tary radiator in large, array-type antennas. Basically, a monopole is a special case of a dipole where one-half of the dipole is replaced by its electromagnetic "image" reflected by the ground. An electric dipole may be considered to be one of the two most fundamental types of antenna. In its most elementary form of two point charges it is used to derive the mathematical expressions for the radiated fields. The other fundamental type is the magnetic radiator shown in Fig. 2. Fig. 2(a) illustrates the simplest form of a magnetic radiator, a single-turn loop. In the early days of broadcast radio the loop antenna, in a multiturn form, was sometimes used with home receivers. Because of its small size and portable nature it is still used for this purpose, especially for portable receivers, but in the form of a compact, ferrite-loaded coil, such that shown in Fig. 2(b). In industrial applications a loop antenna is sometimes used in a modified form for FM transmitting antennas. For microwave applications the magnetic radiator finds use in the form of a "slot" antenna. An elementary form of the slot antenna is shown in Fig. 2(c). It consists of a narrow, half-wavelength-long slot in a sheet of metal and is excited at two points across the slot by a transmission line. For proper impedance match to the transmission line, the points of excitation are usually well off the midpoint of the slot. Slot antennas usually find their application in large, array-type antennas; in such cases the slot antennas are often excited by waveguides passing beneath the slots.

Departing from the elementary radiators, Figs. 3, 4, and 5 show three antenna types employing wire conductors which have widespread use in the lower end of the useful radio spectrum, up to somewhere between 30 and 300 MHz. Figure 3 is a diagrammatic representation of a *Yagi antenna*. It consists of a single driven element—a half-wavelength dipole with a single parasitic element to the rear which acts as a reflector and several parasitic elements in the forward direction, known as directors. Parasitic elements are so termed because they derive their excitation by an electromagnetic coupling to driven elements. The reflector element is slightly longer than its resonance at the operating frequency, which gives it a positive reactance. The directors, on the other hand, are shorter than their resonant length, which gives them a negative reactance; this causes them to enhance the radiation in the forward direction. The Yagi antenna is compact, with a moderately high directive gain. However, it has a very narrow operating bandwidth.

An antenna resembling the Yagi antenna physically, but with very different performance characteristics is the *log-periodic antenna*, illustrated in Fig. 4. Like the Yagi antenna, it consists of a tandem array of dipole elements; however, all the elements are driven, being connected to the transmission line running axially through the array. At any one frequency, only three or four of the elements are radiating, those whose lengths are near resonance at that frequency. At the lowest operating frequency for which the antenna is designed, the longest elements, those at the rear end of the antenna, are in operation. As the frequency of operation is increased, the "active region" moves forward along the antenna, and at the highest design frequency only the forward elements are in operation. In contrast to the Yagi antenna, the log-periodic antenna has only a moderate directivity, but it can be designed for a very wide frequency operating band. This last characteristic has made the log-periodic design popular for consumer applications for TV reception; there the VHF band alone extends from 54 to 216 MHz, a 4 to 1 spread.

Another antenna employing wire conductors but very different in design, is the *rhombic*

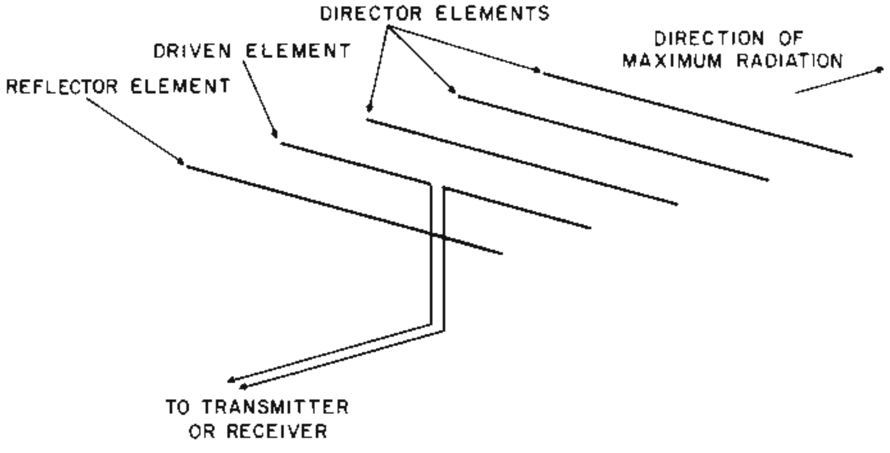

FIG. 3. A five-element Yagi antenna.

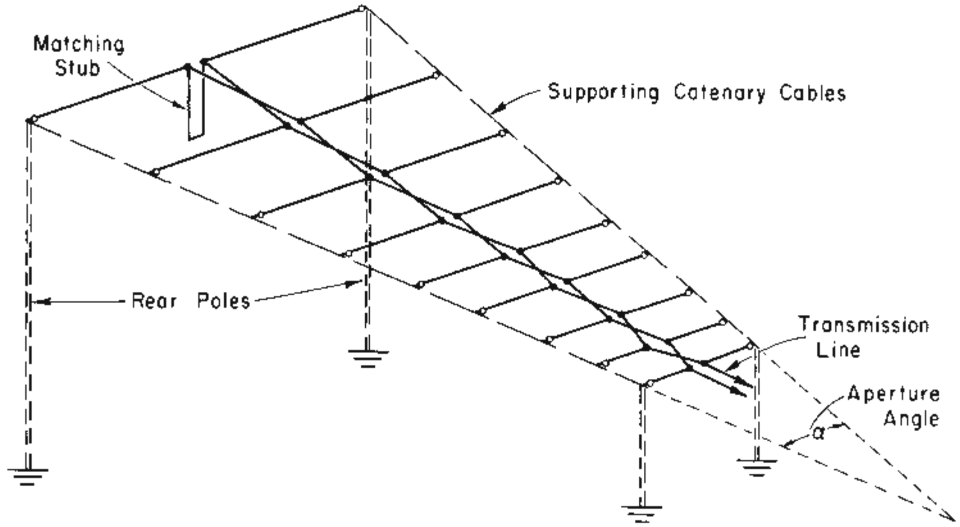

FIG. 4. Horizontally polarized log-periodic antenna.

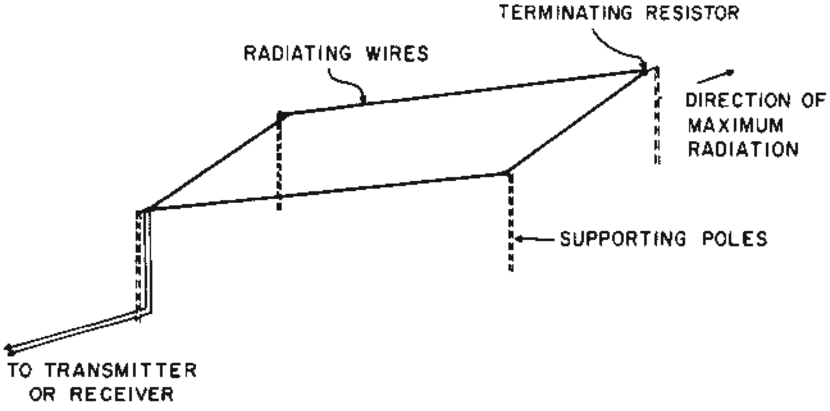

FIG. 5. A rhombic antenna.

antenna, illustrated in Fig. 5. It consists of two wires in rhombic configuration; each side of the rhombus is, characteristically, two to five wavelengths long. Its principal use is for long-distance point-to-point communication in the HF (3–30 MHz) band. Its construction is simple and trouble-free; however, it does require a large site. Its design and construction is described in detail by Harper.[5]

An antenna type which may be considered as transitory between the lower frequency, wire-conductor types and the microwave, reflector-type antennas is the *corner-reflector antenna*, illustrated in Fig. 6. The active element shown in the illustration is a half-wavelength dipole; however, collinear arrays of dipoles can be and have been employed. The key element of this antenna type is the reflector. This consists of two rectangular reflecting surfaces joined at the axis, forming a corner. In operational antennas the metal reflector surfaces are usually replaced by wire screens. The width of the corner reflector must be at least one-half wavelength. In practice, the lengths and the widths are usually one to two wavelengths. The greatest usefulness for this antenna type is in the VHF (30–300 MHz) band. The gains and radiation patterns of the corner-reflector antenna, as functions of length, width, and aperture angle, have been measured in detail at the National Bureau of Standards and reported by Cottony and Wilson.[6,7]

Figure 7 shows two antenna types, a *horn antenna* and a *paraboloid reflector antenna.*

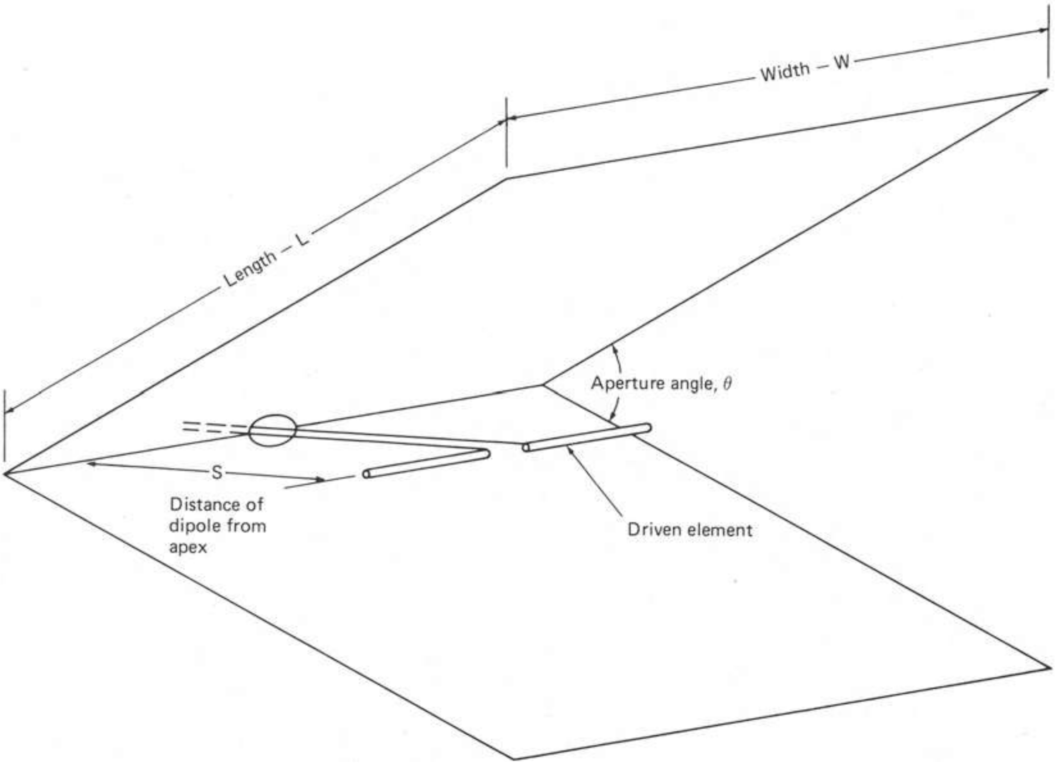

FIG. 6. Diagram of a corner-reflector antenna showing the nomenclature of its parameters.

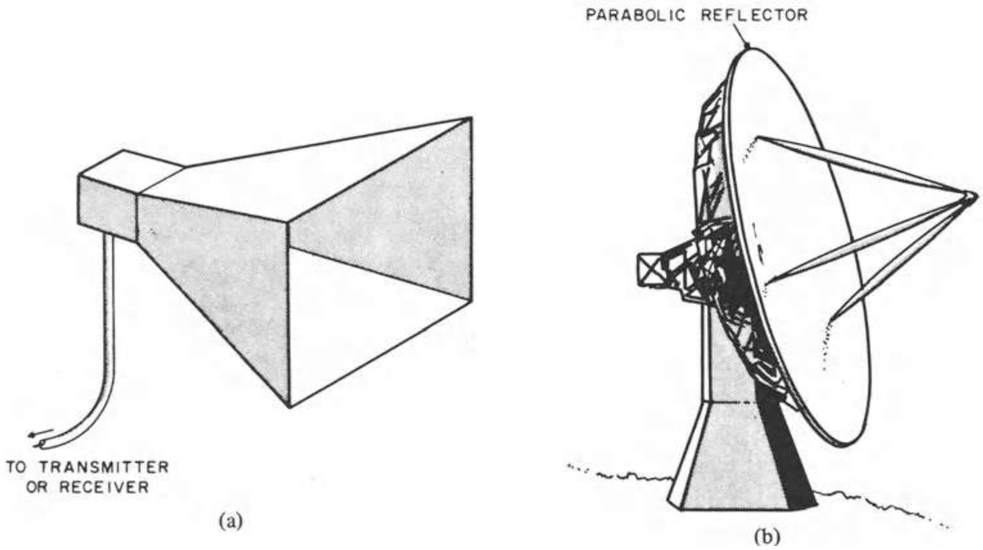

FIG. 7. Examples of microwave-type antennas: (a) horn antenna. (b) paraboloid-reflector antenna.

These are characteristic of the antennas used for microwave frequencies. The horn antenna, Fig. 7(a), is used generally where moderate directivity suffices, but a high front-to-back ratio of directivity is desired. The paraboloid antenna, on the other hand, is used for high-gain applications; it is a quasi-optical device. It is the type widely used for ground stations for satellite communication. For this application it is beginning to some extent to enter the consumer market.

The statement in the introductory paragraph regarding the importance of the terminal impedance of the antenna understates one of the fundamental antenna problems: the relationship between the size of the antenna, expressed in wavelengths, and the properties of the antenna, both its terminal impedance and its directivity. As the size of the antenna is reduced below one-half wavelength, the resistive component of the terminal impedance rapidly diminishes while the reactance increases. As a result, either the operating bandwidth or the radiation efficiency, or both, are rapidly reduced. Numerous papers have been published in an attempt to quantify this relationship, the most recent being that by Hansen.[8] Hansen's paper also lists numerous references to earlier work. It is appropriate to note, however, that the mathematical operations employed by Hansen implicitly limit the validity of the final results to dipoles.

The relationship between the size of the antenna and its power and directive gain is easier to grasp. In the case of quasi-optical antennas, such as horn and paraboloid reflector antennas, (Fig. 7), the opening of the antenna is known as the *aperture*, a term borrowed from optics. The gains of such antennas are directly proportional to the areas of the apertures in wavelengths modified by the illumination taper. The concept of aperture is carried directly to the broadside arrays of dipoles or other elementary radiators. In the case of end-fire arrays and other antennas which depend upon length for directivity, such as Yagi antennas, the concept of aperture loses its applicability. Instead, *equivalent aperture* is sometimes used. The gains of such antennas are roughly proportional to the square root of the antenna lengths expressed in wavelengths.

The preceding discussion of the relationship between the size of the antenna and its gain is correct insofar as the practical applications are concerned. To be complete, however, one should mention the concept of *supergain* or *superdirectivity*. Woodward and Lawson[9] demonstrated that, using arrays of dipoles, it is in theory possible to realize much higher directivities than those predicted by the aperture concept. To realize such directivities, special excitation of elements must be employed. The excitation is such that, while some elements radiate power, others absorb it, feeding it back to the elements that radiate. The gain then becomes a function of the number of elements rather than of the area over which they are arrayed. Uzkov[10] showed that, for broadside arrays, the theoretical gains are directly proportional to the number of elements and, for end-fire arrays, to the square of the number of elements. Bloch, Medhurst, and Pool[11] presented a comprehensive survey of supergain and superdirectivity. To realize even a modest degree of supergain, one should be able to control the excitation currents, both in magnitude and phase, with a very high order of precision. Supergain and superdirectivity are, therefore, of theoretical rather than practical interest.

For a more complete listing and discussion of antenna types the reader is referred to texts on antennas such as the "Antenna Engineering Handbook."[12] For additional discussion of the principles underlying antennas, texts by Kraus[13] and Schelkunoff and Friis[14] are suggested.

ANTIFERROMAGNETISM

Antiferromagnetism is the most common form of magnetic order. It is found in the majority of inorganic compounds of the transition metals, rare earths and actinide elements; it is also found in Cr, Mn, Pt, Pd, and rare earth metals and alloys, although the situation is rather more complicated in the case of metals, and the discussion here will focus mainly on insulators. However, during the last decade great interest has arisen in organic conductors, of which TTF–TCNQ is a typical example. These systems are strongly anisotropic in lattice character, i.e., are quasi-one-dimensional, and their magnetic character is antiferromagnetic. A striking experimental development since the mid-1960s has been the synthesis of magnetic materials which have an effective dimensionality D less than three. Such "low-dimensional" magnets are chemically engineered by inserting large diamagnetic organic "spacer" molecules to minimize the magnetic interactions in one or two directions in the crystal. Low-dimensional antiferromagnets show striking differences in behavior from the familiar three-dimensional antiferromagnets, such as MnF_2, because quantum effects (fluctuations) are particularly pronounced in such systems.

The principal feature of antiferromagnetism is the spontaneous antiparallel alignment of electron spins on neighboring magnetic ions, which takes over from the paramagnetic state (where spin–spin interactions are essentially negligible) as the temperature is lowered. The critical temperature of the antiferromagnetic phase transition is called the Néel temperature (T_N). The strength of the ordering interaction is characterized by the magnitude of T_N, which typically ranges from below 1 K to above room temperature. Some antiferromagnets whose properties have been studied in detail are listed along with their Néel temperatures: (3D) NiO, 520 K; Cr_2O_3, 310 K; MnF_2, 67.4 K; (2D) K_2NiF_4, 97 K; (1D $CuCl_2 \cdot 2(pyr)_2$, (CPC) 1.1 K; $[(CH_3)_4N]$ Mn Cl_3 (TMMC), 0.8 K. (*Note:* (pyr) denotes large organic pyridine complexes.)

The ordering interaction between neighboring metal ionic spins in an insulator is called *superexchange*, since it takes place via an intervening anion, O, F, S, Cl, etc. (cf. direct exchange between adjacent ions as encountered in FERROMAGNETISM). Superexchange results from charge transfer (see BOND, CHEMICAL), and it is best illustrated by a typical example, say MnO.

Ground and Excited States of $(MnOMn)^{++}$

$Mn^{++}O^{--}Mn^{++}$	$Mn^{+(+-)}O^{-}Mn^{++}$
ground state	excited state

In the ground state, the purely ionic configuration, there is no interaction between metal ions. If, however, one of the two bonding electrons of O^{--} is transferred to the Mn^{++} at left, there will be strong Hund's rule coupling within that ion, and also the unpaired electron on O^{-} can couple with the Mn^{++} at right. Since the two bonding electrons on O^{--} have opposite spins, the overall interaction will appear as antiparallel exchange coupling (i.e. antiferromagnetic coupling) between the two Mn ions.

The archetypal form of the Hamiltonian function (the energy) which describes the magnetic properties of the exchange interaction is the Heisenberg exchange form

$$\mathcal{H} = \sum J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j,$$

where $\boldsymbol{S}_i$ and $\boldsymbol{S}_j$ are the spin angular momentum vectors (operators) of a pair of nearest-neighbor ions. (Interactions between more distant neighbors are much weaker and will largely be ignored in what follows.) J_{ij} is the exchange integral (exchange constant) between the spins $\mathbf{S}_i$ and $\mathbf{S}_j$, and is a measure of the strength of the magnetic interaction. For relatively simple systems, J may be calculated quantum-mechanically from first principles. However, in general, J is best regarded as a phenomenological constant, to be inferred from experiment. The Heisenberg Hamiltonian can describe either ferromagnetism or antiferromagnetism. J is negative for ferromagnets, since then parallel spin alignment is energetically favored. Antiferromagnetism is characterized by J positive, which favors antiparallel order.

While the antiferromagnetic exchange interaction produces antiparallel alignment of the spins, their direction with respect to the crystalline axes is a consequence of the magnetic anisotropy. There are three origins of anisotropy: (1) dipole–dipole interactions among the array of ionic moments which gives anisotropy in all but cubic symmetry; (2) Stark-effect interactions of each single ion with the local crystalline electric fields; and (3) anisotropic exchange, a result of spin-orbit coupling and super-exchange between excited orbital states. The latter two mechanisms are important for non-S-state ions, especially in crystals of low symmetry. Crystal field effects are represented by including a term of the type $D\ \Sigma_i(S_i^z)^2$ in the Hamiltonian, where S_i^z is the z-component of the spin angular momentum ($\mathbf{S}_i$) of the ith ion. This term gives rise to spin-anisotropy such that when $D < 0$ easy-axis anisotropy is favored, and when $D<0$ easy-plane anisotropy is favored. For anisotropic exchange in real systems the Hamiltonian may effectively be written:

$$\mathcal{H} = \sum_{ij} (J_{ij}{}^z S_i{}^z S_j{}^z + J_{ij}{}^x S_i{}^x S_j{}^x + J_{ij}{}^y S_i{}^y S_j{}^y).$$

If $J^z > J^x \simeq J^y$ uniaxial anisotropy is present, and when $J^z < J^x \simeq J^y$ easy-plane anisotropy is present. The extreme limit of uniaxial anisotropy occurs when $J^x = J^y = 0$, and is called the *Ising model* of magnetism. The extreme limit of easy-plane anisotropy is when $J^z = 0$, and this is called the *XY model.* When $J^z = J^x = J^y$, the *isotropic Heisenberg exchange model* is recovered.

The effects of an applied magnetic field on the antiferromagnet are represented by the addition to the Hamiltonian of a Zeeman energy term $-g\mu_B H \Sigma S_i{}^z$, where g is the Landé g-factor and μ_B is the Bohr magneton. The phase diagram of an Ising antiferromagnet as shown in Fig. 1. In the H–T plane, the antiferromagnetically ordered phase is enclosed by a second-order phase boundary. Note that antiparallel order is destroyed both by increasing temperature and by increasing magnetic field. The critical field, H_c, is reached when the Zeeman energy tending to align a pair of spins parallel balances the antiferromagnetic exchange energy. At $T = 0$, antiferromagnetic order exists for $H < H_c$, while paramagnetic disorder occurs for $H > H_c$. H_c is therefore a special point. For the pure Ising model, to which Fig. 1 applies, nonphysical effects occur at H_c. There is a nonzero entropy at $T = 0$ and $H = H_c$, which can be calculated exactly in 1D and 2D, and approximately in 3D. This implies a violation of the third law of thermodynamics and reflects the somewhat artificial, or classical, character of the Ising model. Inclusion of terms such that J^x or $J^y \neq 0$ eliminates this defect.

Also shown in Fig. 1 is a different kind of field, namely a staggered field, H_s, which reverses sign at every successive spin site. This is the so-called *ordering field* for an antiferromagnet. For example, an antiferromagnet in a staggered field shows phase behavior similar to a ferromagnet in a direct (ordinary) applied field. It might seem that a staggered field is an artificial concept, not realizable in the laboratory, which is generally true. However, in the case of the complex, six-sublattice-structured antiferromagnet dysprosium aluminum garnet (DAG), application of a direct field in general results in the appearance, in addition, of an "internal" staggered field.

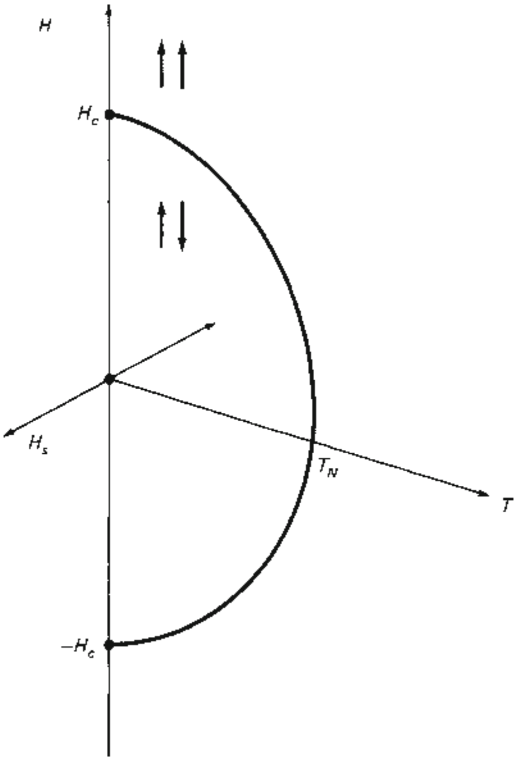

FIG. 1. Phase diagram (schematic) of an ideal classical antiferromagnet. T is temperature, H is direct field, and H_s is staggered field. The arrows suggest the predominant pattern of spin ordering.

The obvious magnetic parameter for experimental measurement is the susceptibility, denoted χ, which is effectively a measure of the response of the spins to an external applied field. In general, there are two susceptibilities to measure in the case of a single crystal sample. One is the susceptibility measured with the field parallel to the easy-axis (easy-plane), called $\chi_\parallel$, and the other, $\chi_\perp$, measured with the field in a direction perpendicular to the easy-axis (easy-plane). In a truly spin-isotropic, Heisenberg, system $\chi_\parallel$ and $\chi_\perp$ are equivalent above T_n. This is not true in general, however. When any type of anisotropy is present $\chi_\parallel$ and $\chi_\perp$ are different. Mean-field theory is a simple, approximate calculational approach applicable to both ferromagnets and antiferromagnets. Further, it is believed to describe phase behavior correctly for magnetic systems in dimensions $D \geqslant 4$, Fig. 2 shows the susceptibilities of an antiferromagnet, in the limit of a vanishing field, in the mean-field approximation. Both $\chi_\parallel$ and $\chi_\perp$ vanish at high temperatures where spin–spin interactions become negligible. $\chi_\parallel$ then exhibits a maximum at the transition temperature T_N and subsequently vanishes as $T \rightarrow 0$. $\chi_\perp$ by contrast, goes to a nonzero value as $T \rightarrow 0$. There is a vanishing total magnetization as the antiparallel alignment of the spins becomes increasingly complete.

It is interesting to observe how Fig. 2 is modified for real antiferromagnets with $D < 4$. This

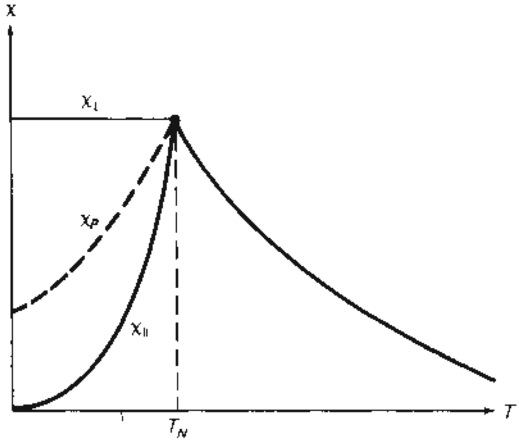

FIG. 2. The susceptibility (schematic) of an antiferromagnet in zero applied field, as a function of temperature, in the mean-field approximation, $\chi_\parallel$ and $\chi_\perp$ are as explained in text. χ_p is the powder susceptibility which is the weighted average of $\chi_\parallel$ and $\chi_\perp$.

is now well known due to exact and accurate approximate calculations in 1D, 2D, and 3D, and is shown schematically in Fig. 3. Both susceptibilities pass through a rounded maximum $T_{\max}$, which is *not* the critical temperature T_N, as the temperature is lowered. In zero-field T_N is manifested as a vertical tangent in both $\chi_\parallel$ and $\chi_\perp$ on the low-temperature side of $T_{\max}$. The difference $\Delta = T_{\max} - T_N$ is a measure of dimensionality, increasing as D decreases. Typically, Δ is about 8% of $T_{\max}$ or less for 3D antiferromagnets, 50–70% for 2D antiferromagnets, and 90% or more for good 1D antiferromagnets. Strictly, $T_N = 0$ for an ideal 1D antiferromagnet with short-range interactions. However, weak residual 3D interactions allow 3D ordering to take place at appropriately low temperatures.

Antiferromagnets show very rich and complex phase behavior when competing interactions are present, and/or as a function of the degree of anisotropy. A special class of Ising-like antiferromagnets are called *metamagnets*, and their H–T phase diagram is shown in Fig. 4, which resembles Fig. 1, except now a high-field portion of the antiferro-paramagnetic phase boundary has become first order. The point at which the boundary changes character, T^*, is a special kind of critical point called a *tricritical* point. At a normal critical point, or along a line of critical points, divergences occur in the thermodynamic properties which are characterized by so-called *critical exponents*. The critical exponents at a tricritical point are markedly different from those at an ordinary second-order critical point. Figure 5, which is an extended version of Fig. 4 including one additional parameter, the staggered field H_s, illustrates the phase behavior of a metamagnet in a more illuminating way. The first-order boundary of Fig. 4 now appears as a line of triple points where three first order

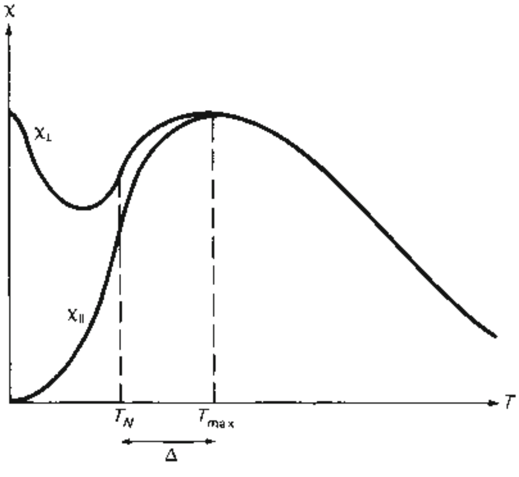

FIG. 3. The susceptibility (schematic) in zero field as a function of temperature according to non-mean-field theories. The difference between T_N and $T_{\max}$ is a function of dimensionality. T_N corresponds to a vertical tangent in $\chi_\parallel$ and $\chi_\perp$.

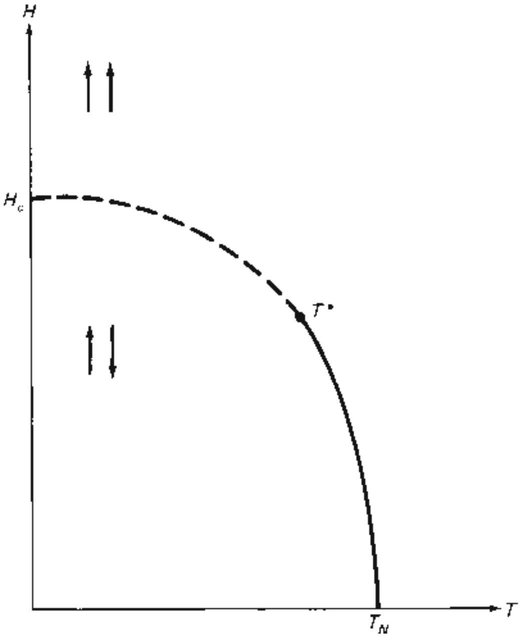

FIG. 4. The H-T phase diagram (schematic) of an Ising-like metamagnet. The hatched portion of the phase boundary is first order and T^* denotes the tricritical point.

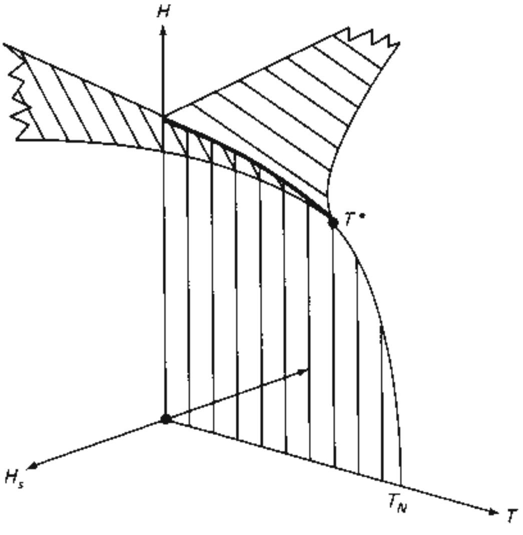

FIG. 5. The extended phase diagram of a metamagnet in terms of parameters T, H, and staggered field H_S. The shaded areas denote first-order two-phase coexistence surfaces.

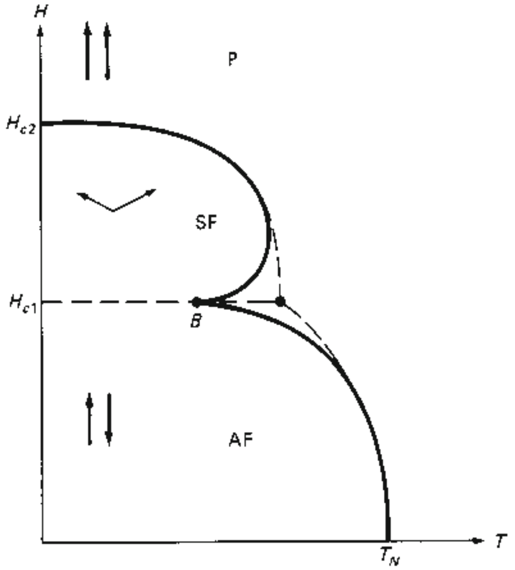

FIG. 6. H-T phase diagram of a spin-flop antiferromagnet in a field parallel to the easy axis. The low-field phase region has antiparallel aligned spins along the easy axis. The high-field phase region has "flopped" spins, aligned at an angle to the field. The boundary between the phases is first order. B is the bicritical point. The dashed lines illustrate the phase boundaries in the neighborhood of the bicritical point in the mean-field approximation.

phase boundary surfaces meet. The tricritical point T^* is the point at which three critical phase boundary lines meet. Examples of metamagnetic systems are ferromagnetic layers with antiferromagnetic interlayer coupling, and systems with nearest-neighbor antiferromagnetic coupling and weak next-nearest-neighbor ferromagnetic coupling. The phenomenon of metamagnetism was first observed experimentally in $FeCl_2$, which is an example of the layer-type system. DAG is also a well known metamagnet.

Another interesting class of antiferromagnets, characterized by rather small anisotropy, consists of the *spin-flop* antiferromagnets. The H-T phase diagram of a spin-flop system is shown in Fig. 6. Two distinct ordered phases appear. In addition to the regular antiferromagnetic phase, a new phase appears at high fields. In this phase, in a classicial vector-spin picture, the spins tend to align themselves *perpendicular* to the applied field on crossing the boundary line, which is first order, ehnce the name spin-flop. This system has two critical fields at $T = 0$, H_1 (the spin-flop field) and H_2. Two lines of critical points meet the first-order line at a special point B. B is a second example of a special type of critical point (these special points are generally called *multicritical points*). B is called a *bicritical point*; from Fig. 6 it may be observed that two critical lines meet at B. When a staggered field is included, the phase structure has several interesting features, but is too complicated to describe here. It should be noted that early calculations of mean-field type showed the three phase boundaries meeting at an angle. Modern calculations of non-mean-field type have indicated that the two second-order lines meet the first-order line tangentially. This effect is difficult to observe in 3D antiferromagnets, but is very prominent in quasi-1D antiferromagnets on account of the low dimensionality. The effect has been experimentally confirmed in both 3D and 1D antiferromagnets. Examples are MnF_2 and TMMC, respectively.

An interesting recent development concerns phase transitions in 3D antiferromagnets of basic lattice structure fcc (or bcc). The low-temperature ordered phases of these multi-sublattice magnetic systems can be fairly complex in terms of spin-ordering arrangements, characterized by doublings of the magnetic unit cell relative to the crystal unit cell as the system goes from a paramagnetic state into an ordered phase as the temperature is lowered. Examples are: Type I antiferromagnets such as UO_2; Type II antiferromagnets such as TbSb, MnO, NiO; and Type III antiferromagnets such as K_2IrCl_6. An order parameter of unusual complexity is required to describe such systems, and experimental testing continues of calculations based on group theoretical predictions of Landau and Lifshitz combined with the currently very popular technique of renormalization group analysis.

Other current areas of investigation where antiferromagnetic exchange interactions are important are Ising systems showing Lifshitz points, multiphase points, and a sequence of modulated phases. This theoretical work has been stimulated by recent magnetization and neutron-scattering experiments on rare-earth pnictides, particularly CeSb.

Spin-glasses are under intensive investigation at this time. They are commonly regarded as systems with random ferromagnetic and antiferromagnetic interactions, resulting ultimately from a modulated, long-range RKKY interaction. Spin-glasses exhibit many curious experimental features, but despite much theoretical effort no clear and definitive microscopic explanation has yet emerged. Systems which have features in common with random spin-glasses, but where enough regularities remain to render the system exactly solvable in a number of cases, are called *spin-frustrated systems*. A typical example is the Ising model on a triangular lattice with nearest-neighbor interactions. The condition for antiparallel spin alignment cannot be satisfied around a triangular unit of the lattice. Hence the origin of the term spin frustration.

Spin dynamics is another area where new theoretical breakthroughs are being made, and where antiferromagnets play a major role. Approximate analytic and computer-based classical calculations are now available in 3D. By contrast, in 1D spin $\frac{1}{2}$ antiferromagnets, many striking quantum mechanical features have been observed, enhanced by the low dimensionality. These developments have led to advances in nuclear magnetic resonance experimental techniques, with corresponding insight into the details of charge distributions around ions. In addition to susceptibility and magnetic resonance, an important experimental technique in antiferromagnetism is neutron scattering, which reveals details of the spin structure array and the effective spin dimensionality D, and probes the nature of the energy excitations.

ANTIPARTICLES

I. Overview: Particles and Quanta. Classification by Statistical Behavior and by Behavior with Respect to the Four Fundamental Interactions One of the great discoveries of modern physics is that for every type of elementary entity of matter and radiation—"particle"—there exists a corresponding conjugate type of entity—"antiparticle." In the antiparticle certain of the particle-defining properties are identical—"conjugation-invariant"—and others—"conjugation-reversing"—are reversed in sign. The reversed sign in a conjugation-reversing property allows one to maintain a conservation law for that property in the dramatic processes of *pair creation* and *pair annihilation* in which an antiparticle is observed to appear and disappear together with the particle to which it is conjugate. In those cases where all the conjugation-reversing properties occur with zero values, the antiparticle is identical with the particle. The progressive recognition of the existence of antiparticles was initiated by Dirac's relativistic anti-electron theory in 1931, and by Anderson's independent experimental discovery of the anti-electron (positron) in 1932.

A simple descriptive and inductive introduction to the fact of existence of antiparticles, and conceptualizations of it, is given in the article entitled ANTIPARTICLES in the first edition of this encyclopedia, and in the articles in the present edition on FIELD THEORY and ELEMENTARY PARTICLES. An enumeration of known particles and antiparticles up to 1983 will be found in the latter. Here we attempt to convey the most general theoretical setting in which the existence of antiparticles, and symmetry of conjugation between particles and antiparticles, may be established. At first a brief overview will be given and then a more detailed systematic discussion. Some of the technical terms used are defined in the sequel.

A major classification of all particle types is according to their statistics or "social behavior." This is based on symmetry or antisymmetry of the mathematical function describing an identical multiparticle state (i.e., a state with two or more particles of the same kind) under interchange in any pair. Those particle types for which there is symmetry under intrapair exchange are *bosons;* those for which there is antisymmetry are *fermions*, which fall into the two subtypes: *quarks* and *leptons*.

Cutting across the boson-fermion classification of particle types according to their *statistical behavior* are other classifications based on their *interaction behavior* or "charges." This refers to their participation or neutrality in the four fundamental physical interactions found in nature: hadronic, electromagnetic, weak, and gravitational. Formerly these were considered to be distinct, as once upon a time, the magnetic interaction and the electrical interaction were considered to be distinct only to be united later in the one electromagnetic interaction. Similarly, at the levels of energy of experiments in which they have been observed until now, the four interactions are distinguished by markedly different intrinsic strengths (coupling constants), roughly in the ratio $1:10^{-2}:10^{-14}:10^{-39}$, as well as different symmetries. Only the first three have hitherto played an important role in quantum particle physics. Particles subject to hadronic interactions are called *hadrons*, the elementary ones, out of which all others are composed being called *quarks.* Composite fermionic hadrons are called *baryons*; all other hadrons are *mesons.* It is found that baryons all carry a nonvanishing *baric charge B* which is very nearly, perhaps absolutely, *conserved*; i.e., up to a very high probability—perhaps certainty—*the total baric charge of the component entities after a reaction equals the total baric charge of the component entities before a reaction.* At both ends of the reaction the total baric charge is computed by simple addition. The baric charge of the elementary hadrons—the quarks—out of which all other hadrons are constructed is $\frac{1}{3}$, and the baric charge of antiquarks is $-\frac{1}{3}$. The only fundamental hadrons directly observed in nature are the composite baryons (quark triplets) with baric charge 1 and the mesons (quark-antiquark pairs) with baric charge 0. The leptons also have baric charge 0. The mesons, however, in contrast to the leptons, do interact hadronically, which is to be expected from their dipolar structure with respect to baric charge. The leptons are elementary, have no quark content and therefore no hadronic interactions. The leptons in turn display what seem to be other types of conserved charges. There appear to be three types, tauleptic charge (for tauon and its neutrino), mu-leptic charge (for muon and its neutrino) and e-leptic charge (for electron and its neutrino). Table 1 diagrams these classifications.

The most fundamental theory that we have of source particles and their interactions is Quantum Field Theory (QFT). The central concept in the classical ancestor of this theory is that of the *force field*, in which the effects of action by a source at any one point are propagated continuously to other points via an intermediary influence, i.e., not by "action at a distance" but by local action from point to point. The quantum interaction field retains some of these features, but in modified form.

The quantum modification of the classical field concept of propagation of influence is a picture of emission and absorption of intermediary entities or excitations—the interaction-quanta—which are exchanged between source-particles and which can also exist free. The conception of these intermediary excitations first appeared explicitly and with incisive success for phenomenological description and prediction in Einstein's 1905 work on light quanta or photons (for which, together with his "work in

TABLE 1. CLASSIFICATION OF PARTICLE TYPES ACCORDING TO SYMMETRY UNDER PERMUTATION OF IDENTICAL PARTICLES (STATISTICS)

		Bosons	Fermions

theoretical physics," he was awarded the Nobel prize in 1921, with no mention of the relativity theories!). The similar intermediary quanta that have been established since that time in theory for the other fundamental interactions, are interpreted as excitations of fields whose potential is distributed over spacetime. Thus we now speak of *gluon fields*, and *intermediate vector boson fields*, along with the photon field.

In QFT, source-particles are also interpreted as excitations of the modes of a field—the appropriate source-particle—field. Upon interacting, a given source field and a given interaction-quanta field can excite or de-excite each other. The excitations which make up our world of substance "sources" are traditionally recognized as systems of one or more "particles;" this corresponds to the fact that whenever we have a "pure" excitation of the source field, i.e., such as occurs in one and only one field-mode, it always comprises an exact whole number of elemental excitations identical with each other. (Similarly for "quanta" in an interaction field.) This exact whole-number multiplicity is already a sufficient basis for calling the theory "quantum." For such an elementary excitation, we shall reserve the term "particle" in the case of source fields ("quantum" in the case of interaction fields) or, more technically, "one-particle" (one-quantum) state. The term "excitation," though not in common technical use, is really more appropriate than "particle" or "quantum" because "excitation" connotes aspects of wave or vibrational patterns, as well as the wave property that all elementary excitations of a given type are indistinguishable from each other.

In summary: The hadronic interaction—also called "strong" or "nuclear" interaction—acts fundamentally between the members of one of the two basic families of *elementary source-particles*. The members of this basic hadronically interacting family have been named "quarks." The other basic family of source-particles, which have no hadronic interactions, are called "leptons." The term "source-particles" is used here for the members of these two families to contrast them with other fundamental massive and radiation entities which transmit interactions; these interaction-transmitting entities we shall designate "*interaction-quanta*." Among these are the "photon" and "weak-interaction vector bosons" and the "gluons" which transmit the hadronic interaction between both quarks and leptons. Tables 1 and 2 diagram these classifications.

Within the two particle families—quarks and leptons—there are many finer distinctions. In our subsequent discussion we shall see that any specific type of source-particle has attributes that come from its belonging to a corresponding space-time symmetry type, one of the "irreducible representations" of the symmetry group of spacetime. Among these attributes, to which different values are assigned in the different spacetime symmetry types, are *mass* and *spin*. Besides being of a given spacetime or *external symmetry type*, each source-particle also is of an *internal symmetry type*—one of those which serve as representations of an internal symmetry group. Corresponding type attributes are *charges* of various kinds—hadronic, electric, and weak, which play a role in the interaction of the various types of particles with the corresponding forces. Interaction-quanta possess similar symmetry attributes.

The electromagnetic interaction is perhaps the simplest. Its internal symmetry group is U_1, the group of all phase factors, i.e., complex numbers of unit magnitude; the corresponding attribute is electric charge. The electromagnetic interaction operates only between electrically charged or magnetically active particles, exchanging energy and momentum. It does not, however, transfer electric charge, i.e., it is itself neutral. Its intrinsic strength, 1/137, is labeled α_e.

The situation is quite different with the hadronic and weak interactions. The hadronic force, and likewise the weak force—in contrast to the long-range electromagnetic and gravitational forces—both are "short-range" forces. This means that the region of appreciable manifestation of the hadronic force is limited to a very small volume around the source particles, basically a quark, from which the force emanates. This force acts only on other quarks or quark structures, but not on leptons.

Both quarks and their intermediary hadronic interactions—"gluon interactions"—are classified according to the symmetry types of an exact $SU_3{}^c$ group, the indicated internal symmetry group of the hadronic interactions. The superscript c stands for "color," a label which takes on the three primary color values R (red), G (green), and B (blue), each symbolic of a particular kind of hadronic charge. Antiquarks come with the complementary three "anticolors" or anticharges. Because of the exact symmetry, the intrinsic strength of all the color charges is the same.

Besides the color charge classification of quarks there are two other type classifications found empirically that are not given by the exact $SU_3{}^c$ group, but which provide an approximate symmetry grouping. There are six "flavors" divided into three families." The three families, each comprising two flavors, are: (1) up (u), down (d); (2) charm (c), strange (s); (3) top (t), bottom (b).

The quark color classification corresponds to the first nontrivial symmetry-type, *triplet* (3) of $SU_3{}^c$. Its threefoldness is represented by R, G, and B. There is a corresponding *antitriplet* ($\overline{3}$) with the three complementary anticolors $\overline{R}$, $\overline{G}$, and $\overline{B}$ for the antiquarks. Thus, combination of three quarks having each of the three colors makes a "white" particle (baryon), or combination of a quark of a certain color and its antiquark makes another type of "white" particle

TABLE 2. CLASSIFICATION OF PARTICLE-TYPE ACCORDING TO SYMMETRY UNDER PERMUTATION OF IDENTICAL PARTICLES (STATISTICS) AND THEIR ROLE AS INTERMEDIARY QUANTA OR PARTICLES IN THE STANDARD MODEL

(meson). Strong interactions between the various quarks depend only on their colors and are governed by an exact unbroken $SU_3{}^c$ gauge group, implying eight massless gluons, which mediate the quark interactions. All structures are governed by the following fundamental rule: *While various flavored quarks can be found mixed in various proportions, only "white" color singlets are found in independent particle entities.*

It is this rule which summarizes in a formal manner the phenomenon of "quark confinement" which one requires in the current theory of strong interactions that has become known as "quantum chromodynamics." As already stated, the hadronic force does not operate on the members of the other set of elementary source-particles found in nature, the leptons; in other words, leptons have no hadronic (or gluon) charges. Also, leptons, unlike quarks, are actually observed in a state of freedom—a fact which suggests that the fundamental hadronic interquark (gluon) interaction is necessary for the "total confinement" which seems to be operating for quarks. The phrase "total confinement" signifies that only 3-quark and quark-antiquark composites have been observed—their quark content being inferred, however, from compelling evidence. This suggestion has been incorporated in the quantum chromodynamic field theory, where the fundamental hadronic force is comprised of the octet of gluon interactions. The mediating gluons are endowed with color and are therefore self-interacting, thereby producing antiscreening between source particles. This property, if it could be proved to increase without limit with distance, would lead to total confinement.

Residually, the hadronic force acts also between the 3-quark composites which we recognize as nucleons, neutrons and protons, which constitute units out of which nuclei of atoms are constructed. This force is, however, relatively (only relatively!) small compared to the interquark force at the same distances. It is analogous to the Van der Waals forces between electrically neutral atoms.

II. Antiparticle Existence Principle: Symmetry, Conjugation As we have already indicated, it is one of the great theoretical and empirical discoveries of modern physics that there is a general *duality* in nature in that to every particle type there exists a mutually annihilating "antiparticle" type with certain *exactly* identical and certain other *exactly* reversed defining properties. The exact duality of particle and antiparticle serves to classify the two sets, that of exactly identical and that of exactly reversing properties. Among the exactly identical properties are the mass and spin, and among the exactly reversing properties are all the fundamental charges. The members of both sets will be called *type-observables* and the following discussion will be concerned with specifying them.

Both sets of type-observables are associated with exact symmetries of the particle types and their interactions. What a "symmetry," or "symmetry operator," is will be defined more precisely later; here we shall designate the aspects of nature to which it applies, and indicate the meaning of the symmetry concept, by the following statement: Nature lends itself to a classification into two kinds of aspects, that of *systems* and that of *natural processes.* A natural process (e.g., motion in an arbitrary electromagnetic field) is generally considered to be a more fundamental feature than a particular system (e.g., the earth), since the process is taken to correspond with a *law of nature* whereas a particular system corresponds to the more special features which we label *side conditions.* (There is a blurring of the distinction in microphysics where the properties—to a certain extent unexplained—of isolated microphysical systems appear to be instances of laws of nature rather than of side conditions; this goes, of course, with the fact that these isolated microphysical systems are found in vast numbers of identical replicas: "elementary particles.") Symmetry operators are applicable to either side conditions or laws of nature or, alternatively, to either systems or natural processes: A symmetry operator of a system or process is a possible change which leaves certain overall relevant characteristics of the system or process unaltered (a possible change is one that can be actually, or in imagination, carried out on the system or process). If we are looking at nature as a whole, and are concerned principally about processes, the relevant characteristics to be preserved are the *dynamics* of transitions between arbitrary initial conditions and the possible final conditions in all *spontaneous natural processes.* In classical physics, this dynamics is given by *differential equations* and it is the form of these and certain parameters appearing in the equations which are to be preserved; in the truer-to-nature quantum physics the dynamics may be expressed even more directly by an array (S-matrix) of *transition probabilities* each of which is to be preserved individually. The additional invariant parameters here are such quantities as the mass and spin of the system (see next paragraph).

The symmetry operators which preserve the dynamics are, first of all, those which correspond to the *homogeneity* (invariance under translations) and *isotropy* (invariance under space-space and space-time rotations) of space-time in regions small enough so that the effects of gravitation may be neglected, i.e., over regions small compared with the reciprocal of the local value of the acceleration of gravity—in units in which the speed of light is 1 and all speeds are dimensionless ratios to this speed. (For all moderate gravitational fields these are very large regions, e.g., for an acceleration equal to the earth's surface gravity the linear dimension of the limiting region is $\approx 10^{18}$ cm ≈ 1

light year.) This set of homogeneity and isotropy operators characterizes the special relativity theory of spacetime and is called the *Poincaré group.* Thus, besides the fundamental conjugation-reversing interaction charges, the principal symmetry-related observables which define particles and antiparticles are those which result from the continuous spacetime symmetries which express homogeneity and isotropy: The invariance of natural evolution processes under an arbitrary spacetime translation (homogeneity) implies existence of conserved four-component energy-momentum $\underset{\sim}{P}$; the invariance under an arbitrary spacetime rotation (isotropy) implies existence of conserved six-component angular momentum $J \sim (\vec{M}, \vec{\mathfrak{N}})$. The conjugation-invariant type-observables here *are mass m* (with which may be associated phenomenologically, as an imaginary part, lifetime τ) and magnitude of *spin*—intrinsic angular momentum—s. Both mass m and spin-magnitude s are spacetime scalars or "invariants," which are algebraic functions of $\underset{\sim}{P}$ and $\underset{\sim}{J}$; by saying that they are invariants, we mean that they are left unchanged by any spacetime translation or rotation. (Actually, as we shall see, it is natural to require that they be invariants—but not necessarily functions—of *every symmetry operation.*) Because two translations *commute* (give the same result if performed in alternate order) there is no theoretical restriction on the possible values of the mass, though empirically such restrictions exist. Because rotations are noncommuting in a characteristic manner, the theoretically allowed values of spin are integral or half-integral multiples of an elementary unit, as observed. In short, the theory of (linear operator) representations of the relativity symmetry group (Poincaré group) prescribes clearly the *existence* of the particle-characterizing properties of spin and mass but only partially explains their *values*: (1) The specific *range* of observed spin values (all half-integral or integral multiples of a fundamental unit) is fully explained; the *allocations* to specific types of particles are partly explained by the general spin-statistics theorem (see following). (2) The specific range of observed masses is not fundamentally interpreted; however, a partial interpretation of the *mass differences* among the strongly interacting particles in a multiplet and supermultiplet in terms of an *approximate algebraic internal symmetry group*, SU_3, does exist.

The occurrence of the duplicity of particle types with the same conjugation-invariant properties (like mass and spin) but opposite conjugation-reversing properties (like electric and baric charge) has been much discussed. In general each member of the double is called the "antiparticle" of the other, and the basic fact that all particle types may be ranged in doubles (allowing for cases of identity between particle and antiparticle types) may be called the "*antiparticle existence principle.*" Later we shall discuss the derivation of this principle as a theorem in the context of other more general principles. We shall review the general basis that has been proposed for it in quantum field theory—which adds the principle of *locality* to general algebraic quantum theory—and in S-matrix theory—which is a stripped-down and occasionally extrapolated version of quantum field theory.

The validity of the antiparticle principle or theorem means that there exists an operator $\hat{\Theta}$ which divides all particle type-observables into two sets and thereby ranges existing particle and antiparticle types in one-to-one correspondence. We call this operator *particle conjugation* and we may restate the antiparticle existence principle: *There exists a particle conjugation operator $\hat{\Theta}$, and a division of symmetry-related observables ("type-observables") in two sets, such that $\hat{\Theta}$ acting on the type-observables of any existing elementary entity of matter and radiation—"particle"—gives the type-observables for an existing conjugate entity—"antiparticle"—with the first set of observables identical—"conjugation-invariant"—and second set reversed—"conjugation-reversing"—in sign. Further, $\hat{\Theta}$ is an "involution": acting on the type-observables of antiparticles it restores the values for the corresponding particles. Thus the operator $\hat{\Theta}$ and the identity, together, make up a two-member "particle-conjugation group," with the conjugation-invariant and conjugation-reversing type-observables belonging respectively to the even and odd symmetry types* ("*irreducible representations*") *of the group.*

What "acting on" an observable means formally will be defined later.

It is to be emphasized that the *exact doubling*, and no more than doubling, as between particle and antiparticle types, is in contrast to the approximate higher multiplicities found in nature. Such are the pion triplet and N* quadruplet of electric charge values, which respectively fit into the larger multiplicities of the meson charge-hypercharge octet and the baryon charge-hypercharge decuplet; these are ascribed to representations of higher algebraic *groups of approximate symmetry*, which will be discussed at a later point.

The conjugation exists not only for free particles and antiparticles but also for *interacting* systems of particles and antiparticles. This larger content of the antiparticle existence principle may be stated as follows: *The conjugation $\hat{\Theta}$ acting on any type-observable of any possible system of particles and antiparticles gives the observable of a corresponding possible system of antiparticles and particles.*

Again, in the following we shall discuss the derivation of this extended principle as a theorem—in the usual interpretation of $\hat{\Theta}$ known as the "C𝒫T theorem"—in quantum field theory and S-matrix theory.

III. Superselection and the Associated Charges; Conjugation Uniqueness Principle; Partial Conjugation Operators Besides the antiparticle *existence* principle there appears to be another principle relating to the *uniqueness* of particle-antiparticle conjugates which, as far as we know, has not been emphasized in the literature. This may be called *the principle of unique superselective conjugation*. We now describe it.

Among the type-observables—the basic observable properties used to define particle types—it is an empirical fact that there are some which are *simultaneously sharply measurable with all other observables*, and yet are not trivial "constant observables"—they are not trivial in that they exhibit different values for different systems. These "superselection observables" which we discuss in detail later are principally the "*superselection charges*" baric B, electric Q, mu-leptic L_μ, electron-leptic L_e, and tau-leptic L_τ (the latter three are included with some reservations in that their empirical basis is not as firm as that for B and Q). B, Q, and (L_e, L_μ, L_τ) are related respectively to the hadronic, electromagnetic, and weak interactions. Besides these, by virtue of the Poincaré-group space-time symmetry there exists another superselection observable; this is the *valence* index $(-1)^{2s_3}$ [for massless particles $(-1)^{2\lambda}$] defined by the *observable component* s_3 of spin [or, for massless particles, the *helicity* λ] defined in the following. The empirical *evidence* for the superselection nature of all these quantities is the total absence of interference terms between systems with different values of any of the charges or of the valence index. (The superselection of the valence index can be correlated theoretically with the fact that the continuous mathematical function describing half-integral spin [helicity] particles requires *two* whole rotations to repeat, in contrast with the continuous function describing integral spin [helicity] particles, which is periodic with respect to a single whole rotation about a point; thus *no coherent linear combination* of the two mathematical functions—i.e., with a definite complex-number phase on one function with respect to the other—is consistent, and physically this means: *no interference phenomena*.)

Besides spin and mass, the numerical values of all the "*superselectables*" (superselection observables) are the principal quantities needed to specify a particle type and to distinguish antiparticle from particle. Under conjugation the valence index remains unaltered: The antiparticle of an integral (half-integral) spin particle also has integral (half-integral) spin. That this must be so is a clear consequence of the fact that s_3 or λ remains integral or half-integral under conjugation; even with s_3 or λ reversed in sign, $(-1)^{2s_3}$ or $(-1)^{2\lambda}$ remains unchanged. By contrast, under conjugation the superselective charges are all reversed. Except in those "totally neutral" cases where these charge values are all zero, the particle type can be distinguished uniquely, under all circumstances, from its antiparticle type by a reversal of sign in all charge values. How is it that when more than one charge occurs with a nonzero value, they all reverse *together* for the antiparticle type? Thus, for example, there is a unique antiproton, negative electrically ($Q = -1$) and with negative baric number ($B = -1$); there does not exist a negative baryon ($Q = -1$, $B = +1$) or a positive antibaryon with protonic mass and spin. The striking general fact that there is exact doubling—with whatever occurring nonzero B, Q, L_e or L_μ, and L_τ reversing simultaneously—seems to be of special significance.

In our discussion we asserted that the spin [helicity], and therefore the valence, remains unchanged under conjugation while the superselective charges undergo the required reversal. A priori there were two possibilities, of which this was one. The other would have been that there exist mutually annihilating particle—antiparticle conjugates which have the spin (helicity) integral for one and half-integral for the other; the two members of such a doublet would exhibit the same, or equal opposite, baric, electric, or leptic charge but opposite valence. Because of conservation of angular momentum, upon annihilation an odd number of half-integral spin particles would appear. Such a situation seems to be in marked contrast to what we observe in nature where, for example, any antimeson and its meson (both hadrons with zero baric charge) have the same integral spin, whereas an antibaryon and its baryon have the same half-integral spin.

The principle involved may be stated as follows: *For reasons as yet unknown, there exist the three fundamental quantum-relevant interactions: hadronic, electromagnetic, weak, with associated superselective charges: baric B, electric Q, tau-leptic L_τ, mu-leptic L_μ and e-leptic L_e. The principle of unique superselective conjugation—an empirically verifiable (or, in principle refutable) assertion—states: The multiplication of particle types by reversals of sign of superselective charges is an exact doubling; i.e., there is a simultaneous reversal of sign of all superselective charges, whereas the type-observables associated with the Poincaré group—mass, spin, and valence—remain unchanged. This allows us to speak of a "unique" antiparticle to every particle. Alternatively described: The particle conjugation operator $\hat{\Theta}$ is inique and, together with the identity operator, defines a unique particle conjugation group such that all superselective charges below to its odd representation.* Only the situation we have described under the heading of the "principle of unique superselective conjugation" appears to occur in nature. The behavior of the valence can be inferred from the fact that the conjugation is a symmetry operation which leaves all Poincaré-group type-observables unchanged.

The uniqueness of conjugation—the simultaneous reversal of sign of all the superselective charges—requires a more subtle explanation. It is customary to interpret the rigorous conjugation operator to be what is commonly called $C\mathcal{P}T$; here C is the electric charge-conjugation operator found to be an exact symmetry in quantum electrodynamics, as also are $\mathcal{P}$ the parity of space reflection operator, and T "time-inversion" (actually "motion reversal") which unlike the first two is an *antilinear* operator (defined formally in the following). By taking the product only of the first two, one defines a linear operator Θ' commonly known as $C^{\mathcal{P}}$ (it has also been called "coparity" by the writer). To our present knowledge Θ' is an exact symmetry for all processes with the sole exception of the weak decays of one single type of particle—the kaon; in these decays invariance under Θ' appears to be broken at the level $\sim 10^{-3}$ [the number 10^{-3} refers to the ratio: Rate $(K^0{}_L \rightarrow 2\pi)$/Rate $(K^0{}_L \rightarrow 3\pi)$].

Following the survey here, and an introductory theoretical orientation, we propose a reason why the principle of unique superselective conjugation must hold: If the universal conjugation operator can be identified with Θ—a symmetry which though nonobservable is linear—and we also assume the von Neumann property of the algebra of all observables, then the principle follows. In the standard interpretation of the conjugation with another operator not Θ', but

$$\hat{\Theta} = C\mathcal{P}T \equiv \Theta$$

all the homogeneity operators, energy-momentum $\underset{\sim}{P}$, are conjugation-invariant and all the isotropy operators, space-space and space-time angular momentum $\underset{\sim}{J}$, are conjugation-reversing and so likewise is the (related) observable component s_3 of the spin. These quantities are not type-observables but rather "state-observables" and we shall discuss them in the following. Their behavior under conjugation is not so clearly indicated empirically as that of the type-observables. For example, with Θ' as a conjugation operator, the $\vec{\underset{\sim}{P}}$ components, rather than the $\vec{\underset{\sim}{M}}$ components, are conjugation-reversing.

Following the discussion of Θ' we give an account of some of the conventional formalism which has been successful in deriving the antiparticle existence principle and the conjugation principle (Θ interpreted as $C\mathcal{P}T$) as theorems in a general context of relativistic quantum theory. There then follows a brief discussion of the special and more stringent form which the general conjugation operator takes for the basic interactions: By combining Θ with parity $\mathcal{P}$ and time-inversion T, or Θ' with $\mathcal{P}$, one defines the operator $\Theta\mathcal{P}T \equiv \Theta'\mathcal{P} \equiv C$, known traditionally as "charge conjugation," which is a kind of "purely internal and unitary conjugation operator." Except for weak-interaction systems and processes, it is again a symmetry.

To understand all this in detail it is necessary first to clarify what we mean by "particles." The fundamental entities of matter and radiation constituting the physical world are associated with observables which are: (I) *quantum-mechanical*; (II) *symmetry-governed*; (III) *invariant* or *covariant* under the governing symmetry. (I) By the quantum-mechanical aspect we mean that a key role is played by probabilistic—more explicitly: *statistically deterministic*—concepts rather than detailed deterministic concepts as in classical physics. This is because of the fundamental fact of nature that any two observables A and B are *not necessarily compatible*, i.e., starting in a given situation and *measuring* the two observables *in alternation*, they do not each repeat their original measure values; instead, the measurements give for each a distribution of *measure-value probabilities* characteristic for that observable when preceded by a measurement of the other. (II) By the symmetry-governing aspect we mean that it is of central importance to classify observables according to their behavior under physically relevant *groups of symmetries*; each individual symmetry is by definition a transformation ("change") which (a) leaves measure-value *probabilities unchanged*, (b) is evolution-independent, and (c) leaves the spacetime type-observables, mass, spin, and valence, unchanged. (III) By the invariance-covariance aspect we mean that among all possible observables—and *relative to a given degree of generality of observation procedures*—there is a division into two classes—the type-observables which are *invariant* with respect to the groups of symmetries, i.e., go into themselves when transformed by any symmetry, and the state-observables which are *covariant*, i.e., mix nontrivially with other members of a set of observables when transformed.

A more explicit discussion follows.

IV. Observables and Their Algebras. Symmetries (I) The modern algebraic version of the quantum-mechanical concepts is streamlined in comparison with the earlier formulations in that the concept of a given state space has receded to the background; with the greater economy and generality of algebraic quantum theory, many results may be demonstrated more elegantly.

(Ia) We consider all directly or indirectly measurable properties which we call *observables* A. The observables constitute an algebra with a certain formal structure. We first remark that observables in quantum mechanics are not all mutually sharp or compatible: In any given situation, keeping all other conditions constant, if we measure an observable A repeatedly we get consistently the same measure value. The same is not necessarily the case if any two observables A and B are measured in alternation repeatedly, keeping all other conditions constant; we find a distribution of values for each rather than a single value. We then say: "A and B are not compatible." Two observables are compatible if in a given system, prepared appropriately and repeatedly in the same way, each observable always exhibits one characteristic definite measure number ("quantum number," "eigenvalue") upon consecutive repeated measurements appropriate to each observable in either order. Constant observables, i.e., those which exhibit only one measure value under *all* circumstances with *all* systems (multiples of the "identity"), are of course compatible with all others. If there is also a nonconstant observable—i.e., in experiments with various systems it yields differing measure numbers—which is compatible with all other observables, we call it a *superselection observable*. We shall discuss some examples later, among them electric charge Q.

In the following, let the complex conjugate of a scalar number, e.g., λ, be represented by a superior bar, $\bar{\lambda}$. Consider an infinite-dimensional linear complex vector space $\mathcal{H}$ with an inner product (ϕ, ψ), i.e.,

$$(\phi, \psi + \theta) = (\phi, \psi) + (\phi, \theta)$$

$$(\phi, \lambda\psi) = \lambda(\phi, \psi) \quad (\lambda\phi, \psi) = \bar{\lambda}(\phi, \psi)$$

$$(\phi, \psi) = \overline{(\psi, \phi)}$$

for all vectors ϕ and ψ; $\mathcal{H}$ is assumed complete in the norm $\| \phi \|$ defined by $| \phi, \phi |^{1/2} \equiv \| \phi \|$, and has a countable basis (every Cauchy sequence of vectors has a limit vector in the space and a complete orthonormal basis can be introduced), i.e., $\mathcal{H}$ is a Hilbert space. The unit vectors of physical interest are only those lying in certain subspaces of $\mathcal{H}$ defined by certain values of the superselectables. These unit vectors, up to an arbitrary phase factor, represent states. Each observable is represented formally by a linear *self-adjoint operator* or "matrix" A acting on the vectors of $\mathcal{H}$. The eigenvalue λ of A for an eigenstate ϕ, i.e., such that $A\phi = \lambda\phi$, is the measure value found for the observable corresponding to A when measured in the state ϕ. The role of self-adjointness is to ensure that all such eigenvalues are bounded and real. What "self-adjoint" means formally and what further properties are to be expected of A is clear from the following discussion.

Besides their action on the vectors of $\mathcal{H}$, one also has the effect of one operator in $\mathcal{H}$ acting on another to give a resultant operator, and in the case of the operators representing two observables, this product of operators represents the successive measurement of the two observables. Two compatible observables are then represented by two commuting operators corresponding to the fact that the two successive measurements give the same result in either order. For brevity the operator representing an observable will also be called an observable. A general operator A is said to be *bounded* or to have a *norm* if there exists a positive number b such that

$$\| A\phi \| \leqslant b \| \phi \|, \qquad \text{all } \phi \text{ in } \mathcal{H}$$

The smallest number b with this property is the *norm of A* and is denoted $\| A \|$. It follows that

$$\| A + B \| \leqslant \| A \| + \| B \| \qquad \| AB \| \leqslant \| A \| \, \| B \|$$

$$\| \lambda A \| = | \lambda | \, \| A \|$$

We now turn to the characterization of the algebra of observables in $\mathcal{H}$. What the algebra formalizes are (1) the property that the numerical values obtained as the result of any measurement are (a) real and (b) bounded; (2) the property that not only is every observable or algebraic function of observables compatible with all superselectables, but that every operator compatible with all superselectables is an observable or algebraic function of observables; in short compatibility with superselectables characterizes the algebra of observables.

The formal structure which satisfies the requirements of these two sets of properties is that of a *von Neumann algebra*, a type of subalgebra $\mathfrak{A} \equiv \{A\}$ of the algebra of all linear bounded (or, equivalently, continuous)operators in $\mathcal{H}$, which subalgebra satisfies two conditions:

1. *$\mathfrak{A}$ IS A C* ALGEBRA*. A C^* algebra involves (a) an *involution* applied to (b) *normed operators*.

a. *Involutive application:* There is a * or *adjoint* application of $\mathfrak{A}$ into itself such that, for any A in $\mathfrak{A}$, A^*—the adjoint of A—has the properties

$$(A+B)^* = A^* + B^*, \qquad (\lambda A)^* = \bar{\lambda} A^*,$$

$$(AB)^* = B^* A^*, \qquad A^{**} = A.$$

An operator for which $A^* = A$ is said to be *self-adjoint*.

b. *Normed operators:* In a C^* algebra we have that all operators are normed and that their norms satisfy

$$\|A^*\| = \|A\|, \qquad \|A^*A\| = \|A\|^2, \quad (\text{all A}).$$

An operator H which satisfies the equation between inner products

$$(\psi, H\phi) = (H\psi, \phi)$$

is called hermitian. It is easy to verify that every eigenvalue of a hermitian operator is real:

$$(\phi, H\phi) = (\phi, \lambda\phi) = \lambda(\phi, \phi) = (H\phi, \phi) = \bar{\lambda}(\phi, \phi).$$

Likewise for every operator which is self-adjoint. Every self-adjoint operator is hermitian, but unbounded hermitian operators are not self-adjoint.

(It can be proved conversely that a hermitian operator which is everywhere self-adjoint is necessarily bounded.)

2. $\mathfrak{A}$ *IS EQUAL TO ITS DOUBLE-COMMUTANT* $\mathfrak{A}''$. The latter is the set of all linear operators in $\mathcal{H}$ which commute with the first commutant which, in turn, is the set of all linear operators in $\mathcal{H}$ which commute with $\mathfrak{A}$.

The algebra of observables is a von Neumann algebra based on self-adjoint operators where simultaneous observability of observables means that the self-adjoint operators, which represent the observables, commute. Since $\mathfrak{A}$ contains all observables and algebraic functions of them, condition (2) means here that a linear operator which is a nonmember of the observable algebra cannot commute with all members of the commutant $\mathfrak{A}'$ of $\mathfrak{A}$. Since $\mathfrak{A}'$ contains, besides the constant operators, only the set of all superselectables and functions of these, the assumption that $\mathfrak{A}$ is a von Neumann algebra requires such a linear nonmember of the observable algebra not to commute with one or more of these superselectables. We shall see in the sequel that this is one of the key points in rationalizing the occurrence of *unique* superselective conjugation as described above.

The possible measure numbers of the observables are represented by the *spectrum of eigenvalues* a_i of A. For simplicity suppose these spectra are discrete. By the *spectral theorem* of Hilbert space theory, A is a linear combination with real coefficients of bounded self-adjoint operators called *projections* (or "projectors") P^A, having the idempotent property $(P^A)^2 = P^A$, with P^A corresponding to the eigenvalue λ. In particular, for describing various specific conditions in which a given system is prepared, one is interested in the subset $\mathcal{S}$ of self-adjoint operators with all eigenvalues a_i nonnegative and such that the sum of all a_i—the "trace"—is equal to unity. We call these unit-trace nonnegative self-adjoint operators "density matrices." These are in one-to-one correspondence with the "states," both pure and mixed, of the earlier less-streamlined formulation of quantum mechanics. (It should be noted, however, that the modern C^*-algebraic quantum theory recognizes much more general "states" than can be represented by density matrices.) Even this subset, consisting of nonnegative self-adjoint operators of trace 1, however, is too large for physics when superselection observables are present. $\mathcal{H}$ is then divided up into mutual totally incoherent subspaces corresponding to the different eigenvalues of the superselection observables; the operators representing *physical observables* act only within each subspace but not between them.

(Ib) *Probabilities.* The concept of probability gives physical meaning to the projection $P_\lambda{}^A$ corresponding to an eigenvalue λ. Suppose a system is prepared repeatedly in the same manner, so that a given density matrix M describes the state of the system, and we measure the observable A each time. On the one hand, the occurrence frequency or *probability measure* for the eigenvalue λ of A in the state M is $|\text{dim}\, P_\lambda{}^A| a_\lambda$ where a_λ is the coefficient of $P_\lambda{}^A$ in the spectral-theoretic direct sum expansion of M—and this probability measure is given by Trace $(MP_\lambda{}^A)$. On the other hand, the eigenvalue λ itself occurs as the coefficient of $P_\lambda{}^A$ in the expansion of A. Thus if—having prepared the system each time in the same way—we repeatedly measure the observable A, the expectation value of A over a large number of similar trials is Trace (MA).

(II) *Symmetries.* A symmetry is a mapping of the set $\mathcal{S}$ of all density matrices onto $\mathcal{S}$ which

(a) preserves probabilities,
(b) is evolution-independent,
(c) leaves mass, spin, and valence index invariant.

A symmetry may or may not also be an observable.

(IIa) Just as in the case of complex numbers in the complex plane, each of the operators in state space may be viewed in an active role as operating on other objects or in a passive role as one of the objects being operated on. A particular kind of operation on an operator A by another operator G is called "transformation of A by G" or a similarity mapping of A by G: GAG^{-1}. (This gives the operator in the G-transformed state space which corresponds to A in the original space, i.e., it accomplishes the corresponding operation upon corresponding states.) If under transformation by G, A goes into itself: $GAG^{-1} = A$, then A is said to be *invariant under* G; more generally, if for each member of a set $\{A_i\}$, GA_iG^{-1} gives a member $A_i' = A_i$ of the set, A_i and all its partners in $\{A_i\}$ are said to be *covariant under* G. If the entire set $\mathfrak{A}$ of all observables is transformed onto itself by G, then we say G performs a similarity mapping of $\mathfrak{A}$.

Condition (IIa) says that a symmetry is a probability-conserving similarity mapping of $\mathcal{S}$. Probabilities are given by the coefficients in the "convex" (i.e., with real positive coefficients) linear combinations into which density matrices can be decomposed according to the spectral theorem. Thus the preservation of probabilities is equivalent to the preservation of convex linear combinations or projectors. There are two kinds of operators which, acting as transforming operators, preserve convex linear combinations of projectors.

1. A *unitary* operator U is *linear*

$$U(\alpha\phi + \beta\psi) = \alpha U\phi + \beta U\psi$$

and *isometric*, meaning there is equality in absolute value of both sides of

$$(U\phi, U\psi) = (\phi, \psi).$$

2. An *antiunitary* operator Θ differs only in that it is *antilinear isometric*, i.e.,

$$\Theta(\alpha\phi + \beta\psi) = \bar{\alpha}\Theta\phi + \bar{\beta}\Theta\psi ; (\Theta\phi, \Theta\psi) = \overline{(\phi, \psi)}.$$

The second condition implies that the antiunitary transform of an operator A is given by

$$A' = (\Theta^{-1} A\Theta)^*, \text{ and therefore } (AB)' = B'A',$$

or there is a reversal of order of operator products if Θ is antiunitary.

It is clear that the transformation $\hat{\Theta}A\hat{\Theta}^{-1}$, where $\hat{\Theta}$ is a unitary or antiunitary operator, preserves convex linear combinations of observables. When we limit A to the subalgebra $\mathcal{S}$ of all density matrices in $\mathcal{A}$, the converse is also true. By the general Wigner-Kadison theorem (Wigner, 1931-1959; Bargmann, 1964; Kadison, 1951) every convex combination-preserving one-to-one map of $\mathcal{S}$ on $\mathcal{S}$ is either unitary or antiunitary. Moreover this mapping operator is unique up to a phase factor. (Wigner's formulation of the theorem was in terms of preservation of absolute scalar products of states rather than of convex linear combinations of density matrices).

We should qualify that, in the presence of superselectables, the symmetry mapping may be from a subalgebra $\mathcal{S}_1$ of density matrices onto some other coherent subalgebra $\mathcal{S}_2$ isomorphic with $\mathcal{S}_1$, but labeled by different values for the superselective observables. This is the case when the symmetry operator Θ' is not a member of the observable algebra. If, in addition, Θ' is linear, we can draw an important conclusion. As we have already emphasized, in this case—because the algebra of observables is a von Neumann algebra—the linear nonobservable symmetry operator Θ' cannot commute with all superselective charges. As the notation has already indicated $CP \equiv \Theta'$ is such an operator; unlike $\Theta \equiv C\mathcal{P}T$, Θ' *is linear*—$\mathcal{P}$ is linear and C (see end of article), as dictated for instance by quantum electrodynamics, is linear. Also, unlike $\mathcal{P}$ or C separately, Θ' *is a symmetry operator* in all cases, with the apparent exception of the neutral kaon decays. Further, except in the small subspace of totally neutral particle states, Θ' *is not a member of the observable algebra*: There is no preparation or measurement procedure, or combination of such procedures, corresponding to turning particles into antiparticles. Thus, overlooking for the moment the difficulty with the neutral kaon decays, Θ' is the natural candidate for a nonobservable linear symmetry operator representing particle conjugation, which cannot commute with all the superselective charges. That Θ' must actually *anticommute* with the superselective charges, e.g., letting Q be the relevant charge:

$$\Theta' Q = -Q\Theta'$$

follows from the fact that all probabilities, including the square of the expected value of the charge, must be preserved. That this happens simultaneously with all superselective charges (principle of "unique superselective conjugation") becomes evident when we recognize the empirical fact that there exist particle types for each case of only one charge differing from zero—all other charges having zero values:

	B	Q	L_μ	L_e	L_τ
baryon, otherwise neutral: Λ^0	1	0	0	0	0
electrically charged hadron, otherwise neutral: π^+	0	1	0	0	0
mu-lepton, otherwise neutral: ν_μ	0	0	1	0	0
e-lepton, otherwise neutral: ν_e	0	0	0	1	0
tau-lepton, otherwise neutral: ν_τ	0	0	0	0	1

Considering each of these systems in turn, we draw the conclusion that each of the superselective charges, when occurring singly, anticommutes with the symmetry operator Θ', so that, for consistency, when several occur together with nonzero values, they must all reverse together. An example is the proton p $(B = 1, Q = 1)$ which, under conjugation of the decay $\Lambda^0 \to p^+ + \pi^-$ has to give the unique antiparticle $\bar{p}$ $(B = -1, Q = -1)$.

We note that to be able to draw the conclusion that a superselective charge is reversed by a nonobservable symmetry—"conjugation"—it was necessary for that superselective charge to occur with an eigenvalue unequal to zero, while *all* others have zero eigenvalues (this is what we mean by "otherwise neutral"). The argument will, however, not go through if we have not established the conjugation invariance of that one remaining superselective observable, which is not a charge, i.e., the valence $(-1)^{2s_3}$ [or $(-1)^{2\lambda}$ for the massless case]. This conjugation invariance is assured, however, because the valence must always be +1 or −1 depending upon the integer or half-odd integer value of the spin; but, by condition (c), a symmetry leaves the spin and therefore the valence index invariant.

It is striking that the only violations of Θ' which prevent it from being taken as a universal conjugation under which interactions are invariant are in the neutral kaon decays. The neutral kaon case is precisely the one in which there exists no superselective charge which by its reversal defines the difference between particle and antiparticle. Only the approximately conserved "strangeness" or "hypercharge" (see following) is available as a possible charge to discriminate between K and $\bar{K}$.

(IIb) We note with emphasis the importance of condition (IIb). Though every unitary or antiunitary operator preserves probabilities, it is not necessarily a symmetry. The requirement of evolution independence is what brings the enormous number of unitary and antiunitary operators in $\mathcal{H}$ down to the physically significant subset of symmetry operators. Evolution independence may be described as a "generalized time independence." The evolution matrix—known as the "S-operator" or "S-matrix"—is an operator which takes any one of a set of *initial asymptotic* states to any one of a set of *final asymptotic* states, where the states are characterized by the values of certain observables and where "initial" and "final" refer to appropriate boundary conditions. The initial and final set can be the same and be a complete set spanning the entire state space. (In the case of the "collision states" appropriate to scattering problems, this condition is known as *asymptotic completeness*, and it goes with unitarity, $S^* = S^{-1}$, of the S-matrix). The evolution matrix is a replacement of a "moment-to-moment" time-displacement operator by an overall or global "before-and-after" operator. The need for such a replacement is evident when we reflect on the fact that the passage of "time" is relative to the observer, according to the special relativity principle which governs nature—at least locally. In fundamental processes, only the before-and-after relations described by the S-matrix have an observer-invariant significance, and *the formal expression of the property of evolution independence, which every symmetry* G must satisfy may be stated: *When the symmetry is performed first and followed by evolution, it gives the same result as when evolution is performed first and then the symmetry.*

For a unitary symmetry U this condition takes the form

$$SU = US$$

which may be read either way as: $SUS^{-1} = U$, "the evolution matrix leaves every unitary symmetry invariant"; or $USU^{-1} = S$, "every unitary symmetry leaves the evolution matrix invariant."

For an antiunitary symmetry Θ, because initial and final states are interchanged under the action of Θ, the evolution-independence condition has to be stated as

$$S\Theta = \Theta S^*$$

where S^*, the adjoint of S, takes final to initial states; this equation is easily checked by letting the right and left hand sides operate respectively on a final state f. The results of the sequence of operations on the right and left can be symbolized as follows (primes indicate Θ-transformed states and f indicates the result of S operating on i):

$$(f' \leftarrow i', i' \leftarrow f) = (f' \leftarrow i, i \leftarrow f).$$

The relation for S and Θ may then be rewritten

$$S^* = \Theta^{-1} S \Theta$$

and, referring back to the expression given earlier for the antiunitary transform of an operator, we see that, even though it is not a simple similarity invariance, this relation can be expressed by a statement parallel to that for the unitary case: "every antiunitary symmetry leaves the evolution matrix invariant." It is clear that for finding the S-matrix, which is central in elucidating fundamental processes, the knowledge of its symmetries is invaluable.

The symmetries of any system form one or more groups. In general there are discrete groups of symmetries (e.g., the permutations of identical particles in a multiparticle system), and continuous groups of symmetries. In the latter case the *generators* are of particular importance. Let G be any symmetry operator differing infinitesimally from the identity operator I. Then the "business end" of this operator defines a generator $\mathcal{G}$: $G = I + \epsilon\,\mathcal{G}$. In this case the transformation by G of any operator A goes—to the first order in ϵ—into A plus the commutator $[\mathcal{G}, A]$ of $\mathcal{G}$ with A:

$$GAG^{-1} \simeq A + \epsilon[\mathcal{G}, A] \qquad [\mathcal{G}, A] \equiv \mathcal{G}A - A\mathcal{G}.$$

The invariance of A under all members of a group $\{G\}$ requires then that the commutator of A with all generators of $\{G\}$ be zero. In particular the S-operator must commute with the generators of any symmetry group.

The S-operator governing the evolution of fundamental processes, is a particular though important case. Its structure, as well as the definition of particle types which undergo the fundamental processes, is elucidated by considering the invariant and covariant bedfellows of the S operator. Quite generally, in its passive role as an operand, any operator will be found to have certain transformation or covariance properties under all the generators of a given group of state space transformations. This characteristic transformation behavior, as well as the relation structure of operators with each other, plays a key role in deciding whether an operator may be interpreted as representing a physical quantity having that transformation behavior. The generators themselves are usually merely covariants of the group, but certain polynomials or functions of them may be invariant; a function of generators which is invariant—i.e., commutes with all generators—is called a "Casimir operator" or "Casimir invariant" of the group.

(IIc) This condition is roughly equivalent to the one otherwise expressed by the statement that a symmetry operation should leave the subspace of one-particle states invariant. We have already seen its usefulness in our argument concerning the invariance of the valence index under conjugation.

(III) As we have already indicated, by the "invariance-covariance" aspect of the fundamental physical entities we mean that among all possible observables there is a (heuristic) division in two classes:

I. A subset which we call "invariant" or "particle type-defining";

II. all other observables which we call "covariant" or "state-defining."

In our formulation both subsets will be characterized by labels associated with symmetry groups. The first set of observables—used to define fundamental *particles*—are certain *external and internal Casimir invariants*, so called because they are associated with external and internal symmetry groups governing the fundamental systems. In contrast the second set of observables—used to characterize the *states* in which fundamental particles are found—are *covariants* of these same external and internal symmetry groups. We shall see how this very valuable distinction is nevertheless relative to the degree of generality of the phenomena being considered.

The external symmetry group is the *proper spacetime symmetry group*, i.e., the group of all rigid translations and rotations in spacetime (Poincaré group). The covariants here are physical representatives of the four translation generators—the components of the energy-momentum $\underset{\sim}{P}$—and of the six rotation generators—the space-space and space-time components of the angular momentum $\underset{\sim}{J} \sim (\vec{M}, \vec{\mathfrak{N}})$. The two principal Casimir invariants here define the principal external properties of elementary particles: Their magnitudes give the numerical values of the first two of these properties, mass m and spin s. These numerical values label the possible "symmetry types" or *irreducible representations* ("reps") of the proper spacetime symmetry group.

We have discussed the general doubling in Nature of particle types for which the conjugation-invariant observables are identical, whereas the values of all other type-defining observables are exactly opposite for the two members of the double; and we have introduced the mapping operator $\hat{\Theta}$ which acts on observables. Formally, $\hat{\Theta}$ "acting on" an observable means transforming according to $\hat{\Theta}(\ )\hat{\Theta}^{-1}$. The superselective charges: B, Q, L and ℓ, and λ are included among the type-defining conjugation-reversing observables, and give $-B, -Q, -L, -\ell, -\lambda$ under this transformation.

What about the behavior of state-characterizing observables under $\hat{\Theta}$? These also may be sorted out once and for all into two sets, conjugation-invariant and conjugation-reversing. From now on we use the generic symbol Σ to represent all conjugation-invariant observables, and the symbol R to represent all conjugation-reversing observables, whether type or state. Thus, $\hat{\Theta}$ is an operator which maps the subalgebra of symmetry-related observables onto itself according to

$$\hat{\Theta}\,\Sigma\,\hat{\Theta}^{-1} = \Sigma \qquad \hat{\Theta}\,R\,\hat{\Theta}^{-1} = -R.$$

Closely related to the existence of antiparticles—almost but not quite as firmly established empirically—is the further fundamental fact that not only may all *types* be arranged in matched particle-antiparticle pairs by $\hat{\Theta}$, but also that $\hat{\Theta}$ is *represented in* $\mathcal{H}$ *by an antiunitary symmetry* Θ. We call this *the conjugation principle*. That $\hat{\Theta}$ should be represented ("implemented") by an *operator* Θ, unitary or antiunitary, in $\mathcal{H}$ is a purely mathematical consequence of $\hat{\Theta}$ mapping onto itself the subalgebra of density matrices (Wigner-Kadison). The nontrivial physical point of the conjugation principle—a key point, commonly referred to as "the $C\mathcal{P}T$ Theorem"—is that Θ is not just an operator but is a *symmetry* operator. In other words the evolution operator S, and the Poincaré invariants, mass spin, and valance (and therefore the dynamics of all fundamental processes), are invariant under Θ, i.e., $\hat{\Theta}$, *which we have defined as a mapping of symmetries on symmetries, itself gives rise to an antiunitary symmetry*. More explicitly, the conjugation principle may be stated: *The conjugation operator* $\hat{\Theta}$ *is represented in state space* $\mathcal{H}$ *by* (1) *an evolution-independent mapping* Θ *of states in* $\mathcal{H}$ *onto other states in* $\mathcal{H}$, *such that:* (2) *transition probabilities are preserved, with initial states being mapped on final and final on initial;* and (3) *mass, spin, and valence* are preserved.

$$S\Theta - \Theta S = 0 \tag{1}$$

$$\begin{aligned}(\psi_{\Sigma',R'}, \psi_{\Sigma,R}) &\longrightarrow (\Theta\psi_{\Sigma',R'}, \Theta\psi_{\Sigma,R})\\ &= (\psi_{\Sigma,-R}, \psi_{\Sigma',-R'})\end{aligned} \tag{2}$$

$$\Theta m^2 - m^2\Theta = 0 \qquad \Theta s(s+1) - s(s+1)\,\Theta = 0 \tag{3}$$

We emphasize that the conjugate of the original initial (final) state plays the role of the final (initial) state in the conjugate process, of which the rate is identical to that of the original process. Again we shall discuss later how the conjugation principle may be derived as a theorem in the context of general theory.

V. Conjugation-Invariant and Conjugation-Reversing Observables The mass squared is the squared magnitude of the energy-momentum four-vector (Table 3). The spin comes in as follows: In general there is defined a four-component polarization operator W_α made up by the outer product of the linear momentum operators and the angular momentum operators. (The time component $W_0 = \vec{P} \cdot \vec{M}$ is the *longitudinal polarization*.) There are two cases generally recognized to be of physical interest, $m^2 > 0$ and $m^2 = 0$. In the massive case, W_α yields as the measure of its invariant magnitude the spin s according to the formula $W^2 = m^2 s(s+1)$.

By a general spin-statistics theorem of relativistic quantum theory, the spin of a one-boson system is integral and of a one-fermion system half-integral.

In the case of zero-mass particles, W splits into two parts, each consisting of a pair of components. The pair of components perpendicular to the momentum define, by the sum of their squares, the "continuous spin" invariant r^2 where r is a real nonnegative number. The remaining components, longitudinal and timelike, are equal in this case, and they yield another invariant, the projective index $\sigma = 0$ or $\frac{1}{2}$ or valence index $+1$ or -1, which specifies the integral or half-integral character of the forward angular momentum (i.e., the projection along the direction of motion). For $r > 0$ this forward angular momentum takes on an infinite discrete ladder of values, while for $r = 0$ the ladder breaks up into its individual segments (the representation matrix reduces to the direct sum of its diagonal entries). In these $r = 0$ cases the forward angular momentum—now an invariant—takes on a unique integral or half-integral value, the helicity, λ, and the valence index ceases to be an independent invariant—just as it happens in the massive case. All these relations and cases are summarized in Table 2.

In nature only cases where the continuous invariant r is equal to zero seem to occur. As we have indicated, the two sets—particle-defining observables and state-defining observables—are associated respectively with two sets of labels of mathematical groups—groups which describe the symmetries of natural systems. We have discussed one of these sets: Each fundamental entity belongs (in its mathematical description) to an irreducible representation—"rep"—of the symmetry groups governing all physical systems, and the type-characterizing observables are associated with the Casimir operators whose eigenvalues are the labels specifying the rep. What are the other labels with which the state-characterizing properties are associated? They are the labels for the *rows* of the reps and do not have the same invariant significance as the rep labels since various basis systems of states may be chosen to span the vector space constituted by each rep. The type-observables have relatively stable values, defining the identity of the particle, so that it may be recognized as the same at the end as at the beginning of a process; whereas the state observables are more labile, having values which can vary between the beginning and end of the many processes in which the identity—e.g., m and s—of the particle is unaltered. For example, a rep of the Poincaré group comprises a vector space of states, the vector space consisting, •.g., of states of all momenta and longitudinal polarizations associated with a particle of given mass and spin. Alternatively, a basis of angular momentum

TABLE 3. GENEALOGY OF THE EXTERNAL-PROPERTY INVARIANTS MASS m AND SPIN s OR HELICITY λ

	Energy-Momentum	Total Angular Momentum	Polarization Vector

Timelike Energy Momentum. Standard form taken when state is limited to the subspace of states in which the center of mass is at rest.	$P_0^2 - \sum_{k=1}^{3} P_k^2 \equiv m^2$ $P_0 = m$ $P_1 = 0$ $P_2 = 0$ $P_3 = 0$	$M_1 = S_1$ $M_2 = S_2$ $M_3 = S_3$	$\sum_{k=1}^{3} W_k^2 - W_0^2 = m^2\ s(s+1)$ $W_0 = 0$ $W_1 = mS_1$ $W_2 = mS_2$ $W_3 = mS_3$
Lightlike Energy Momentum. Standard form taken when state space is limited to the subspace of states in which the momentum is in the x_3 direction.	$m = 0$ $P_0 = p$ $P_1 = 0$ $P_2 = 0$ $P_3 = p$	$M_1 - \mathfrak{N}_2 = T_1$ $M_2 + \mathfrak{N}_1 = T_2$ $M_3 \qquad = \mathcal{H}_3$	$\sum_{k=1} W_k^2 - W_0^2 = r^2$ $W_0 = W_3 = \mathrm{pH}_3$ $W_1 = pT_1$ $W_2 = pT_2$ In case $r = 0$ $W_a \equiv \lambda P_a$ $\lambda = \underset{\sim}{M} \cdot \underset{\sim}{P}/\lvert\underset{\sim}{P}\rvert$

might be chosen. The state-characterizing observables include then energy-momentum $\utilde{P}$, and angular momentum $\utilde{J}$, or $\utilde{W}$, depending on the basis chosen.

We have in the Poincaré group an example of how the very valuable distinction between particle-defining labels and state-defining labels is relative to the degree of generality of the observations. Suppose that we limit the allowed changes of observation systems (or "frames of reference") to space rotations, so that the external symmetry group reduces to the rotation subgroup of the Poincaré group. Then the fourth component—the energy P_0—of $\utilde{P}$, which in the full group is merely a covariant, becomes an invariant, $P_0 = (\vec{P}^2 + m^2)^{1/2}$, corresponding to the Casimir operator $\vec{P}^2$ of the space rotation group. This example illustrates the general proposition that as the scope of observation is increased, it becomes more and more natural to view different particles merely as different states associated with one supersystem.

We turn now to the internal properties of particles. As already remarked, Fermionic hadrons are called *baryons*, bosonic hadrons are called *mesons*; nature permits us to define *baric* charge B equal to ±1 for the former and 0 for the latter in such a way that the total baric charge is conserved in all processes. For some unknown reason baric charge is related to spin or statistics.

So far only fermionic leptons of two types—electron or e-type and muon or mu-type—are known, but the existence of bosonic leptons involved in weak interactions has been conjectured. Again, in accord with exact conservation in all processes, nature permits us to define: (1) *electron leptic charge* ℓ, equal to ±1 for electrons and e-neutrinos, and 0 for muons and mu-neutrinos; (2) *mu leptic charge* L, equal to ±1 for muons and mu-neutrinos, and 0 for electrons and e-neutrinos. (The universality of the muon- and electron-leptic charge labeling—based on the phenomena observed in weak interactions—is not quite certain.)

Intermediate between hadronic and weak interactions in strength is the electromagnetic interaction. Here nature permits the definition of a conserved *electric charge* Q equal to ±1 and 0 for various particles, hadronic and leptonic, as the case may be.

Another way to regard the existence of these internal charges, in which the aspect of conservation is derivative rather than primary, is in terms of symmetries. In this way too we are led to four independent universally observable internal properties; baric, electric, muon- and electron-leptic charge B, Q, L, and ℓ, defined by symmetries associated with the behavior of particles under the three fundamental quantum-relevant interactions: strong, electromagnetic, weak. Each of the types of charge may be associated with an SU_1 ("special"—i.e., unimodular—"unitary" group on one object), i.e., groups of *evolution-independent* transformations having the form $e^{iB\phi}$, $e^{iQ\phi}$, $e^{iL\phi}$, $e^{i\ell\phi}$, respectively (ϕ is an arbitrary parameter ranging over all elements of each group). In these cases B, Q, L, and ℓ are the sole generators—indeed Casimir operators of their respective SU_1 groups.

With the specification that they are generators of symmetries—i.e., evolution-independent—it comes about that, as in the case of energy-momentum and angular momentum, the sum total value of each of the internal charges is conserved in any process. In the case of mass and spin of a composite system, the addition is vectorial rather than simply algebraic, and in the case of mass, there may also be a contribution due to internal energy changes. In contrast, the charges have values which are simply additive in a composite system. As already mentioned, the sign reversal of the values of the charges for antiparticles is essential to maintaining the conservation laws in the processes of *pair creation* and *pair annihilation* in which antiparticles are observed appearing and disappearing with their conjugate particles. Only those particles for which the values of all charges are zero, e.g., the photon γ, the neutral pion π^0, and the η, ρ, ω, and ϕ mesons are identical with their antiparticles; these are called "self-conjugate particles." Any number of these may occur together with pair creation or annihilation. Examples are

$$e^- + e^+ \to 2\gamma \qquad e^- + e^+ \to 3\gamma$$

depending upon whether the spins of the electrons are antiparallel or parallel.

As indicated earlier there is an external property or type observable, the *parity operator* $\mathcal{P}$ associated with invariance of non-weak evolution processes with respect to the discrete operation of space inversion (reflection). When one extends the proper Poincaré group to include space inversion, the symmetry types and the corresponding states double. Naively one says that $\mathcal{P}^2 = 1$, and that the parity of a one-particle state or one-antiparticle state is +1 or −1 according as the state function is preserved or reversed in sign when the space coordinates upon which the state function depends are all reversed. (Properly speaking the term "parity" as used here means "the eigenvalue of the parity operator when applied to the state," and the state must therefore be an eigenstate of $\mathcal{P}$.) Actually the result of a double inversion can be asserted to equal the identity only up to a phase factor—a complex number of modulus 1, namely $\mathcal{P}^2 = \exp(i2\alpha_R)$, where α_R is some arbitrary phase angle which may be different for the states associated with each superselective family—i.e., for each set of particle types with given values of the charges, electric, baric, mu-leptic, electron-leptic, and hypercharge Y (see later discussion): $\{Q\ B, L, \ell; Y\} \equiv \{R\}$. Examples of such families are (1) the self-conjugate or totally neutral ($Q = B = L = \ell = 0$) "nonstrange" ($Y = 0$) mesons; (2) all the nonstrange mesons of positive electric charge; etc. With $\mathcal{P}^2 = \exp(i2\alpha_R)$ the two possibilities for the effect of $\mathcal{P}$ are multiplication by $\exp(i\alpha_R)$ and $-\exp(i\alpha_R)$. Within any given family, by renormalizing, $\mathcal{P} \to \exp(i\alpha_R)\mathcal{P}$, one can reduce to the two alternatives +1 and −1. See PARITY.

More explicitly, we describe the situation as follows. Within any *superselective sector*, i.e., a superselectively separated subspace of state space, we assume the "principle of maximum coherence" to hold: *any two physical states ϕ and ψ can cohere into a single physical state, with the relative phase angle of ψ with respect to ϕ in the coherent superposition $\phi + \psi$ unambiguously determined.* Observationally the phase angle β appears in the interference term $2\,|(\phi, \psi)|\cos\beta$ in the scalar product

$$(\phi + \psi, \phi + \psi) = (\phi, \phi) + (\psi, \psi) + 2\,|(\phi, \psi)|\cos\beta.$$

If, under reflection, ϕ and ψ behave the same ($\phi + \psi \to \phi + \psi$) the interference term remains unchanged, and we say the *relative parity* of ϕ and ψ is +1; if they behave oppositely ($\phi + \psi \to \phi - \psi \equiv \beta \to \beta + \pi$) the interference term changes sign, and ϕ and ψ are said to be of relative parity −1. Relative parity, being a special case of relative phase factor, has the transitivity property, i.e.,

$$\mathcal{P}(A \text{ with respect to } B) \times \mathcal{P}(B \text{ with respect to } C) = \mathcal{P}(A \text{ with respect to } C).$$

In the coherent superposition case where ψ has relative parity −1 with respect to ϕ, $\phi + \psi$ is not a parity eigenstate though it is a physical state. For simplicity and brevity we shall refer to all physical states with definite charges and Poincaré group indices, which are also parity eigenstates, simply as particles, even though from some points of view they are composite: n-particle states, particle-antiparticle states, etc.

The vacuum state (i.e., with no particles present) has the same values, $\{R\} = 0$, for the superselective charges as the totally neutral particles. Thus the relative parity of any totally neutral particle with respect to the conventionally chosen parity of the vacuum, $\mathcal{P} = +1$, is empirically determined. This is called the *intrinsic parity* of the particle. Because of the extraordinary empirical fact that the set of all fermions is coextensive with that of all leptons or baryons, as exhibited by the equivalence: half integral spin $\rightleftharpoons$ either B or L or $\ell \neq 0$, the totally neutral particles occur only among the bosons and only for these is the intrinsic parity unambiguously determined. Another way of obtaining the same result follows from the fermion side of the above empirical equivalence. The reason why a boson can have an unambiguous parity (relative to the conventionally chosen parity of the vacuum, $\mathcal{P} = +1$) is that the continuous function describing it obeys the "Columbus principle," i.e., that a 360° movement of the observing apparatus around an axis restores the original description. Because the description of a one-fermion system does not obey this principle, the intrinsic parity of a one-fermion system is not uniquely defined.

A fermion intrinsic parity is, however, often assigned conventionally, as for the nucleon family where it is taken to be +1. More generally, as a consequence of the isospin and SU_3 groupings of particle types with respect to hadronic interactions (see later discussion), it is natural to assign those in the SU_3 multiplet the same intrinsic parity. It is important to emphasize however that the choice of relative parity between two superselectively separated particle types (e.g., neutron and proton) is only conventional. This is because any two physical states ϕ and ψ lying in different superselective sectors can not cohere into a physical state, and the behavior of the relative sign of ϕ with respect to ψ under a space inversion cannot be deduced since there is no interference to be observed. It is true however that within each superselective sector a choice, albeit conventional, of the intrinsic parity of one particle, A, determines that of any other particle, B, according to the rule derivable from the transitivity property

$$(\text{Intrinsic Parity})_B = (\text{Relative Parity})_{B/A}\ (\text{Intrinsic Parity})_A$$

By its nature as a phase factor—the eigenvalue of a discrete symmetry operation rather than of a generator of a continuous symmetry operation—the parity of a composite system (product state) is the product of the parities of the parts. Thus given the parities of the parts the parity of the composite is determined, but there are cases where the converse is not true: other than in totally neutral cases, particle states are prevented from combining into states (coherent superpositions) with the antiparticle states by the different values—of one or more superselective charges. This has the consequence that the intrinsic parity of the antiparticle with respect to that of the particle is not defined. In the case of a system made up of a particle and its own antiparticle (which is therefore always equivalent to a totally neutral boson and consequently in the same superselective sector as the vacuum) the intrinsic parity of the *pair* is however defined. In the case where the pair consists of a boson and its antiboson the intrinsic parity of the system is +1. (If the boson itself is totally neutral then of course it and the antiboson must have the same parity, either +1 or −1; but if it is not totally neutral it can be assigned $\mathcal{P} = e^{i\alpha}$, and then the antiboson must be assigned $\mathcal{P} = e^{-i\alpha}$; α can be arbitrary, e.g., $\alpha = \pi/2$ so that boson and antiboson could be assigned opposite parity.) The intrinsic parity of a given fermion-antifermion pair (constituting, therefore, a one-boson system) is, however, always -1. (If the conventional assignment of $\mathcal{P} = +1$ is made for the nucleon, then $\mathcal{P} = -1$ for the antinucleon; but if $\mathcal{P} = e^{i\phi}$ for the nucleon, then $\mathcal{P} = e^{i(\pi-\phi)}$ for the antinucleon—and ϕ can be arbitrary, e.g., $\phi = \pi/2$ so that both nucleon and antinucleon have the same parity, i.

The general result that $\mathcal{P} = +1$ for a boson particle-antiparticle pair and $\mathcal{P} = -1$ for a fermion particle-antiparticle pair is derivable theoretically by applying the assumption of analyticity, in the sense of complex function theory, to the description of scattering processes. This is done in the manner indicated later, in connection with the derivation of the antiparticle existence theorem, by analytic continuation of the scattering amplitude for the process

$$a + b \rightarrow a + c$$

to a region where it corresponds to the process

$$b \rightarrow \bar{a} + a + c.$$

It is confirmed observationally by selection rules which hold in various pair annihilation processes.

We also have some observables associated with approximate internal symmetries in processes in which only the strong interactions are important: The hypercharge Y, isospin I, and isoparity G are observables characterizing certain isomultiplets of nearly coincident mass but differing electric charge into which the mesons or baryons group. These isomultiplets are of the internal symmetry group SU_2. The members of each isomultiplet have the same baric charge and differ by consecutive values of the electric charge Q. The hypercharge Y is the sum of the lowest and the highest electric charges in the isomultiplet. The isospin magnitude I is a number which measures the multiplicity of the isomultiplet as $2I + 1$. The full significance of Y comes in a further grouping of these SU_2 isomultiplets into hypermultiplets belonging to the higher symmetry group SU_3 which has been found very successful. The isomultiplets within each hypermultiplet still have the same baric charge B but differ by consecutive values of the hypercharge Y. Further suggested higher internal symmetries have been found partially successful.

In the hadronically relevant isomultiplets (associated with an SU_2 group) the generator I_3 is an observable which is conjugation-reversing. The hypercharge Y which, under purely hadronic interactions, is a generator of an SU_1 symmetry group, is again a conjugation-reversing observable, i.e., behaves like a "charge." Both of these results are confirmed as follows. There are three generators I_1, I_2, I_3 for the isospin group SU_2. This group has identically the same Lie algebra—and therefore the same theory—as spatial angular momentum. By convention the observable component—represented by a diagonal matrix—is taken to be I_3. The ladder of diagonal elements has of course the three properties found with angular momentum: (1) It is equal-runged; (2) it is symmetrical about zero—thereby specifying integral or half-integral units of isospin as eigenvalues; (3) it is finite, i.e., begins with $(I_3)_{\min} = -I$ and ends with $(I_3)_{\max} = I$. The operational significance of the observability of I_3, i.e.,

$$I_3 = Q + \text{const}$$

plus the definition of Y as $Q_{\max} + Q_{\min}$, then leads to the Gell-Mann-Nishijima relation

$$Q = I_3 + Y/2.$$

Clearly, along with Q, I_3 and Y are conjugation-reversing.

The invariant isospin I of an isomultiplet is, like spin s to which it is analogous, conjugation-invariant. Under appropriate conditions there is also an *isoparity* G which, like space parity $\mathcal{P}$, is conjugation-invariant. G is defined unambiguously only for hadronically interacting systems for which $B = Y = 0$ (and of course $L = \ell = 0$), i.e., for hadronic systems which, "neutral" in every other respect, need not be electrically neutral. All such systems can be connected directly or through a sequence of intermediate systems to a basic number of pions; the latter are stable against hadronic decays. The isoparity G equals $+1$ or -1 according to whether the basic number of pions is even or odd. Individual pions then have odd isoparity and, as its name and the rule indicate, isoparity is multiplicative for a composite system. Among mesons, G can be defined only for the $Y = 0$ "nonstrange" isomultiplets for which I is integer because $Q_{\max} = -Q_{\min} = I$ cannot be half-integral insofar as has been established for any actual particle. (In practice such isomultiplets are either isosinglets or isotriplets since in none of the well established meson systems does I exceed 1.) There are 17 such hadronically unstable mesons for which G is very well known; in every case it is found to be conserved in the purely hadronic decays of these particles. (*Review of Particle Properties*, April 1973). G is violated in other interactions as, for instance, in the decay of the hadronically stable lightest η meson (550 Mev) into three pions by virtual electromagnetic interactions.

In the generalization to SU_3, with the grouping of isomultiplets to hypermultiplets, B remains an invariant while Y which was (a non-Casimir operator) invariant for SU_2 becomes a (covariant) generator. The electric charge Q which was originally the unique generator—and therefore, trivially, the Casimir invariant—of an SU_1 group, and became a displaced generator of the isospin SU_2 group through the Gell-Mann-Nishijima relation, becomes a regular generator in the SU_3 group.

To sum up then, the set of type-defining observables includes (in the massive case) mass m, spin s, parity $\mathcal{P}$ (with certain qualifications in fermion systems), and also electric, baric, muon- and electron-leptic charges (Q, B, L, ℓ) and (with certain qualifications) hypercharge Y, isospin I, isoparity G, and SU_3 rep labels p and q. In the massless cases occurring in nature the type-characterizing observables comprise besides helicity λ, parity $\mathcal{P}$, isoparity G, and muon- and electron-leptic charges L and ℓ (the latter three with qualifications). The values taken by these observables classify all existing entities into particle types.

VI. Derivation of Antiparticle Existence and Conjugation Principles from Relativistic General Quantum Theory; Other Results We turn now to a discussion of proposed theoretical derivations of the antiparticle principle and the conjugation principle from very general theory with a minimum of supplementary features.

Successful theories in physics are often built in stages: (1) a *general theory* with room for further structure (thermodynamics, Maxwell's *E-M* theory without constitutive relations, etc.); (2) more particular theories filling out the structure. The primary general theory of elementary particles and antiparticles is *relativistic general quantum theory*, and the two more particular theories which fill out, in alternative ways, what is to a large extent the same structure are: (1) *general quantum field theory* and (2) its somewhat stripped-down version known as *S-matrix theory*. (In taking these theories to be adequate we are trusting that the problems of making them applicable universally, i.e., also to infinite range interactions—zero mass quanta—as in electrodynamics, can be resolved by appropriate procedures or reformulations, e.g., algebraic quantum theory. It is to be noted that difficulties associated with the possible occurrence of zero mass particles are common to both the S-matrix theory and the field theory.)

The formal ingredients of relativistic general quantum theory, which is the common basis of the two more particular theories, are:

(I) Relativistic elements expressing: (A) continuous *spacetime symmetry or invariance* of natural processes under the Poincaré (inhomogeneous Lorentz) group of translations, rotations, and uniform velocity shifts; (B) operational *possibility of distinguishing before and after* in natural processes (distinction between forward and backward light cones). (C) More specific than any of the preceding postulated elements is the assumption that no zero mass particles occur.

(II) Quantum mechanical elements expressing: (A) the merely *statistical determination* in nature; (B) *the disturbance by the act of observation of physical systems*—which is related to mere statistical determination; (C) within the context of mere statistical determination, the *causal independence* of well separated experiments; (D) *analyticity of the collision or S-matrix elements* in its arguments.

(III) A somewhat more specific quantum mechanical assumption than the above refers to the operational *impossibility of counting, as distinct, particles of the same kind*.

(I) We have already discussed in some detail the manner in which the existence of spacetime symmetry allows us to define particle types and states.

(IIA) This general quantum mechanical principle takes the form of assuming the existence of a Hilbert space of *asymptotically free 1-particle momentum eigenstates*. A scalar product of these states with themselves and with each other is defined. The one-particle states may be added. When added they obey the *superposition principle*: Any linear combination (except for certain superselection restrictions) is itself a state. Conversely any given first state may be considered as a linear combination of a complete set of states built up beginning with any other second state. The probability of finding the second state immediately after establishing the first state is given by the square of the *probability amplitude* which is itself given by the scalar product of the second state with the first.

(IIB) Takes the form of recognizing that arbitrarily chosen observables are not necessarily compatible with each other. A *complete set of compatible observables* (C.S.C.O.) is any set needed to define the states uniquely, and the individual state is labeled by the set of values which the C.S.C.O. takes on for it. The states are represented as rays in a Hilbert space, the observables as linear operators. Compatibility (noncompatibility) of two observables is represented by commutativity (noncommutativity) of the corresponding two operators. In many instances two such operators anticommute, and this is how quantum theory describes the reversals of sign of certain properties under Θ as indicated above. Thus we have

$$\Theta Q + Q\Theta = 0 \quad \text{or} \quad \Theta Q\Theta^{-1} = -Q$$

$$\Theta B + B\Theta = 0 \quad \text{or} \quad \Theta B\Theta^{-1} = -B, \text{ etc.}$$

where the similarity transformation on the left of the second equation on each line represents the effect of conjugation on the corresponding charge operator.

(IIC) Besides the scalar product and the addition of one-particle states, one may also consider taking ordered outer products of one-particle states with the objective of representing multiparticle states. This is straightforward in the quantum field theory. In a somewhat old-fashioned but picturesque manner the quantum field may be described as a linear superposition of creation and annihilation operators. The field with its constituent operators and associated excitation states may be described as somewhat analogous to an idealized piano constructed with an infinitude of key-hammers (creation operators) and individual pedals (destruction operators) associated with each possible tone (excitation state); this tone can be excited to various degrees (corresponding to the number of particles in that state). All nonempty states are produced by the creation operators, acting on the *vacuum state*; the latter corresponds to the totally quiescent piano. In this formalism, in the simple case of noninteraction the basic states are *n-particle states*, n having all possible values. A specific n-particle state $|n_1, n_2, \cdots > \equiv |\underset{\sim}{n}>$ is characterized by the set of *occupation numbers* $n_1, n_2, \cdots (n_1 + n_2 + \cdots = n)$ specifying the numbers of particles having quantum numbers $q_1, q_2, \cdots$. The state $|0, 0, \cdots > = |\text{vac}>$ is called the *vacuum state*, and assumption (IC) excluding zero mass particles implies that there is a *mass-gap above the vacuum state*.

In the quantum field theory the assumption that corresponds to causal independence of well separated regions is that of locality, i.e., that field operators at spacelike-separated points commute. This, together with the assumption (IC) that zero mass particles do not occur, suffices to derive the existence and uniqueness of the set of *stationary collision states* in which arbitrary numbers of beams of stable particles collide and produce final stable particles as interaction products. These collision states define a unique *evolution-governing collision matrix* (S-matrix) whose matrix elements are the probability amplitudes for transitions between the asymptotic initial and final states at $t = -\infty$ and $t = +\infty$ (assumption (IB) tells us that we can distinguish between these "in" and "out" states). The collision matrix has the "*cluster decomposition*" *or* "*connectedness*" *property*; i.e., when particles interact the interaction (amplitude) is a sum of subinteractions (subamplitudes) by clusters, of particles two at a time, three at a time, etc., each cluster accompanied by a remaining set of noninteracting particles. The contribution to the S-matrix subamplitude for each noninteracting particle involves a Dirac δ-function expressing the constancy of momentum and energy of that particle, whereas the interacting clusters contribute combinations of amplitudes which are non-δ-functions with momentum-energy variables as arguments.

In the S-matrix approach, which seeks to circumvent the assumption of a local field, the existence of the S-matrix is postulated directly, with the cluster decomposition property as that one of its properties which expresses the causal independence of well separated experiments. This leads (Froissart and Taylor, 1967) to the representation of multiparticle or collision states by ordered outer products of one-particle states, such that these are given by the standard creation operator formalism of the field theory.

If in addition one more assumption is made: *asymptotic completeness*—that there are no additional states besides those that are superpositions of collision states—the quantum field theory also derives the *unitarity*, $SS^+ = S^+S = 1$, and certain *analyticity properties of the collision matrix*. The unitarity expresses the fact that the total probability summed over all processes is unity—the conservation of probability. Unitarity and analyticity have to be assumed ad hoc in the S-matrix approach, as the price of avoiding the locality assumption of the field theory.

The dependent variables of which the S-matrix elements are functions are prescribed by the "relativity" or "Lorentz-Poincaré invariance" of the theory (IA). This requires that the laws of nature be invariant under spacetime-interval preserving transformations. Here it means that any S-matrix element is a scalar under these transformations, or that the amplitude combinations corresponding to interacting clusters are functions of spacetime-invariant variables only, i.e., scalar products of the four-momenta of the interacting particles (or their sums and differences).

(IID) This assumption is that of *analyticity of the probability amplitudes* as functions of the invariant variables. As we have remarked, it is derivable—in a complicated way—from locality in the field theory, but it has to be introduced ad hoc in the sparser short-circuiting S-matrix approach. The assumption is sometimes called "causality," but it is probably more restrictive mathematically than what is implied by the causality concept.

(III) leads to a condition on the *statistics* associated with a given particle type. *Identical multiparticle states*, i.e., states containing two or more particles of the same kind, occur in nature only with *symmetry or antisymmetry* (of the mathematical function describing the multiparticle state) under interchange in any pair. This symmetry difference gives a major classification of all particle types; this is usually described as a classification according to "statistics" or "social behavior," since those with interchange symmetry—called *bosons*—tend to aggregate in the same momentum state, whereas those with antisymmetry—called *fermions*—tend to exclude each other from the same state.

From these general ingredients, either in the field theory version (Streater and Wightman, 1964; Jost, 1965), or in the stripped-down S-matrix version subject to a subtle proviso concerning analytic continuations (Olive, 1964; Lu and Olive, 1966; Froissart and Taylor, 1967), one can derive a number of remarkable general results:

1. *Hermitian analyticity.* Hermitian conjugate amplitudes are associated with the same analytic functions.

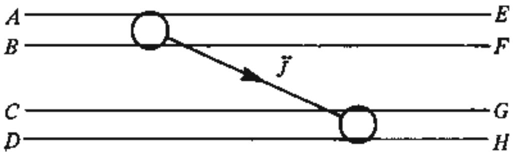
2. *Existence of antiparticles.* The argument by traditional field theory is detailed later. The argument as presented by the S-matrix protagonists is interesting and worth sketching. It depends on matching singularity structures of different subamplitudes when the cluster-structure is inserted in the unitarity relation $SS^* = 1$. This leads, e.g., to a relation between the amplitude A_{44} for the complete cluster interaction

$$A + B + C + D \to E + F + G + H$$

and the amplitudes A_{23}, A_{32} for the sequential interactions

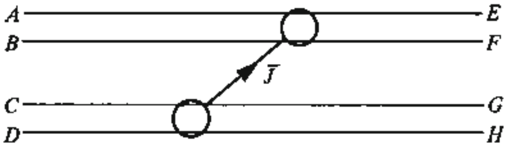
$$A + B \to E + F + J \qquad C + D + J \to G + H.$$

The bubble diagrams and the equation below express this relation



$$(q^2 - m^2) A^*_{44}|_{q^2=m^2} = A^*_{23}A^*_{32}.$$

Left and right sides of this equation are analytic functions of their variables and one can continue the equation analytically to a different part of the physical region for A_{44}. In the new part of the physical region the continued pole represents the two successive interactions



$$C + D \to G + H + \bar{J} \qquad A + B + \bar{J} \to E + F$$

The new particle $\bar{J}$ has the same mass as J but opposite internal charges (since they obey a rule of additivity). Thus the antiparticle principle is proved and becomes the *antiparticle theorem* (provided the analytic continuation brings us back to the "right side" of the physical region singularity of $A_{44}{}^*$).

3. *Crossing.* Since, under analytic continuation, residues also continue (provided there exists a path of analytic continuation in the complete amplitude joining the two points and lying within the mass shell section—sufficient condition) the argument also demonstrates the property known as "crossing," i.e., that the amplitude for a process in which a given initial particle disappears without issue is the same function as for a process, otherwise identical, except that the corresponding antiparticle appears without antecedent:

$$\text{Ampl}\,(A + \cdots + N + J \to A' + \cdots + N')$$
$$\sim \text{Ampl}\,(A + \cdots + N \to \bar{J} + A' + \cdots N').$$

4. *$C\mathscr{P}T$ or Conjugation Theorem.* In the S-matrix approach to the $C\mathscr{P}T$ theorem, similar considerations of residues of single particle poles are used as in discussing the crossing theorem. The proviso, made in all the S-matrix arguments, concerning existence of "right paths" joining particle and antiparticle poles are related to the two basic facts used in the field theory proofs of the conjugation theorem:

a) vacuum expectation values of products of field operators are boundary values of analytic functions;
b) the spacetime inversion $x \to -x$ can be connected with the identity transformation through complex Lorentz transformations.

With the help of these two facts one can prove the existence of an antiunitary Θ, acting on fields, which has the properties of a symmetry. For example, for a scalar field $\Phi(x)$ the two basic facts a) and b) lead to the identities (ψ_0 is the vacuum state):

$$[\psi_0, \Phi(x_1) \cdots \Phi(x_n)\,\psi_0]$$
$$= [\psi_0, \Phi(-x_n) \cdots \Phi(-x_1)\psi_0]$$

for the vacuum expectation values of the products of field operators at any number of spacetime points $x_1, \cdots x_n$. Because of the reversal of order of operators, these identities are equivalent to the existence of an antiunitary Θ satisfying

$$\Theta\Phi(x)\Theta^{-1} = \bar{\Phi}(-x).$$

But then it follows that Θ maps stationary collision in-states onto stationary out-states of the corresponding antiparticles with the same momenta and opposite spin projection.

$$\Theta\psi_{\text{in}}(p_1 \cdots p_k) = \psi_{\text{out}}(p_1{}' \cdots p_k{}').$$

The symbol p_j represents the momentum $\underset{\sim}{p}_j$ and spin of the jth particle of the colliding beams, and $p_j{}'$ stands for the same momentum but opposite spin projection for the antiparticle. As an immediate consequence, we have the equation between the S-matrix element for the particle reaction $p_1 \cdots p_k \to \underline{p}_1 \cdots \underline{p}_m$ and the S-matrix element for the antiparticle reaction

$$\underline{p}_1' \cdots \underline{p}_m' \to p_1' \cdots p_k':$$

$$\overline{[\psi_{\mathrm{out}}(\underline{p}_1, \cdots \underline{p}_m), \psi_{\mathrm{in}}(p_1 \cdots p_k)]}$$

$$= \overline{[\Theta\psi_{\mathrm{out}}(\underline{p}_1 \cdots \underline{p}_m), \Theta\psi_{\mathrm{in}}(p_1 \cdots p_k)]}$$

$$= [\psi_{\mathrm{in}}(\underline{p}_1' \cdots \underline{p}_m), \psi_{\mathrm{out}}(p_1' \cdots p_k')]$$

$$= [\psi_{\mathrm{out}}(p_1' \cdots p_k'), \psi_{\mathrm{in}}(\underline{p}_1' \cdots \underline{p}_m')]$$

5. *Spin-statistics theorem.* It is found in nature, so far without any demonstrated exception, that bosons have integral spin and fermions half-integral spin. This is the spin-statistics relation. It has been derived in field theory with various degrees of generality. (See Streater and Wightman, 1964, for a very general proof.) In the S-matrix approach (Lu and Olive, 1966), again provided certain plausible features are contained in the singularity structure, the relation between spin and statistics is established. It is found that connectedness—together with Lorentz invariance, unitarity, and analyticity—implies that the connected parts for processes involving particles with the wrong relation between spin and statistics vanish, so that such particles are unobservable.

Besides the behavior under Θ of the S-matrix and the type- and state-characterizing observables, we may be interested in the behavior under Θ of fields, and interactions between fields, which are also operators in quantum field theory. For all but the weak interactions, an additional symmetry over and above the universal Θ symmetry holds. This is what is traditionally known as "charge conjugation" and denoted by the symbol C. As we have already remarked, it corresponds to $\Theta\mathscr{P}\mathrm{T}$ where $\mathscr{P}$ is the (unitary) space reflection operator, and T is the (antiunitary) time-inversion (more properly "motion-reversal") operator. Besides interchanging initial with final states, T reverses the signs of the three space-space components of $\underset{\sim}{J}$ (the angular momentum $\vec{M}$) and of the three space components of linear momentum $\vec{P}$; $\mathscr{P}$ reverses the signs of the latter and of the three spacetime components of $\underset{\sim}{J}$, the centroidal moments $\vec{\mathfrak{N}}$, The net result of combining T with Θ then is to undo the antiunitarity, restoring the original order of before and after, and also to undo the conjugations of all external state observables. Thus $\Theta\mathscr{P}\mathrm{T} \equiv C$ is a kind of "internal conjugation operator."

VII. Charge Conjugation in Lagrangian Quantum Field Theory C-conjugation ("charge conjugation") plays an important role in the history and elementary discussions of fundamental particles. We here review its traditional treatment in the Lagrangian form of quantum field theory—a theory which was originally inspired by the analysis of oscillations and waves in classical physics where fields are simply numerical functions of space and time. The quantum version of the theory requires that the fields be operators. Also, the theory, necessarily a many-particle theory, is best described at first for the noninteracting case when we can take the basic states to be n-particle states, characterized by the set of *occupation numbers* $n_1, n_2, \cdots (n_1 + n_2 + \cdots = n)$ specifying the numbers of particles having quantum numbers $q_1, q_2, q_3, \cdots$ corresponding to a complete set of commuting observables (C.S.C.O.): $Q_1, Q_2, Q_3, \cdots$. The state $|0, 0, 0, 0, \cdots\rangle$ with all $n_i = 0$ is the *vacuum state.* As in any vector space, there is also the *zero vector* 0. The single-step destruction operator a_α for particles, and creation operator $b_\alpha{}^*$ for antiparticles associated with the αth quantum number are introduced in the usual way (see FIELD THEORY) such that they satisfy the standard commutation (anticommutation) rules if the particles satisfy Einstein-Bose (Fermi-Dirac) statistics. One then introduces the *field operator*, which is a linear expansion in the a_α and $b_\alpha{}^*$ (all α), and which formally satisfies certain field equations, the latter usually being chosen on the basis of a classical analogy or on the basis of relativistic covariance and general agreement with experiment. All of the consequences of interest then follow from the definition of the field operator and from that of the C-conjugation operator:

$$Ca_\alpha C^{-1} = \eta_c b_\alpha \qquad Ca_\alpha{}^* C^{-1} = \overline{\eta}_c\, b_\alpha{}^*$$

$$Cb_\alpha{}^* C^{-1} = \eta_c a_\alpha{}^* \qquad Cb_\alpha C^{-1} = \overline{\eta}_c\, a_\alpha.$$

Here η_c is a phase constant ($|\eta_c| = 1$) which is nonmeasurable and can be chosen +1 by convention. If particle and antiparticle are identical then $b_\alpha = a_\alpha$, and η_c becomes measurable and equal to ±1, two physically distinct cases.

For a specific theory, particularly if it is given in Lagrangian form in which case each of the symmetry observables is defined by a symmetry operation on the Lagrangian, these observables can be written as bilinear functionals in the field operators.

As an example, we consider the case of a scalar (spin zero) charged field $\Phi(x)$ associated with a mass m, and satisfying the Klein-Gordon equation

$$(\Box + m^2)\,\Phi(x) = 0$$

For the C.S.C.O. we choose the linear momentum and the (not-independent) energy. Denoting the destruction operator for the particle of momentum $\underset{\sim}{k}$ and energy $k_0 = \sqrt{\underset{\sim}{k}^2 + m^2}$ by a_k, and the creation operator for the corresponding antiparticle by $b_k{}^*$, the field operator is given by

$$\Phi(x) = \frac{1}{\sqrt{2(2\pi)^3}} \int \frac{d^3k}{k_0} \left(a_k e^{-ikx} + b_k{}^* e^{\,ikx}\right)$$

An explicit representation for C is

$$C = \exp\left[\frac{\pi i}{2}\sum_{k}(a_k{}^* - \bar{\eta}_c\, b_k{}^*)(a_k - \eta_c b_k)\right]$$

and for the total energy-momentum operator, obtained for instance from the Lagrangian for the Klein-Gordon equation above, we have

$$P_\mu = \int \frac{d^3k}{k_0}\; k_\mu(a_k{}^*a_k + b_k{}^*b_k)$$

It is now possible by direct calculation to establish whether P_μ (or any other observable) commutes or anticommutes with C. In this way we can derive for all the free physical fields which have been considered applicable to nature, the results stated earlier in this article concerning preservation and reversal of signs of the fundamental quantum numbers.

It is possible in a similar way to examine the validity of invariance under C-conjugation of the *interactions* between fields. For instance, the electromagnetic interaction between the electron-field current j_μ and the photon-field potential A_μ is $j_\mu A_\mu$. The two results found for the separate fields by the methods described in the foregoing.

$$Cj_\mu C^{-1} = -j_\mu \qquad CA_\mu C^{-1} = -A_\mu$$

then guarantee that

$$Cj_\mu A_\mu C^{-1} = j_\mu A_\mu$$

Similarly, C-invariance holds for the accepted forms of strong interactions.

C-invariance *does not hold* for the *V-A* (polar vector minus axial vector),four-fermion type of weak interaction occurring, e.g., in β-radioactivity. As we have seen, however, for quite general interactions with *proper orthochronous* spacetime symmetry, provided they are *local*, there is automatically invariance under the combined operation $C\mathcal{P}T \equiv \Theta$ ($C\mathcal{P}T$ theorem). "Proper orthochronous" spacetime symmetry of the interactions means that they are invariant under rotations, translations in space and time, and shifts to uniformly moving frames: "locality," in practice, means that the interactions consist of a linear combination of products of the fields and finite-order derivatives of the fields. Equality of mass and lifetime, antiequality of charge and magnetic moment, and (with certain restrictions) conjugacy of decay schemes for a particle and its antiparticle all follow from $C\mathcal{P}T$ invariance alone. And this rests only on proper spacetime symmetry, general principles of quantum theory, and the locality requirement (or, in the S-matrix rendition, the requirements of connectedness and analyticity).

ARCHITECTURAL ACOUSTICS

Although the practice of architectural acoustics involves a wide variety of special problems and techniques, the basic reasons for acoustical design are simply:

(a) to provide a satisfactory acoustical environment, not too noisy and often not too quiet, for people at work and relaxation;

(b) to provide good hearing conditions for speech; and

(c) to provide a pleasant acoustical environment for listening to music.

Designing for Satisfactory Acoustical Environment Each acoustical situation must be treated as a system comprised of three parts; source, transmission path, and listener. When the properties of the source are known, the transmission path can be modified to attenuate the sound to suit the listener's needs.

Sources. Noise sources are specified in terms of the total acoustical power radiated in each of a number (generally between 8 and 25) of contiguous frequency bands.[1,2] A standard set of ten bands is listed in Table 1.

Because of the wide range of sound powers encountered in practice, it is customary to express them in a logarithmic form. Thus we speak of the strength of a sound source in terms of *sound power level*, W, in decibels, defined by item 1 in Table 2.

TABLE 1. STANDARD OCTAVE FREQUENCY BANDS

Lower and Upper Frequency Limits of Each Band (Hz)	Geometric Mean Frequency of Each Band (Hz)
22.1- 44.2	31.5
44.2- 88.5	63
88.5- 177	125
177 - 354	250
354 - 707	500
707 - 1,414	1,000
1,414 - 2,828	2,000
2,828 - 5,655	4,000
5,655 -11,310	8,000
11,310 -22,620	16,000

We note that sound power W is expressed in watts.

A listener does not experience the total sound power from a source, since it radiates in all directions, but rather the proportion that arrives at his ear. Thus we speak of *sound intensity*, I, as the sound power passing through a small area at the point of observation. The units are watts per square centimeter or per square meter. *Sound intensity level*, L_I, in decibels, is defined by item 2 in Table 2.

Until recently there has been no commercially available instrument for measuring sound intensity, so it has usually been determined indirectly from the mean-square sound pressure, p^2, i.e., the time average of the square of the instantaneous sound pressure in the acoustic wave. This quantity can be determined readily with a pressure microphone. The relation is given by:

$$I = p^2/\rho c \text{ watts/m}^2 \tag{1}$$

where, ρ is the density of air (or other gas) in kilograms per cubic meter and c is the speed of sound in air in meters per second. *Sound pressure level*, L_p, in decibels, is defined by item 3 in Table 2.

Instruments and techniques for the measurement of sound pressure levels are widely available.[2] Typical measured values of sound power levels for many sources are given in references 1 to 3.

Paths. Sound may travel from a source to a receiver by many paths, some in the air (outdoors or in a room), some through walls, and some along solid structures. In the latter two cases, the sound is radiated into the air from the vibrations of the surfaces.

Outdoors, the relation between the sound pressure level measured at distance r from a source and the sound power level of the source is given by,

$$L_{p\theta} \doteq L_w + DI_\theta - 20 \log_{10} r - 11 \text{ dB} \tag{2}$$

where it is assumed that the source is near a hard-ground plane at a distance r in meters from the receiver (also near the plane) and that the source produces different sound intensities in different directions, θ, as described by a *directivity index*, DI_θ (see reference 2). If the source radiates sound equally in all directions, then $DI = 0$. In practice, sources generally have directivity indexes in the range of 0 to 12 dB in the direction of maximum radiation. At large distances, r, there will be losses in the air itself at frequencies above 1500 Hz. Also, wind, temperature gradients, and air turbulence may reduce or augment the value of $L_{p\theta}$ determined from Eq. (2).

TABLE 2

Decibel Scale	Abbreviation	Reference Quantity	Definition
Sound power level	L_W	$W_{\text{ref}} = 10^{-12}$ watt	$10 \log_{10} \frac{W}{W_{\text{ref}}}$ dB
Sound intensity level	L_I	$I_{\text{ref}} = 10^{-12}$ watt/m^2 $= 10^{-16}$ watt/cm^2	$10 \log_{10} \frac{I}{I_{\text{ref}}}$ dB
Sound pressure level	L_p	$p_{\text{ref}} = 20$ micropascal $= 0.0002$ microbar	$10 \log_{10} \frac{p^2}{p^2{}_{\text{ref}}}$ $= 20 \log_{10} \frac{p}{p_{\text{ref}}}$ dB

In a room, the sound pressure level produced by a nondirective source is given by,

$$L_p \doteq L_W + 10 \log_{10} \left(\frac{1}{4\pi r^2} + \frac{4}{R}\right) \text{dB} \quad (3)$$

where r is the distance between the receiver and the microphone and R is the *room constant* in square meters. $R = S\bar{\alpha}$, where S is the total area of all wall, ceiling and floor surfaces in square meters and $\bar{\alpha}$ is the average absorption coefficient for the whole room (see Reference 2). Typical values of R are found in Fig. 1.

In practical cases, we are often interested in the sound pressure level produced in a room separated by a partition (wall) from a room in which the source is located. We assign a *transmission loss*, *TL*, in decibels to the intervening wall. Curves of transmission loss versus frequency for several different building structures are given in Fig. 2 and reference 4. The equation relating

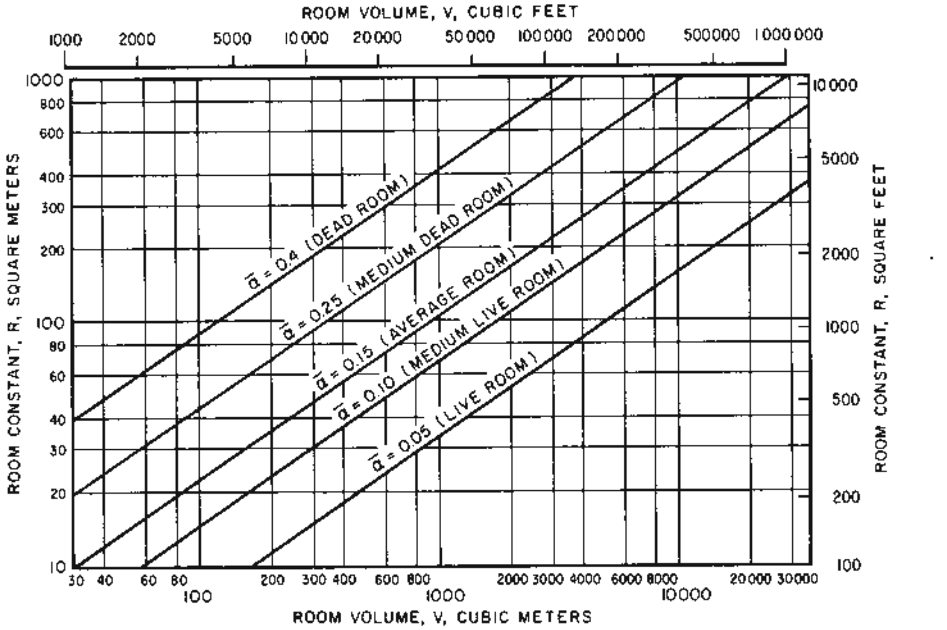

FIG. 1. Approximate value of room constant R for five categories of rooms ranging from "live" to "dead." Metric units referenced at bottom and left, English units top and right. The Greek letter $\bar{\alpha}$ indicates the percentage of the energy that is removed from a sound wave when it reflects from an "average" surface of the room. It is called the average sound absorption coefficient.

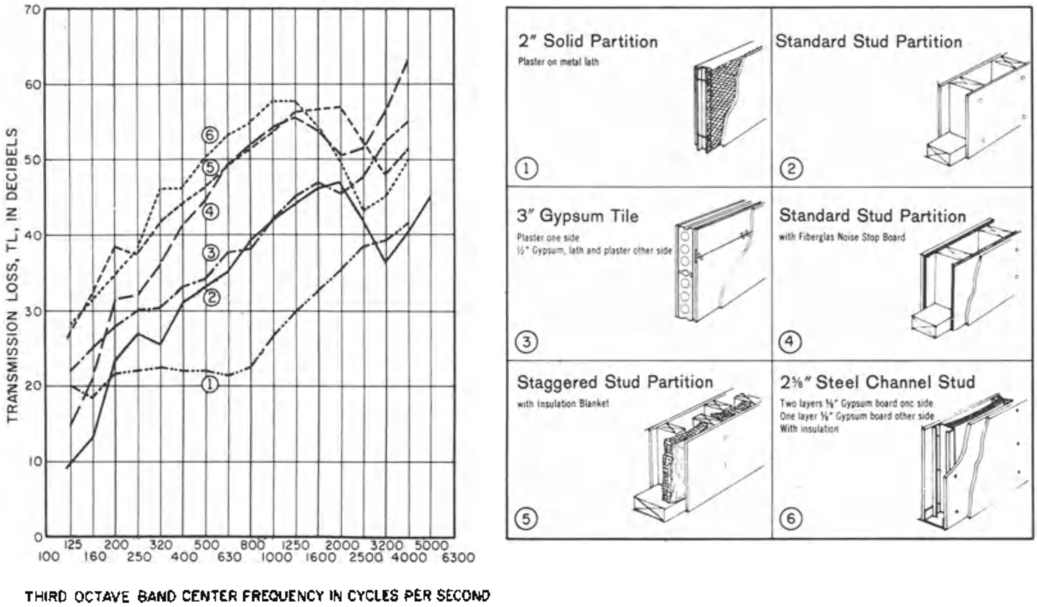

FIG. 2. Transmission loss, TL, of six typical building structures.

L_P to the L_W of the source* is,

$$L_{p_2} = L_{W_1} - TL + 10 \log_{10}\left(\frac{S_W}{R_1}\right) + 10 \log_{10}\left(\frac{1}{S_W} + \frac{4}{R_2}\right) \text{dB} \qquad (4)$$

where L_{p_2} is the sound pressure level in the second room produced by a source in the first room; TL is the transmission loss of the common wall; S_W is the area of the wall in square meters, and R_1 and R_2 are the room constants for the first and second rooms respectively, in square meters. It is assumed that the sound pressure level is measured near the common wall; in the center of the room it may be 3 to 5 dB lower.

Technique. It is apparent from Eq. (4) that the techniques for noise reduction indoors are threefold. First, make every effort to reduce the sound power radiated by the source, i.e., use quiet ventilating fans, quiet typewriters, quiet factory machinery, and so forth. Enclose noisy machinery in separate rooms or in enclosures. Mount vibrating machinery on resilient pads or springs. Second, provide walls with suitably high transmission losses between rooms. For example, between adjoining apartments, walls 4 to 6 of Fig. 2 are usually satisfactory, while walls 1 to 3 are not. On the other hand, walls 2 and 3 would be satisfactory between rooms of the same apartment, while wall 1 would not. Finally, increase the room constants by adding sound-absorbing materials to either or both rooms, e.g., carpets and draperies, or acoustical materials on ceiling or walls or both. The sound-absorbing efficiencies of various materials are given in references 2, 3, and 5.

It is of great importance to observe that when a wall is placed between two rooms or when an enclosure is built around a noisy machine, the structure must be hermetically sealed, or, if airflow is necessary, it must be conducted in and out of the enclosure through suitable silencers. A hole even as small in diameter as a pencil can render an otherwise satisfactory wall or enclosure acoustically inadequate.

In cases of very high noise levels where it is acoustically impractical to quiet or isolate the machine, then ear plugs, ear cushions, or both, must be worn by personnel exposed to the noise.

Criteria for Design. Acceptable noise levels in rooms of various types in each of eight octave frequency bands are shown by Fig. 3 and Table 3.

Auditoriums for Speech Three goals must be met in the design of auditoriums for speech. First, the ambient noise levels must be sufficiently low (see Table 3). Second, speech must be loud enough in all parts of the room so that faint syllables can be heard in the presence of normal audience noise. This second goal is achieved in small auditoriums (under about 500 seats) by proper shaping of the front part of the hall so that the speaker's voice is directed uniformly to all parts of the hall. In large halls (over 500 seats), electronic amplification of

*When the only sound path between the two rooms is through the common wall.

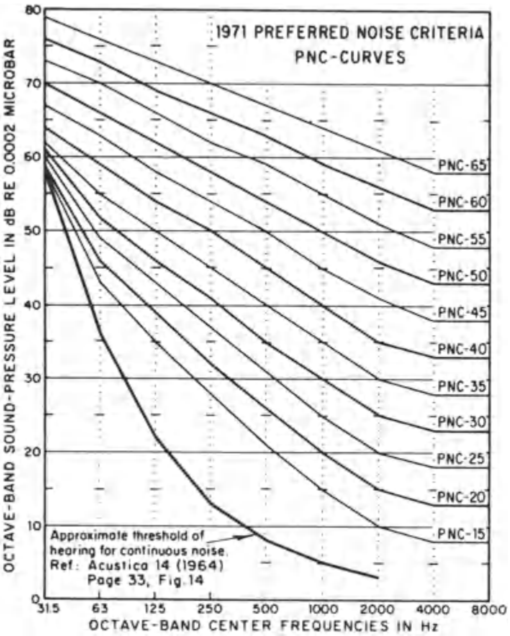

FIG. 3. Preferred Noise Criteria (PNC) curves for various types of building spaces given in Table 3. Measurements are made with an octave band filter and the readings in each band should not exceed that shown on the appropriate PNC curve.

speech is usually necessary. Third, the reverberation in the auditorium should be sufficiently low that speech is distinct. In auditoriums where there is no sound system, this requirement means that either the ceiling should have an average height of less than 30 ft above the main floor, assuming that the seats are upholstered and that there are no large floor areas without seats. If the ceiling height is over 30 ft, sound-absorbing materials will have to be added to the walls, and perhaps to the rear ceiling to control the reverberation. A satisfactory shape of a 500-seat auditorium for unamplified speech is shown in Fig. 4.

Auditoriums for Music There appears to be no single, ideal architectural solution for the acoustical design of a hall for music. Successful acoustics have been achieved with rectangular, fan or wedge, horseshoe, and even asymmetrical, plans. But though this is true, the many attributes of musical-architectural acoustics are so closely interrelated that if a hall is to be successful, the architect must solve all requirements simultaneously.

The music of each era of the past was composed for a different acoustical environment. Music of the Baroque period (Bach and earlier), except for organ music, was composed for small halls with relatively short reverberation times. (That is to say, a loud sound should take about 1.5 seconds to die down to inaudibility after its source is cut off abruptly. This quantity, *called mid-frequency reverberation time*, is measured with full audience present at 500 to 1000 Hz and averaged.) Music of the Classical period (early Beethoven, Mozart and Haydn) was composed for larger halls with medium reverberation times (about 1.8 sec). On the other hand, music of the Romantic period (after 1850), was in general, composed for fairly large halls with long reverberation times (about 2.0 sec). Today, halls must not only accomodate a musical repertoire extending over centuries, but often they must seat so large an audience that they become an entirely new type of space in which to perform music.

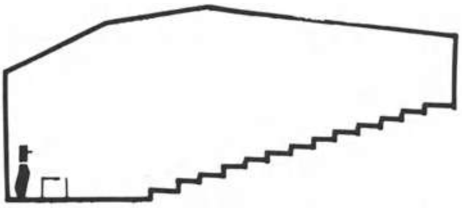

FIG. 4. Satisfactory ceiling shape for a speech auditorium with less than 500 seats.

In the development of the design of a hall, the acoustics dictate the cubic volume and strongly influence the orientation of every sound-reflecting surface, the interior materials, and even the seating.

Concert hall and opera house design is complex,[6,7] but some guiding principles stand out. The seating capacity should be low, below 2200 if possible. The ceiling should have an average height of 45 ft, if there are no balconies, or 55 ft with balconies, measured above the floor beneath the main floor seats. The hall should be narrow, or other means such as suspended panels should be provided for producing early sound reflections at listener's positions. Finishes for the interior should primarily be plaster on lath. Not

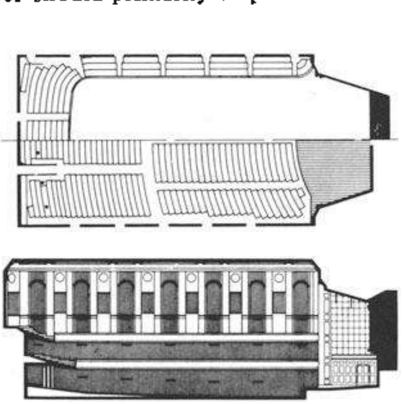

FIG. 5. Drawings of Symphony Hall, Boston, Mass.

TABLE 3 RECOMMENDED CATEGORY CLASSIFICATION AND SUGGESTED NOISE CRITERIA RANGE FOR STEADY BACKGROUND NOISE AS HEARD IN VARIOUS INDOOR FUNCTIONAL ACTIVITY AREAS.

Type of Space (and acoustical requirements)	PNC Curve*	Approximate L_A, dBA
Concert halls, opera houses, and recital halls (for listening to faint musical sounds)	10 to 20	21 to 30
Broadcast and recording studios (distant microphone pickup used)	10 to 20	21 to 30
Large auditoriums, large drama theaters, and churches (for excellent listening conditions)	Not to exceed 20	Not to exceed 30
Broadcast, television, and recording studios (close microphone pickup only)	Not to exceed 25	Not to exceed 34
Small auditoriums, small theaters, small churches, music rehearsal rooms, large meeting and conference rooms (for good listening), or executive offices and conference rooms for 50 people (no amplification)	Not to exceed 35	Not to exceed 42
Bedrooms, sleeping quarters, hospitals, residences, apartments, hotels, motels, etc. (for sleeping, resting, relaxing)	25 to 40	34 to 47
Private or semiprivate offices, small conference rooms, classrooms, libraries, etc. (for good listening conditions)	30 to 40	38 to 47
Living rooms and similar spaces in dwellings (for conversing or listening to radio and TV)	30 to 40	38 to 47
Large offices, reception areas, retail shops and stores, cafeterias, restaurants, etc. (for moderately good listening conditions)	35 to 45	42 to 52
Lobbies, laboratory work spaces, drafting and engineering rooms, general secretarial areas (for fair listening conditions)	40 to 50	47 to 56
Light maintenance shops, office and computer equipment rooms, kitchens, and laundries (for moderately fair listening conditions)	45 to 55	52 to 61
Shops, garages, power-plant control rooms, etc. (for just acceptable speech and telephone communication). Levels above PNC-60 are not recommended for any office or communication situation	50 to 60	56 to 66
For work spaces where speech or telephone communication is not required, but where there must be no risk of hearing damage	60 to 75	66 to 80

*See Reference 2 for other rating curves.

over 20 percent of them should be wood if the strength of the bass tone is to be preserved. Irregularities on all the surfaces should be provided to produce diffusion and blending of the sound. Above all, avoid echo, noise and tonal distortion. Finally, the orchestra enclosure should provide sectional balance in the orchestra and permit the musicians to hear each other.

Boston Symphony Hall, one of the world's best-liked concert halls, is rectangular, as shown in Fig. 5, and meets the general requirements listed above. Its mid-frequency reverberation time, with full audience, is 1.8 sec.

ASTROMETRY

Astrometry deals with the space-time behavior of celestial bodies and therefore belongs to the classical field of astronomical studies. It is often referred to as fundamental, positional or observational astronomy.

Early astrometric investigations were directed mainly toward establishing a suitable frame of reference for the determination of the complex motions of the planets, while the studies of the positions and motions of the individual stars as well as the various stellar systems gradually developed as improved precision of observations made it possible to discover and observe these motions.

The fundamental, and perhaps most difficult, problem of astrometry is the establishment of a reference system against which the motions of the celestial bodies can be measured.

The principal planes involved in the spherical coordinate systems usually used in astrometry are the equator, defined by the rotation of the earth on its axis, and the ecliptic, defined by the revolution of the earth around the sun. The positions of both these planes vary continuously in a most complicated manner due to gravitational forces and couples between earth and the moon, the sun, and the principal planets. Such motions of the reference planes are reflected in the positions of the stars referred to them.

The motions of these planes cannot be derived entirely from theory alone, but must be deduced from observed changes in the positions of the stars which, in turn, are also in motion. This complication has forced the construction of the astronomical coordinate system to proceed by a series of successive approximations which are still in progress. Initially, the sun, and planets were observed against the "fixed stars." From these observations came the first approximations of the motions of the solar system by the laws of dynamics and of the effect of the changing orientation of the earth's axis of rotation (precession) upon the positions of the stars. Successive repetitions of the observational process have gradually improved our knowledge of these and other motions affecting the fundamental planes of the coordinate system, each improvement resulting in an increase in our knowledge of the positions and motions of the stars.

Observational programs for the improvement of the celestial coordinate system are long and tedious and must be conducted with meticulous care. They make use of highly developed instruments and observing techniques which, in combination with adopted theories of the rotation of the earth and its motion around the sun, enable the positions of the equator and equinox to be derived anew and the positions of the stars to be related to them. Each such program is an independent effort to reconstruct the celestial coordinate system. Meridian circles have generally been used for this kind of work. The results of such programs are said to be fundamental and are usually published in the form of star catalogs.

From time to time, when sufficient fundamentally observed catalogues have accumulated, they are combined with similar earlier material to form a *Fundamental Star Catalog.* This catalog is usually regarded as the best representation that may be had of the celestial coordinate system at the time of its publication; the right ascensions and declinations of the stars in the catalog define the system for the equinox and epoch chosen for the catalog. The proper motions in combination with the adopted values of the constant of precession permit the system to be referred to equinoxes and equators at other epochs.

The latest and most precise of the fundamental catalogs is designated the *FK4* and was published by the Astronomischen Rechen-Instituts, Heidelberg, Germany in 1963. The catalog contains the positions (right ascension and declination) and the changes with time (precession and proper motion) of 1535 stars. These data were compiled from nearly 200 star catalogs containing observations over a span of 110 years. Its successor, the *FK5*, will appear in 1984, with data compiled from more than 250 catalogs of approximately 3 million observations. Two other fundamental catalogs that have been extensively used are the *GC, Albany General Catalogue of 33342 Stars* and the *N30, Catalog of 5268 Stars.*

The coordinate system provided by the positions and motions of the stars in a fundamental catalog serves as a reference system for the measurement of other star positions and proper motions which must be carried out for a variety of problems originating in the study of stellar motions, in geodesy, in the determination of time, in space research and others.

With the exception of the *GC*, which contains all the stars brighter than the 7th magnitude, fundamental catalogs do not contain a complete list of all stars down to a certain magnitude as, for example, the survey catalogs do. The prototype of the survey catalogs for star positions is the *Bonner Durchmusterung* which contains the positions of 320000 stars to a limiting magnitude of 9.5 and north of declination -2°. Although the observations for the catalog were made in the middle of the past century, the catalog and the charts made from it have been an extremely useful tool for astronomers for identification of star fields. The survey was later extended to the south celestial pole by the Bonn, Cape and Cordoba Observatories.

Positions of the fainter stars on a fundamental system are obtained by a close coordination between visual and photographic programs. The positions of a selected number of moderately bright stars (7th to 9th magnitude) are related to the fundamental system by meridian circle observations. These stars are then used as a position reference for the photographic observations of the fainter stars, thus tying them to tne fundamental system.

An example of this procedure is the large astrometric project initiated toward the end of the nineteenth century and carried out by international cooperation.

The fundamental system adopted for this undertaking was embodied in the *FC* (*Fundamental-Catalog für die Zonen-Beobachtungen am Nördlichen Himmel*) developed by Auwers. The visual program, designated the *AGK* (*Astronomische Gesellschaft Katalog*), was carried out through the collaboration of 12 northern hemisphere observatories and resulted in the determination of the positions with respect to the *FC* of 144128 stars to the limiting magnitude of 9 and north of -2° declination. The extension of the visual work into the southern skies was gradually carried out by other observatories. The adjunct photographic program known as the *Carte du Ciel* or the *Astrographic Catalogue* called for observations down to approximately the 11th magnitude covering the entire sky by 2° X 2° fields. Originating in 1887, the program was completed by 1970 and involved the participation of 18 different observatories. The positions in the catalogs are given in the form of rectangular coordinates as measured on the plates, but by means of auxiliary tables, these coordinates can be translated into right ascension and declination. Each field was photographed a second time with a longer exposure with a limiting magnitude of 14 to be used for the purpose of star charts.

Several other catalogs of photographically derived positions have been published. Among the catalogs of this nature may be mentioned the *AGK2* (*Zweiter Katalog der Astronomischen Gesellschaft*) and the Yale and Cape photographic catalogs.

The *AGK2* was related to the fundamental system represented by the *FK3* (*Dritter Fundamentalkatalog des Berliner Astronomischen Jahrbuchs*) through the use of simultaneous visual observations of about 13000 moderately bright stars in making the plate reductions. The *AGK2* plates were taken at the Bonn and Bergedorf Observatories and covered the sky in 5° X 5° overlapping fields from -2° to the north pole. The resulting catalog contains the positions of over 180000 stars for the mean epoch of 1930. Between 1956 and 1959 a second photographic series of observations of these stars was carried out at the Bergedorf Observatory. The measured positions on the plates were reduced to the system of the *FK4* by use of the positions of some 21000 reference stars observed simultaneously through an international cooperative program involving 12 meridian circles in the northern hemisphere. A comparison of the plate results at the two epochs gives rather accurate proper motions with respect to the fundamental system for the entire 180000 stars. The majority of these stars are brighter than the 9th magnitude. A good many, however, are as faint as the 11.5 photographic magnitude. The catalog is named the *AGK3*. Except for gaps between +85° to +60°, +50° to +30°, and -50° to -60°, the Yale Zone Catalog covers the sky from +90° to -90° declinations, while the Cape catalogs provide a complete coverage from -30° declination to the south pole. Both series of catalogs were taken by zones of declination by use of wide-angle cameras (from 5° X 5° to 10° X 14°) and were reduced to a fundamental system (not always the same one) by use of contemporary meridian circle observations. The mean epochs of the positions in these catalogs range from the early 1930's to the late 1940's. The stars in these catalogs are similar in magnitude range to those in the *AGK2* and *AGK3*. A catalog especially prepared for geodesy and other computer oriented research based on accurate satellite orbits is the Smithsonian Astrophysical Observatory Catalog (SAO). It is derived from selected visual and photographic catalogs, contains positions and proper motions of 259,000 stars, and covers the entire sky in zones of 10-degrees-wide declinations. It has been published in book form and as a set of star charts, but like the other catalogs previously mentioned, it is also available in machine readable form from the Centre de Données Stellaires at the Observatoire de Strasbourg, and from NASA-Greenbelt, Maryland. A program of observing 20000 stars in the Southern Hemisphere with meridian circles is now nearing completion. Known as the *SRS* (*Southern Reference Star*) *Program*, it has been carried out through international cooperation with northern observatories (U. S. Naval Observatory, Pulkovo Observatory, and Hamburg-Bergedorf) participating with stations in Argentina, Chile, and Australia, respectively. The positions and proper motions of these stars in the fundamental system are intended for use in obtaining new positions and proper motions of some 200000 stars in the Southern Hemisphere observed photographically.

An important source for obtaining proper motions of the fainter stars is a combination of early photographic plates with recent ones taken with the same telescope. The proper motions derived in this way are relative proper motions and require further reductions for transformation into absolute proper motions in a fundamental system. This procedure has been followed in several extensive programs aimed at solving such problems as determining the solar motion, and deriving secular parallaxes and galactic rotation.

Proper motions for tens of thousands of stars have been obtained by this method while radial velocities for a lesser number of stars have been determined from the spectroscopic application of the Doppler principle. Besides the proper motion and radial velocity, the distance of a star is needed to determine its motion in space. For stars beyond 100 parsecs from the solar system it becomes increasingly difficult to obtain all three factors involved, and often knowledge of stellar motion is either based on proper motions or radial velocities alone. However, by various statistical devices substantial information about stellar motions has been obtained.

On the basis of these studies, the sun's velocity has been determined to be about 20 km/sec towards a point in space not far from Vega, although the amount and direction of the motion varies depending upon the chosen group of stars.

As a result of the sun's motion through space, the stars show a parallactic or secular shift which can be used to determine their distances. Because of the individual motions of the stars, this method is applicable only to groups of stars with the assumption that their individual motions are random. By means of the secular parallax method, general ideas of the distances of stars up to 1000 parsecs have been obtained.

From statistical studies of proper motions and radial velocities, it was found in 1927 that the stars in our galaxy are moving in orbits not greatly inclined to the galactic equator. The observations are consistent with the assumption that the principal force governing the motions is gravitational with the center of mass near the galactic center. The period of rotation at the sun's distance from the center is 2×10^8 years.

There are, at the present time, two programs in progress which will attempt to establish absolute stellar proper motions using the distant galaxies as a reference frame, the assumption being made that those objects do not show any systematic rotation with respect to the local inertial frame of rest.

A large number of proper motion studies of galactic clusters has been carried out in order to establish membership of the individual stars in the field. Because of the high internal precision required for this work, these studies have been confined primarily to long-focus telescopes, with plates taken over time intervals of 50 or more years.

Several surveys of the sky for stars with high proper motion, largely with the aim of finding absolutely faint stars, have been carried out over the past several decades. Two such surveys are one with the 48-inch Schmidt telescope at Mt. Palomar and the other with the 13-inch telescope at Lowell Observatory. They cover 80 percent of the sky to a limiting magnitude of 21 and 17 respectfully. In surveys of this magnitude, it is essential that telescopes of not too large focal length be used to limit the number of plates needed to cover the sky and that the "moving" stars be found by rapid scanning of the plates. These surveys have drastically increased the known number of white-dwarf, sub-dwarf, and faint red-dwarf stars, which, at the present time attract much interest among astronomers.

An important area within astrometry is the determination of the distances of individual stars. Because of the extremely small quantities to be measured, the ultimate in precision is required. The geometric method of measuring distances is based upon the surveyor's principle: the object is observed from both ends of a base line. In determining the trigonometric parallax of a star, the semimajor axis of the earth's orbit is used as the base line. Reliable individual distances have been measured in this way for several thousands of stars within 30 parsecs of the solar system. The majority of the photographic plates in these determinations were obtained with long-focus refracting type telescopes, and the plates measured on manually operated measuring machines. The discovery of the large number of intrinsically faint stars in the solar neighborhood with apparent magnitudes beyond the practical limits of the refracting type telescope demanded the development of a reflecting-type telescope with greater light gathering power, and with a highly stable optical system. Such a telescope, named an astrometeric reflector, has been in operation since 1964. In combination with a high precision automatic measuring machine, parallaxes have been achieved with a precision of 2 milliarcseconds, thereby obtaining reliable distance determinations to 150 parsecs by this method. The importance of stellar distance determination is realized from the fact that the distance of a star must be known before its intrinsic luminosity and its rate of energy generation can be determined.

Studies of the stars in the solar neighborhood have revealed that the majority of them are components of double and multiple systems. Since the motions of the stars within a system are governed by their mutual gravitational attraction, it is possible to determine their masses by use of Kepler's third law (see KEPLER'S LAWS OF PLANETARY MOTION), whenever their orbital motions and the parallax of the system become known. This is the only direct way masses of the stars can be determined.

Routine observations of the motions in binary systems began about 150 years ago. Originally all observations were carried out visually. Although this method continues to be used for close pairs, it has been largely replaced by a more accurate photographic method for wider pairs.

Various searches for double stars have produced some 75000 visual binary systems, but for only a small fraction (approximately 100) of these systems are data available for determining the individual masses with an accuracy of 30 per cent or better. These masses range from about 0.08 solar mass for a star 3000 times less luminous than the sun to 6 times the sun's mass for a star 100 times more luminous than the sun. Larger masses, as high as 50 to 100 times the solar mass, are found among the very close binaries such as eclipsing and spectroscopic binaries. Although these objects cannot be resolved into individual components, their orbital motions can be determined from the periodic variation in light and radial velocity (observed Doppler shift).

Stellar masses smaller than the value of 0.08 quoted above have been discovered in recent years by intensive photographic studies of nearby single stars and components in double stars. These studies, representing the ultimate in accuracy in photographic astrometry, have revealed unseen companions of such small masses that, according to theoretical estimates, they are either stars so small that they will never burn nuclear fuel or planets of the size of Jupiter.

Aside from demands for such utilitarian purposes as navigation, geodesy and space research, astronomers themselves are making heavy demands for substantial gains in quality and quantity in astrometric observations, extended to fainter and fainter stars.

The discovery of the intrinsically faint stars in the solar neighborhood has demanded an extensive parallax program with an entirely new telescope of special design.

Positions and space velocities on a large scale of the individual stars and of stellar systems within our galaxy are essential to understand its dynamics and evolution as well as the physical properties and evolution of the individual stars which populate it.

To accomplish this, new instrumental and analytical techniques are currently being introduced which take advantage of the latest technological developments in automation.

Within recent years measurements with a precision of a few milliarcseconds have been achieved in astrometry in both the optical and radio spectrum by means of interferometry. In the optical spectrum, speckle interferometry of close binaries has achieved standard errors of 5 milliarcseconds in their relative positions, while long baseline optical interferometry of the order of 50 meters is capable of very high resolution of one milliarcsecond. Similar accuracies are expected in transcontinental radio interferometry. High precision optical and radio position measurements are currently being carried out of radio sources and their optical counterparts to improve the relationship between optical and radio reference frames, with the possibility of establishing an inertial reference frame from the measurements of the cosmological distant quasars.

Astrometry from space observations will be a reality within the next few years. Among these projects can be mentioned the astrometric satellite by the European Space Agency (ESA), named *Hipparcos*. With this satellite, in a geostationary orbit, it will be possible to observe some 10,000 stars during a 2-3 year mission. Positions, yearly proper motions, and parallaxes with an accuracy of two milliarcseconds are projected. Similar accuracies are expected in the astrometric programs planned with the *Space Telescope* of NASA, which is scheduled to be in orbit by 1986.

ASTRONAUTICS*

Future historians may record that the age of space flight marked a turning point in modern times. Its physical principles—the laws of motion of celestial bodies—marked the turning point of medieval times. From Copernicus to Kepler to Galileo to Newton, the Aristotelian myth of a man-oriented universe succumbed to the conception of a detached mechanically oriented universe, operating through laws which were a synthesis of the new knowledge gained in the formerly separate domains of terrestrial and celestial mechanics. Mankind never quite recovered from that detachment.

Weight and Weightlessness In Newtonian mechanics, weight is understood to mean the force that an object exerts upon its support. This would depend on two factors: the strength of gravity at the object's location (things weigh less on the moon) and, as Newton called it, the quantity of matter in a body (its "mass"). At any given location, where gravity is fixed, mass can be measured relative to a standard by noting the extension of a spring to which it and the standard are successively attached. Alternatively, the unknown and standard may be hung at opposite ends of a rod and the balance point noted. However, by an entirely separate experiment, mass can also be measured by noting the resistance of the object to a fixed force applied horizontally on a frictionless table. The measured acceleration provides the required basis of comparison with the standard. Needless to say, all objects measure identical accelerations when freely falling in the vertical force of gravity. This merely means that, unlike the arbitrary force we apply horizontally in the experiment above, gravity has the property of adjusting itself in just the right amount, raising or lowering its applied force, to maintain the acceleration constant.

It was well known that objects appear to increase or decrease their weight (alter the extension of the spring) if the reference frame in which the measurement takes place accelerates up or down. As gravity did not really change, however, most people were inclined to draw a distinction between *weight* defined as $m\mathbf{g}$, where m is the mass and $\mathbf{g}$ is the local gravity field, and the *appearance of weight*, the force of an object on its support as measured by the spring's extension. One way to avoid the difficulty has been to speak of an *effective* **g**, which takes into consideration the frame's acceleration. For example, at the equator of the earth, we measure, say by timing the oscillation of a pendulum, the effective **g**, some 0.34 per cent less than the **g** produced by the mass of earth beneath our feet. If the earth were rotating with a period of an hour and a half instead of 24 hours, our centripetal acceleration at the equator would cause the effective **g** to vanish completely, our scales would not register, objects would be unsupported, and for all practical purposes they and we would be weightless.

Formally, we could state that any accelerating frame produces a local gravitational field $\mathbf{g}_{acc}$ that is equal and opposite to the acceleration. Thus, a rotating frame generates a centrifugal $\mathbf{g}_{acc}$ opposing the centripetal acceleration. We have at any point

$$\mathbf{g}_{eff} = \mathbf{g} + \mathbf{g}_{acc} \tag{1}$$

where **g** is the field produced by matter alone (e.g., the earth). By identical reasoning, an object in orbit, whether falling freely in a curved or in a straight path, will carry a reference frame in which $\mathbf{g}_{eff}$ is zero, for its acceleration will always exactly equal the local **g** by the definition of the phrase, "freely falling."

This concept was placed on a firm footing by Einstein who maintained that Eq. (1) is reasonable not only in mechanics but in all areas of physics including electromagnetic phenomena. We arrive at the inevitable conclusion that we cannot distinguish by any physical experiment between an apparent **g** accountable to an accelerating frame and a "real" **g** derived from a local accumulation of mass. This central postulate of the General Theory of Relativity also unified the two separate conceptions of mass. An object resting on a platform that is accelerating toward it will resist the acceleration in an amount depending on its inertia. It presses against the platform with a force equal to that it would have if placed at rest on the surface of a planet with local field equal and opposite to the acceleration of the frame.

General Principles of Central Force Motion The gravitational force between point masses is inverse square, written

$$m\mathbf{g} = -\frac{\gamma m' m}{r^2}\,\hat{\mathbf{r}} \tag{2}$$

where the center of coordinates from which the unit vector $\hat{\mathbf{r}}$ is described lies in m', one of the masses. Thus, the force on m is directed $-\hat{\mathbf{r}}$, toward m' and is proportional to $1/r^2$ with γ the constant of proportionality. The quantity **g** is the force on *m divided by m* (or normalized force) for which the name "gravitational field of m'" is reserved. Of course, if m were in the field of a collection of mass points, or even in a continuous distribution of mass, the summated or integrated **g** at the location of m would no longer be an inverse square function with respect to any coordinate center. However, in one special case, the inverse square functional form would be preserved: if the source mass were symmetrically distributed about the coordinate center. This would be the case if the source

*John Wiley & Sons, Publishers, has kindly permitted extensive use of copyright material from "Physical Principles of Astronautics" by Arthur I. Berman, who is also the author of this article.

were a spherical shell or solid sphere, of density constant or a function only of r. The sun and earth can be regarded, at least to a first approximation, as sources of inverse square gravitational fields.

There are some important general statements we can make about the motion of an object placed with arbitrary position and velocity in a centrally directed force field, i.e., a field such as the one described, which depends only on distance from a central point (regardless of whether or not the dependence is inverse square). As the force has only a radial and no angular components, it cannot exert a torque about an axis through the center. This means that the initial angular momentum is conserved. Now angular momentum is a vector quantity and therefore is conserved both in direction and magnitude. It is defined by $\mathbf{r} \times \mathbf{p}$, where $\mathbf{r}$ is the position vector to the mass of momentum $\mathbf{p}$. The direction of the angular momentum vector is thus perpendicular to the plane containing $\mathbf{r}$ and $\mathbf{p}$. As this direction is permanent, so also must be the plane. The planar motion of the object can be expressed in polar coordinates, so that by writing $\mathbf{r} = r\hat{\mathbf{r}}$ and $\mathbf{p} = m(r\hat{\mathbf{r}} + r\dot{\phi}\hat{\phi})$, we find the specific angular momentum (angular momentum per unit mass) called h, to be

$$h = r^2\dot{\phi} \tag{3}$$

This too then must be a constant of the motion.

Consider now the rate at which area is swept out by the radius vector, dS/dt. We recall from analytic geometry that $dS = \frac{1}{2}r^2\phi$. Thus

$$\frac{dS}{dt} = \frac{h}{2} \tag{4}$$

so that this is a constant of the motion as well. On integration, we conclude that the size of a sector that is swept out is proportional to the time required to sweep it out. In the case of a closed orbit, the total area S would then be related to the specific angular momentum as

$$S = \frac{hT}{2} \tag{5}$$

This sector area-time relationship is Kepler's second law of planetary motion which was induced from Tycho Brahe's observation of Mars without prior knowledge of gravity and its central character.

The Laws of Kepler Kepler stated two other laws of planetary motion: The orbits of all the planets about the sun are ellipses (a radical departure from the circles of Copernicus), and the squares of their periods are proportional to the cubes of their mean distance from the sun, this mean being the semimajor axis of their ellipses. The third law pertained to the one characteristic common to all the planets: the sun. Taken together, the three laws led Newton to the concept of gravitational force and its inverse-square form.

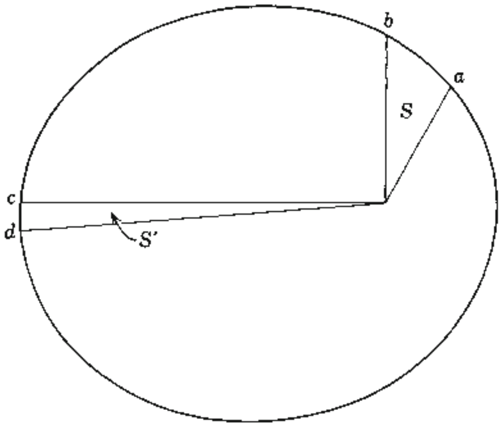

FIG. 1. Kepler's second law. The sector area S swept out is proportional to the time required for the planet to move from a to b. Thus, if $t_{\text{cd}} = t_{\text{ab}}$, then $S' = S$.

By applying Newton's law of motion $\mathbf{F} = m\mathbf{a}$, a relationship between $\mathbf{a}$, the second derivative of the position vector, expressed in polar form, and $\mathbf{F}/m$ or $\mathbf{g}$, as given by Eq. (2), leads to the familiar conic solution for the trajectory of an object in an inverse square field.

$$\frac{1}{r} = \frac{\gamma m'}{h^2} + A\cos(\phi - \phi_0) \tag{6}$$

where A and ϕ_0 are constants. A rotation of axis will eliminate ϕ_0, thereby aligning the coordinate axis with the conic's major axis. Also, by expressing the general conic, an ellipse or hyperbola, in terms of the usual parameters of semimajor axis a and eccentricity ϵ, we can relate the geometric parameters to the gravitational-dynamical constants, viz:

$$h = [\gamma m' a(1 - \epsilon^2)^{1/2} \tag{7}$$

and

$$\frac{1}{r} = \frac{\gamma m'}{h^2}(1 + \epsilon\cos\phi) \tag{8}$$

Note that by substituting Eq. (7) into Eq. (5) and expressing the area of an ellipse as $S = \pi a^2(1 - \epsilon^2)^{1/2}$ we arrive at Kepler's third law,

$$T = \frac{2\pi}{(\gamma m')^{1/2}} a^{3/2} \tag{9}$$

The *energy* of the orbiting object can be calculated with ease by evaluating it at an extremal point, say the nearest point to the gravitational source, called pericenter or perifocus. As the energy is constant, it is immaterial where the calculation is made. Here the velocity has only an angular component so that the kinetic energy for a unit orbiting mass is $\frac{1}{2}v^2 = \frac{1}{2}r^2\phi^2$. The potential energy at pericenter is $-(\gamma m'/r_{\text{pe}})$ where

r_{pe} is the distance of the unit mass from m', the focal point. Here $\phi = 0$ so that by Eq. (8),

$$\frac{1}{r_{pe}} = \frac{\gamma m'}{h^2}(1 + \epsilon) \qquad (10)$$

On substituting Eq. (7), we find the total kinetic and potential energy to be

$$E = -\frac{\gamma m'}{2a} \qquad (11)$$

Our conclusion: All objects in orbit with the same major axes have identical periods and identical energies per unit mass. Knowledge of E is invaluable in determining an object's speed when its distance from the source is known, and vice versa.

In the event that the orbiting object's mass is not negligibly small compared with that of the gravitational source, one must take note that the combined center of mass, from which the acceleration is described, no longer may be assumed to lie in the center of the gravitational source. This complicates our equations somewhat, for the accelerating force still is expressed relative to the center of the source (if spherical). The adjustment that results, when center of mass coordinates are transformed to relative coordinates in the expression for acceleration, requires our equations to take the form $\gamma(m' + m)$ wherever formerly $\gamma m'$ appeared.

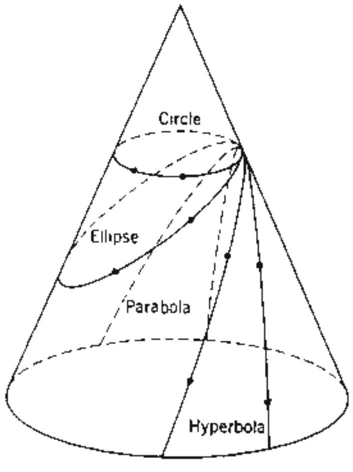

FIG. 2. Conics formed by the intersection of planes inclined at various angles with the axis and sides of a cone. Ellipses and hyperbolas are general curves in astronautics, i.e., general solutions of the two-body problem, while the circle and parabola are special cases. An object in circular orbit is at constant distance from the gravitational source and therefore has constant potential energy; it moves at constant speed and therefore has constant kinetic energy. An object in a parabola is in a transition curve between an ellipse and hyperbola; its major axis, therefore, is infinite and its total energy zero.

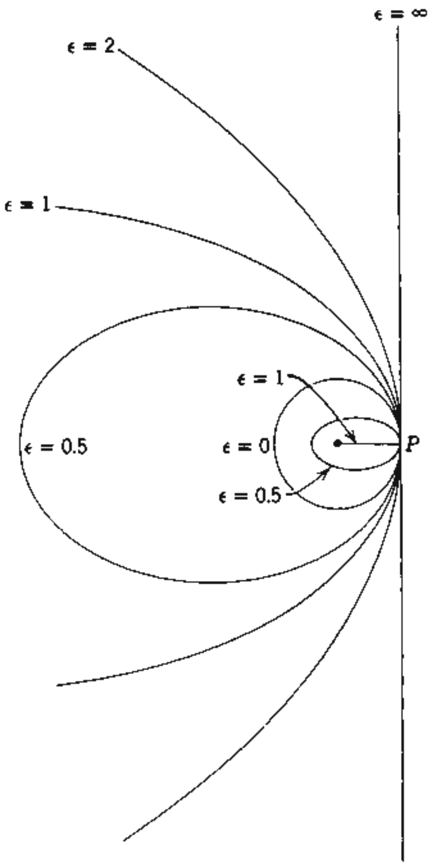

FIG. 3. Orbits of differing eccentricities and major axes which pass through a common point. Higher speeds correspond to higher energies and longer major axes. For an ellipse the eccentricity ε is the ratio of the distance to the focus (gravitational center) from the point of symmetry of the curve to the semimajor axis of the ellipse. For a hyperbola it is the ratio of the distance to the focus from the point of symmetry of the hyperbolic pair to the semimajor axis.

Disturbances in the Central Field The earth, of course, is spherical to only a first approximation. More accurately, it is an ellipsoid of revolution about a minor axis—an oblate spheroid. Still more accurately, it appears to be slightly pear-shaped and, in addition, its figure is distorted by continuous local variations. The spheroidal figure, nevertheless, accounts for nearly all the anomalous effects on satellite orbits. For one thing, the gravitational force on the satellite is no longer centrally directed; the excessive mass in the equatorial plane produces a force on the satellite directed out of its orbital plane. The resultant torque causes the direction of the angular momentum vector to change; i.e., the plane containing the satellite's ellipse turns. The plane turns continuously about the polar axis maintaining its angle with the axis and with the

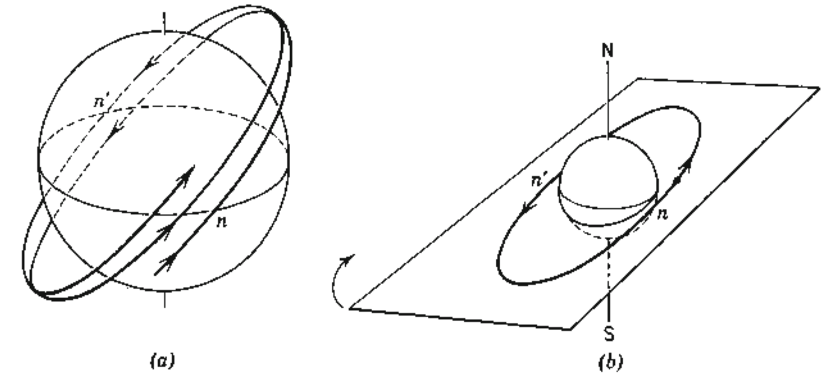

FIG. 4. The orbit of an earth satellite. The earth's equatorial bulge causes retrograde motion of the points of intersection n and n' of the orbit and equatorial plane. This can alternatively be interpreted as a retrograde motion, about the north-south axis, of the plane containing the closed orbit. The plane moves in the direction shown by the arrow in (b), maintaining a constant angle with the axis.

equatorial plane constant. The turning rate is greatest for low orbits and small angles of inclination with the equator. For polar satellites, the plane remains fixed. A separate effect of this equatorial bulge perturbative force is the slow turning of the ellipse's major axis *within* the orbital plane. This effect vanishes at an inclination of 63.4°; the major axis turns backward at inclinations above this angle and forward below.

Astronautical Examples From the preceding material some interesting problems in astronautics can be solved readily. Suppose (Fig. 5) an astronaut releases himself at a speed δv of 10 m/sec from a satellite in a small circular orbit about the earth. What would be his velocity and that of his satellite when at their maximum separation if his initial thrust is (a) the same as that of the satellite in its orbit, (b) toward the earth's center, and (c) normal to the orbital plane? Also, what would be the maximum separation between astronaut and satellite and where would it occur?

Writing E in terms of both the kinetic-potential energy sum at any point in orbit, and its constant value given by Eq. (11), we find that the speed at the astronaut's perigee in (a) can be written

$$v^2 = \frac{\gamma m'}{r_0}\left(2 - \frac{r_0}{a}\right) \qquad (12)$$

where r_0 is the satellite's orbital radius and a the astronaut's semimajor axis. If

$$v_c^2 = \frac{\gamma m'}{r_0} \qquad (13)$$

where v_c is the satellite's circular speed, found by letting $a = r_0$ in (12). We have all the information needed to find the distance of separation between ellipse and circle as

$$\begin{aligned} 2a - 2r_0 &\simeq \frac{4r_0\delta v}{v_c} \\ &= \frac{4(6.38)\,(10^3\text{ km})\,(10\text{ m/sec})}{7.9\,(10^3)\text{ m/sec}} \\ &= 32\text{ km}. \end{aligned} \qquad (14)$$

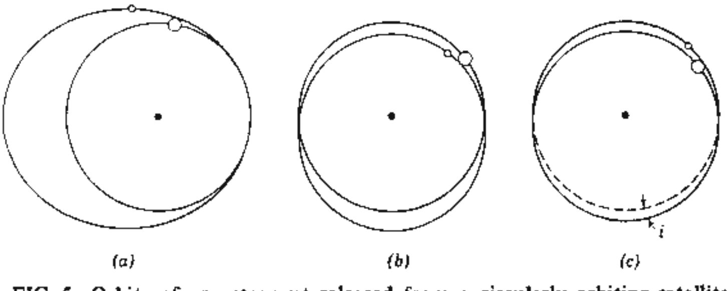

FIG. 5. Orbits of an astronaut released from a circularly orbiting satellite (*a*) in the direction of satellite motion, (*b*) toward the center of attraction, and (*c*) normal to the orbital plane. In the last case the astronaut moves in a new orbital plane inclined to that of the satellite by angle *i*.

By applying angular momentum conservation—that is, the apogee speed times the focal distance at apogee equals the perigee speed times the focal distance there (or simply Eq. (7))—we find that the astronaut will have a relative speed at apogee of 30 m/sec.

In (b), the astronaut will orbit in an ellipse in the plane of the satellite's circle that intersects the circle twice. As his injection velocity is radial, his specific angular momentum is that of the satellite. This, together with Eq. (12), where now v at launch is not the linear sum of δv and v_c but the square root of the sum of the squares of these terms, leads directly to the orbital parameters a and ϵ. We find the latter as $\delta v/v_c$ and the orbital separation at apogee as 8 km with the speed there relative to the satellite as 10 m/sec, the same as at launch.

The astronaut moves out of the satellite's orbital plane in (c) and into a new plane inclined at angle $i = \delta v/v_c$. The maximum separation between orbits now becomes $ir_0 = 8$ km. But the astronaut never departs more than 20 m from his initial distance from earth, so his speed is always close to that of the satellite.

Rocket Propulsion A rocket operates by the simple principle that if a small part of its total mass is ejected at high speed, the remaining mass will receive an impulse driving it in the opposite direction at a moderate speed. As δm_e, the propellant, leaves at speed v_e with respect to the rocket, the remaining rocket mass m receives a boost in speed δv such that

$$\delta m_e v_e = m\, \delta v \qquad (15)$$

If additional equal propellant mass is ejected at the same speed, the boost in rocket speed is slightly greater than before as the rocket mass has been slightly depleted by the prior ejection. Indeed, if the residual rocket mass eventually were minuscule, its boost in speed could reach an enormous value. The integrated effect of these nonlinear boosts is found as

$$v_t - v_0 = v_e \log_e \frac{m_0}{m_t} \qquad (16)$$

where v_0 and m_0 are the rocket speed and mass at some arbitrary initial time and v_t and m_t are the same quantities at some time t later.

From these simple considerations, it is apparent that the highest rocket velocities are attained if we could increase the propellant speed as well as the mass ratio m_0/m_t. The mass ratio can be maximized by obvious methods such as choosing a high-density propellant which cuts the tankage requirement or avoiding unnecessarily complicated apparatus for ejecting propellant at high speed. A nuclear rocket, for example, may perform well in its ability to eject propellant an order of magnitude higher in velocity than conventional chemical rockets; nevertheless, the penalty required in reactor weight and shielding severely limits its effectiveness.

Specific impulse is one performance characteristic which applies to the propellant's ability to be ejected at high speed regardless of the weight penalty required to do this. It is the impulse produced per mass of propellant ejected, or $m\delta v/\delta m_e$, or, by Eq. (15), simply v_e. In engineering usage, it is impulse per *weight* of propellant ejected, or v_e/g_e where g_e is the acceleration of gravity at the earth's surface. Its units are seconds, and it can be interpreted as the thrust produced by a rocket per weight of propellant ejected per second. By itself, thrust is of little importance unless it is sustained for a significant time by a large backup of propellant tankage. It is here that the mass-ratio term in Eq. (16) would play an important role in any evaluation of a rocket's true performance.

It is important to realize how sensitive is the energy imparted to a moving vehicle to a given boost in speed. If an object, say a rocket, moving at some speed v gets a boost in the same direction in an amount δv, then its increase in kinetic energy is $v\delta v + \frac{1}{2}(\delta v)^2$. Thus, if a rocket receives a small boost in speed, say from turning on its engine for a short time, the rocket can thereby receive a very *large increase* in kinetic energy provided it was already moving fast before getting the boost.

This principle is made use of in the firing of a multistage rocket. Suppose, for example, that we have a two-stage rocket of similar components: The "burnout" speed of each stage is the same, lifting each to the same apogee. We compare the effect of two firing programs: In the first case, firing of the upper stage is delayed until its apogee as booster payload is reached, but in the second case its firing takes place close to the ground immediately following booster burnout. Assuming that the force of gravity is constant at all heights, air drag is negligible, and the burnout time is small compared with the flight time, the apogee of the payload of the second case will be twice as high as in the first.

Transfer Orbits If one wishes to leave one orbit and enter another by rocket, an optimum path is generally chosen to minimize the total propellant required. Nevertheless, this should not be done at the expense of unduly long flight times, complicated guidance equipment, or high acceleration stresses. These would require unprofitable weight expenditures which would offset the frugality in propellant tankage.

Let us examine a simple but recurring example of a transfer problem, that of leaving a reference frame or space platform in one circular orbit and entering another larger one concentric with the first. If the transfer path were radial or near radial (a so-called ballistic orbit) then one would have to launch at a large angle to the direction of motion of the frame, accomplished only by a velocity component opposed to the frame's motion. On reaching the outer platform, a soft landing can be made only by a substantial rocket velocity boost tangent to the orbit.

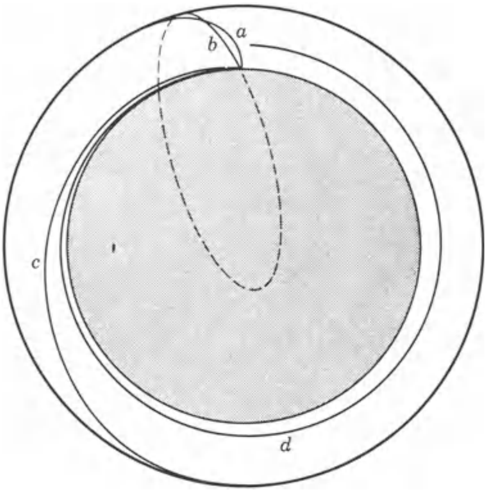

FIG. 6. Four launch trajectories into a satellite orbit about a planet. (a) If that planet has an atmosphere, the rocket may ascend in a "synergic" trajectory from the planetary surface to the final orbit, i.e., it cuts through the denser portions in an initially vertical path and gradually bends over into a horizontal path during burnout. (b) If there is no atmosphere it may ascend from the ground in a ballistic ellipse. This same ascent path may be chosen if the departure is from a parking orbit or "space platform" close to ground level. A far better choice would be (c) the Hohmann ellipse, with pericenter at the planet's surface and apocenter at the satellite orbit. Burnout time is assumed short in both this and the ballistic case. (d) A vehicle such as an ion rocket, which can sustain a microthrust for a very long time, cannot be launched from the ground but only from a parking orbit. It will spiral out to the desired altitude with few or many turns about the planet, depending on the magnitude of the thrust relative to that of the gravitational force.

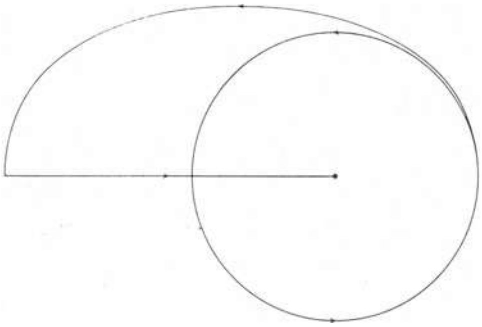

FIG. 7. Reaching the center of attraction from a circular orbit by a double-thrust maneuver. The rocket enters an eccentric ellipse by a forward thrust, and at apocenter reverses thrust to cancel the small orbital speed there, enabling it to fall radially into the source. By this maneuver radioactive waste could be brought to the sun at up to 40% saving in propellant.

Clearly, the total propellant expenditure would be far greater than one alternative of launching the rocket in the direction of motion of the first frame with just sufficient speed to reach the outer circle, timed so that the outer frame will meet the spacecraft. The transfer orbit will be an ellipse contangent with both circles. The outer frame will be moving much faster of course at the contact point as the major axis of its orbit is much greater [see Eq. (11)], but the difference in speed is not nearly as pronounced as for the ballistic transfer case. A differential speed increment at contact completes the maneuver.

The return trip, from an outer to inner circle, is made by following the second half of this cotangent ellipse, named the Hohmann transfer orbit after the German engineer who discovered its optimal property with regard to propellant expenditure. In the return case, the spacecraft is launched in opposition to the outer platform's motion. This removes kinetic energy and forces the spacecraft to fall in closer to the attractive center in order to make cotangent contact with the inner circle. The total propellant expenditure from the outer to the inner platform is the same as for the original journey.

An interesting question arises if one wishes to leave a frame for an outer orbit when it initially is in an elliptical orbit rather than a circle. Should we depart from apocenter where we are furthest from the gravitational source and closest to our destination? Or should we depart instead from some other point in the ellipse?

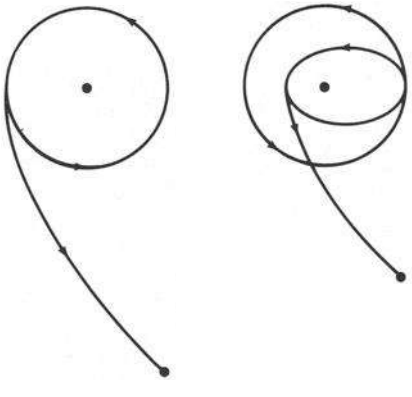

FIG. 8. Alternative ways to escape from a circular orbit to "infinity." *Left:* The rocket simply blasts off into a parabola or hyperbola. *Right:* The rocket *reverses thrust* to fall into a close-in ellipse and then at the *pericenter* or *near apsis* of the ellipse (perigee if orbiting about the earth) it blasts off into a parabola or hyperbola. Despite the loss of circular orbital energy in maneuver (b), it is preferred to (a) provided the energy remaining in the hyperbola after completely leaving the gravitational field exceeds the escape speed at the radius of the circular orbit. (If the arrows were reversed the figures would represent alternative maneuvers for *entering* a circular orbit from infinity.)

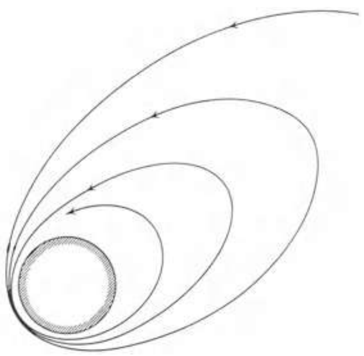

FIG. 9. Atmospheric-entry braking "ellipses," a trajectory controlled by gravity and the reverse force of atmospheric drag. Drag is concentrated at the pericenter, where air density is high. This acts to decrease the major axis and eccentricity of the ellipse, so that the orbit gradually approaches a circle. This analysis is somewhat idealized, however, and in an actual case the pericenter lowers slightly and the major axis turns in each successive cycle.

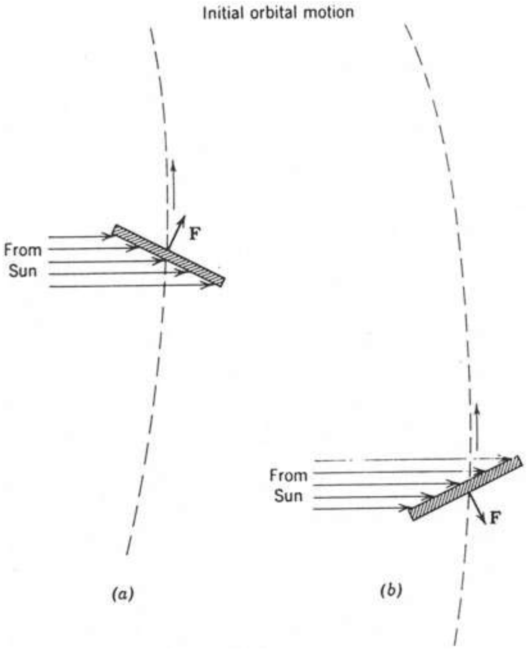

FIG. 10. Orientation of a solar sail for a voyage from earth to (*a*) a superior, and (*b*) an inferior planet. **F** is the vector sum of the forces due to the incident and reflected beams. When **F** is aligned as in (b) it constitutes a drag and causes the sail to spiral into the sun.

Paradoxically, our best launch point is at pericenter, for here the largest possible amount of energy will be transferred to the spacecraft for a given expenditure of propellant. This was noted in the previous section. A given thrust applied for a given time interval will do more work on the spacecraft when it is moving fast, as at pericenter, for it covers a greater distance during the interval. This advantage offsets the undesirability of being at a lower potential energy point at pericenter.

Powered Trajectories In the usual operation of a solid- or liquid-propelled rocket, the propellant is depleted in a time negligibly small compared with the total flight time. The trajectory analysis may generally be considered as that of a free orbit subject to burnout initial conditions as in the discussion above. If, however, the propellant ejection is sustained over long periods, as in an ion-propelled rocket, the trajectory analysis is necessarily complicated, for, in addition to the varying gravitational force, the vehicle, of slowly diminishing mass, is subject to a thrust which may be changing both in direction and magnitude. Even one of the simplest thrust programs, a constant thrust in the direction of motion, requires an electronic computer analysis in order to obtain the position and velocity at future times (see ELECTRIC PROPULSION).

The continuous-thrust trajectory is a spiral with many advantages over the orbital ellipses. First, the lower sustained thrust precludes the high-acceleration stresses associated with rapid-burning chemical rockets. Much of the structural weight usually needed to withstand these stresses can be replaced by propellant. Also, flights to the extremities of a gravitational region may take a shorter time in a spiral trajectory. In a long Hohmann ellipse, for example, most of the journey is made at very low speed. In a powered spiral, on the other hand, the spacecraft could be made to move fast, for the thrust, though small, is integrated over many months.

The spiral concept is ideal for rockets where very high ejection velocities are feasible by using electromagnetic or electrostatic particle accelerators, but only at the expense of a low propellant flow rate and relatively heavy power-generating equipment. However, the propellant reserve, and thrust, could then last the required long time. Such an ion rocket with its very low thrust-to-weight ratio could hardly be expected to take off from the ground, and could only take off from an orbital platform. In the vacuum of space, the ion beam meets its ideal environment.

ASTROPHYSICS

Starting with the advent of photography and the study of stellar spectra in the second half of the nineteenth century, astrophysics now includes optical and radio observations of planets, stars, clusters, interstellar material, galaxies and clusters of galaxies, and their interpretation. Radiation from these external sources provides information on the direction of the source, its velocity, composition, temperature and other physical conditions, including magnetic fields, density, degree of ionization, and turbulence. The term "astrophysics" is generally understood to include all these aspects except the measurement of direction (ASTROMETRY–positions of stars in the sky and changes due to parallax and proper motion), and the orbits of planets, asteroids and comets (celestial mechanics). Because of its proximity, the sun can be studied in more detail than other stars; its structure and its influence on the nearby planets and comets are the concern of SOLAR PHYSICS and are closely related to geophysics and stellar astrophysics. Study of the motions of stars in pairs, groups, clusters, associations, and galaxies is the overlap of celestial mechanics with astrophysics, and the study of the distribution and patterns of motion of the distant galaxies is the overlap with "COSMOLOGY."

Astrophysical studies of *planets* began in the 1930s with measurement of their spectra, showing the composition of the atmospheres of Venus, Mars, Jupiter, Saturn, and Neptune. These spectra showed bands of CO_2, CO, H_2, CH_4, NH_3, and other, more complex molecules. The atmospheres of Jupiter, Saturn, Uranus, and Neptune seemed to have about the same atomic composition as the Sun, and theoretical models of Jupiter showed that its core must consist of metallic hydrogen under high pressure in the interior. Starting in 1959, the space age brought spacecraft missions to Mars, Venus, Mercury, Jupiter, and Saturn, with landings on Venus and Mars (as well as Earth's Moon), and measurements *in situ* of their atmospheric composition, density, and temperature. Venus probes in 1970-75 found the most extreme conditions; surface pressure and density about 100 times the Earth's, temperatures of 750 K, and possible seas of acetic acid. The high temperature is attributed to atmospheric gases, mostly CO_2, that let sunlight in but prevent the outward, long-wavelength thermal radiation from leaving the atmosphere.

High-speed jet-stream motions were detected in the atmospheres of Venus, Mars, Jupiter, and Saturn. On Venus, they produce changing cloud patterns, on Mars they produce global dust storms, and on Jupiter and Saturn they produce vortices that show as small white spots, but bypass the giant red spot on Jupiter (explanation still unknown). By far the most dramatic Voyager (1981) photos are those of Saturn's rings (Fig. 1). Earth-based observations showed none of the detail of the hundreds of single rings, some of them entwined by the gravitational effects of nearby small moons. Less impressive rings were also found around Jupiter, and Earth-based observations showed rings around Uranus. These rings are related to stages in the origin and evolution of the solar system, probably the remnants of proto-planet clouds of gas and dust that formed the giant planets in much the same way as the solar nebula formed the Sun and planets. From all this, the new science of planetology developed among astrophysicists, geophysicists, meteorologists, and geochemists.

Comets have been observed and recorded by men for several thousand years. Starting in the 1920s, astrophysicists observed their spectra, which showed that as a comet approaches the Sun, sunlight boils off various molecules to form a coma around the nucleus, then two long tails, pushed out away from the Sun by radiation pressure and by the solar wind—outward moving electrons and ions ejected by the Sun. The dust tail, showing in reflected sunlight, is formed of dust released from the comet nucleus as frozen gases boil off; the ion tail is formed from ionized gases that show an emission-line spectrum. These two tails deviate from one another because the solar wind blows in a slightly different direction from solar radiation.

The Oort cloud of comet nuclei (named after Jan Oort, a Dutch astrophysicist) is believed to be the outer fringe of the solar nebula condensed from gas and dust to form nuclei revolving about the Sun at distances larger than 50 Astronomical Units (1 A.U. = 93 million miles, the distance from Sun to Earth). These small bits of frozen gas and dust represent the early composition of the solar nebula. Every now and then, one gets deflected from its circular orbit to a highly elliptical orbit, falling toward the Sun, sweeping around at perihelion close to the Sun with large coma and long tails, then receding from the Sun out to aphelion, losing coma and tails, then falling back in again. Halley's Comet is the archetype of these long-period comets, returning to the Sun every 75 years. In 1985-86 it will reappear. European and Soviet spacecraft are expected to rendezvous with Halley's Comet then in an effort to

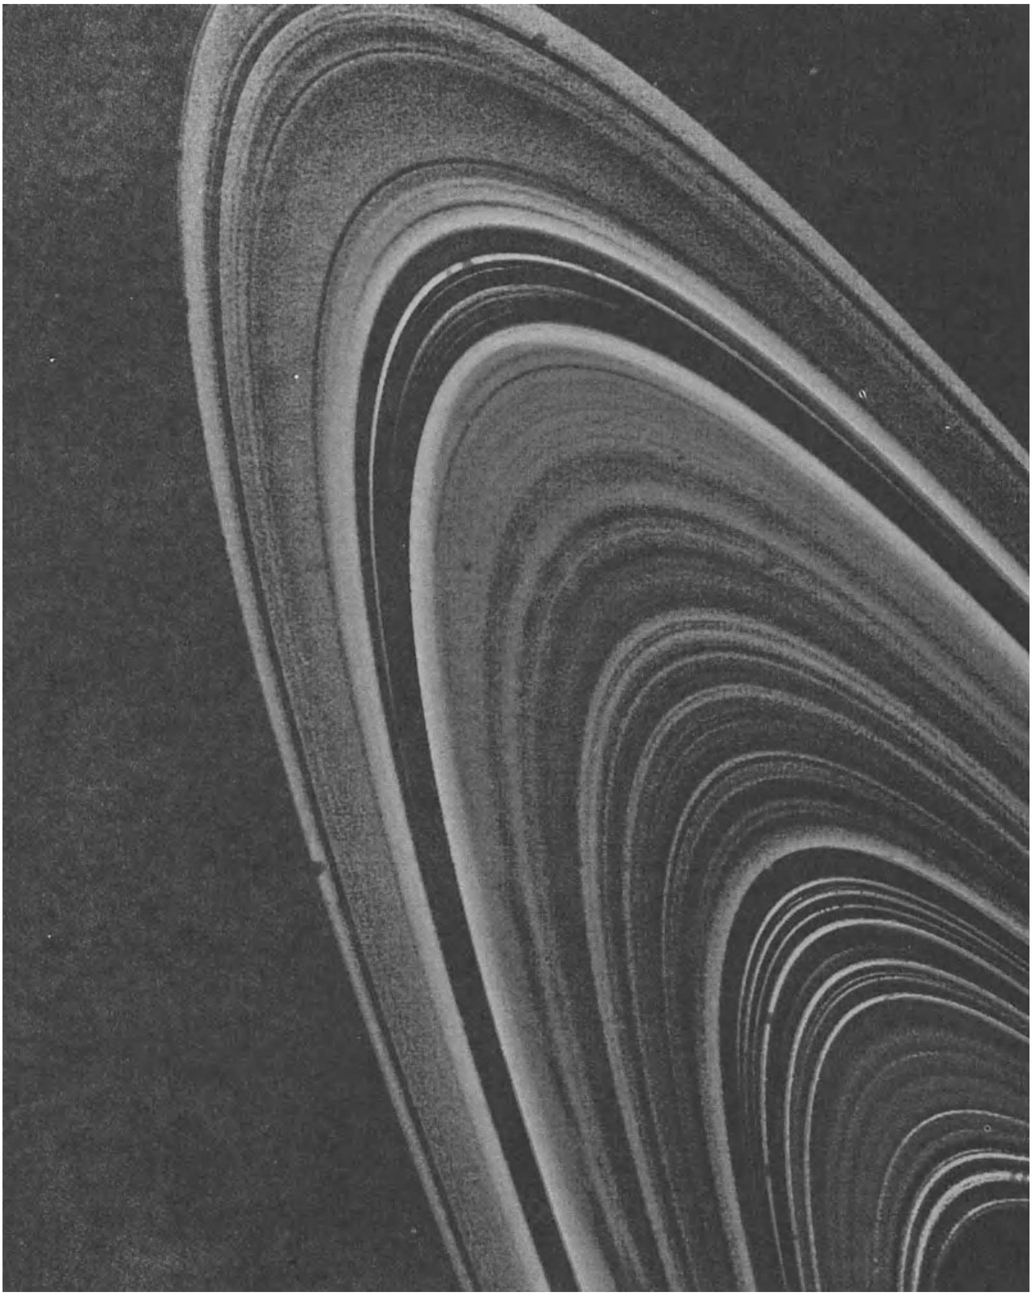

FIG. 1. Saturn's Rings; NASA JPL color photo.

photograph the size of its nucleus and to sample the gas and dust boiling off. Astrophysicists want to determine what the frozen gases in the nucleus are; spectra of the coma show only molecules that have been dissociated by sunlight. The nature of these gases, and the included dust, may help with calculations of how the primordial solar nebula cooled and contracted about 5 billion years ago. The planets' sizes, masses, densities, rotations, distances from the Sun, satellites and rings, and the thousands of asteroids between Mars' and Jupiter's orbits, provide the rest of the data needed for a theory of the origin and evolution of the solar system. A recent discovery adds the fact that Pluto has a small moon, whose orbit provides the first firm measure of Pluto's mass, much smaller than expected.

The *instruments* used by astrophysicists have multiplied during the past two decades, and their resolving power (needed, for instance, to detect Pluto's small moon close to that planet) has increased enormously. Telescopes for the 1980s (see reference) include the 2.4-meter (95-inch) Space Telescope (Fig. 2), the Very Large Array of radio receivers near Soccorro, N.M., and the orbiting Einstein x-ray telescope launched in 1978. The European Space Agency is supplying Space Lab with a cooled infrared telescope to be flown on NASA's Space Shuttle. Space Telescope and VLA can resolve objects as close as 0.02 arc-sec apart, and detect objects 100 times fainter than previously possible. Very long baseline interferometry is achieved with radio dishes thousands of miles apart; the slightly different arrival times of radio waves from the same object provides resolution of 0.001 arc-sec or better.

Optical telescopes, both in orbit and ground-based, are fitted with spectrographs that spread the incoming light into a spectrum of colors from short wavelength to long, using a finely ruled grating or an echelle to resolve wavelengths as close as 1/100,000 of their size. This high spectrographic resolving power allows very small Doppler shifts to be measured, and the spectral lines of different atomic isotopes to be detected.

Needed for orbiting telescopes and spectrographs, electronic detectors have been developed to substitute for photographic emulsion, and are now being used in ground-based observatories as well. The most successful is the charge-coupled device (CCD). Arrays of 800 minute CCDs, 15 microns on a side, turn out digital information on each pixel (picture ele-

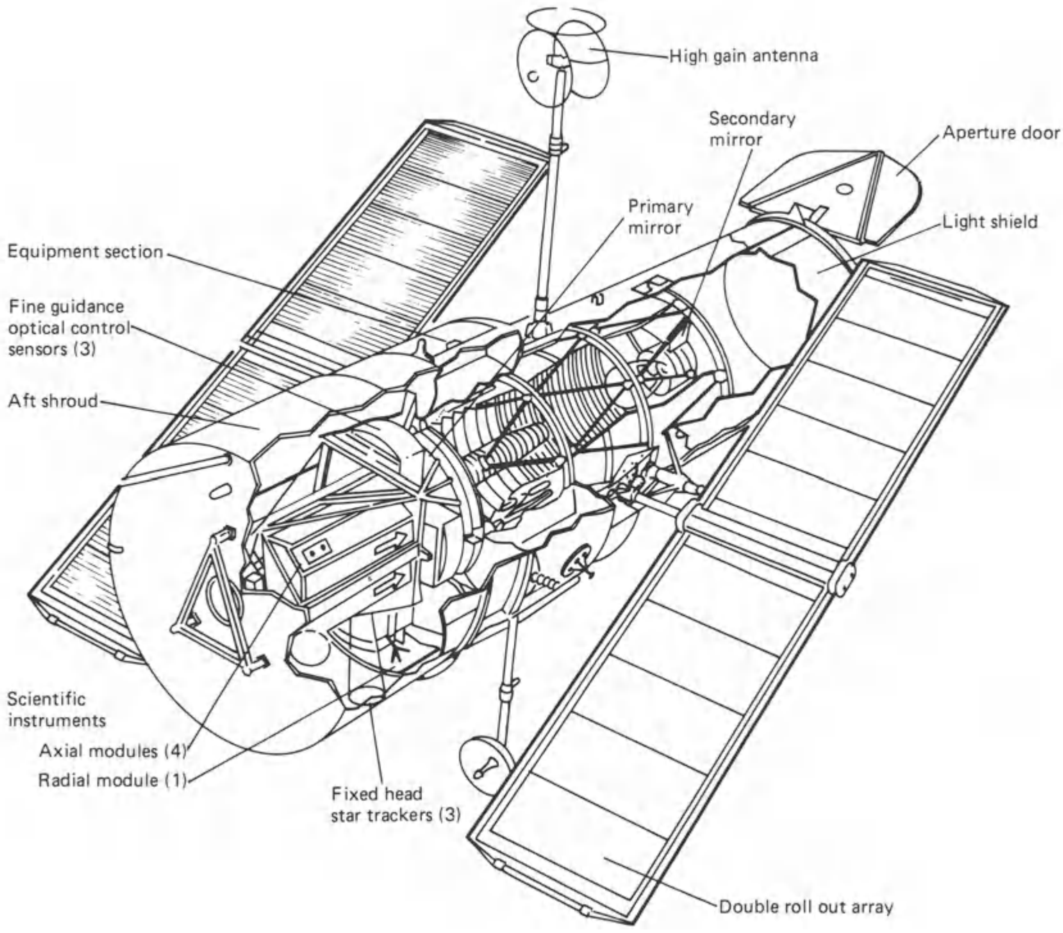

FIG. 2. Diagram of Space Telescope; Longair & Warner, "Sci Res with ST" NASA CP-2111.

ment) in an image or a spectrum. These digitized data can be fed directly into a computer for processing. Such use of electronics and computers has changed the observer's role in astrophysics. Instead of spending long cold nights at the eyepiece of a telescope in an unheated dome and developing his plates or film in a photographic darkroom, he now prepares computer programs in advance, picks the object he wants on a TV screen in the comfortable control room, and waits during a suitable "integration time" for his processed results to be printed out or graphed by the computer.

Early studies of *stellar spectra* revealed differences due primarily to surface temperature and described by the sequence of spectral types ranging from "O" (30 000 K or more) through "B," "A," "F," "G," and "K" to "M" (2000 to 3000 K). The type of a spectrum is set by relative intensities of lines and bands due to ions, atoms, and molecules. The earth's atmosphere limits the wavelength region observable from terrestrial observatories since ozone and other constituents are opaque at wavelengths $\lambda <$ 3000Å, and water vapor bands block much of the region $1.2\mu < \lambda < 8\mu$. The ionized layers block radio waves longer than 20 meters. Nevertheless, thousands of spectrum lines, mostly in absorption, have been identified in the range $3000 < \lambda < 12000$Å, and the pattern of lines within one spectral type has been found to vary with a second parameter, the "luminosity class" designated by roman numerals "I" (highly luminous "super giants") through "II", "III", "IV" to "V" ("dwarfs" of relatively low luminosity).

The continuum between spectral lines has an intensity distribution with wavelength that roughly matches Planck's theoretical distribution for a blackbody, $B(\lambda)\, d\lambda = 2hc^2\lambda^{-5}(e^{hc/\lambda kT} - 1)^{-1}$ where T is the temperature that accounts approximately for the ionization and excitation of atoms producing the star's line spectrum, or the dissociation of molecules producing bands—that is, for the spectral type. In so far as the lines can be ignored, the color of a star is approximately that of a blackbody of temperature T and the total ("bolometric") luminosity is given by $L_b = 4\pi R^2 \sigma T^4$, where R is the radius of the star and σ is Stefan's constant. The "apparent brightness" of a star (observed optical flux) depends upon its distance, D, and its luminosity in the wavelength region observed—approximately $4000 < \lambda < 6500$Å for visual observations and $3700 < \lambda < 5000$Å for photographic observations through glass optics. Recently the introduction of photoelectric equipment has allowed more accurate measurements in smaller wavelength regions. Standard measures are designated U (ultraviolet), B (blue), V (visual), I (infrared), etc., and are usually expressed in magnitudes, an inverse, logarithmic scale. An increase of 5 magnitudes corresponds to a decrease in brightness by a factor 100. By successive approximations in such measurements of many stars, it has been possible to correct for the effects of interstellar absorption and limited wavelength range, as well as for the inverse-square law ($1/D^2$), to obtain total luminosities and colors. The luminosities are often expressed in "suns", that is, multiples of the sun's luminosity (about 4×10^{33} ergs/sec). Analogous measurements at radio frequencies are expressed as the flux in watts/square meter/cycle/second. Spectrophotometric measurements from rockets and artificial satellites above the earth's atmosphere have been made in the far ultraviolet, and it is to be expected that the intensity distribution, $I(\lambda)$, will soon be observed for all wavelengths from 10^{-4} Å to several km.

X-ray observations started in 1962, using ionization chambers and Geiger counters mounted on rockets and sent up for a few minutes above the earth's atmosphere. As the rocket rotated, the x-ray detectors scanned part of the sky, but the angular resolution was at first poor (about 3°). Still, these early observations showed several discrete sources (Sco X-1, Sco X-2, Tau X-1, Cyg X-1, etc.) named for the constellation in which each is located.

Later orbiting x-ray observatories (Uhuru, HEAO, Einstein Observatory) have detectors with much higher space resolution; they can locate x-ray sources to within a few arc-minutes. Many of these sources have been identified with optical objects; they are many light-years distant, and their energy output is very high. Some are star-like in size, and thought to be the remnants of old supernovae—possibly neutron stars; others are whole galaxies, and our Milky Way has a faint x-ray background. The measured flux is given in counts/cm^2-sec, each count representing a quantum of about 1 Å wavelength, or about 10^4 eV, or 1.6×10^{-8} erg.

Gamma rays of wavelength about 10^{-3} Å (energy 10 MeV) can also be detected above the atmosphere using scintillation counters—crystals that emit a flash of light when penetrated by a gamma ray. Such detectors are sensitive, but not accurate in direction. However, the directions of gamma-ray sources have been accurately determined by using three or more gamma-ray detectors timing gamma-ray pulses or "bursts." These times, accurate to microseconds, determine direction from the differences in time of arrival at spacecraft in known positions. Since 1975, scores of gamma-ray bursters have been located, and there is a diffuse gamma-ray background all over the sky, indicating many more distant sources. Solar flares emit gamma rays, and other stars probably do the same. The strong gamma-ray sources are probably distant galaxies, but bursters seem to be in our Milky Way Galaxy, and are thought to be neutron stars or black holes with matter falling into them to produce the bursts. At least six are located at the centers of globular clusters.

The major gap in observed spectra, I(λ), is from $\lambda = 0.08$ to 2.5 mm, between the far infrared and short radio waves. In the far infrared, measurements from high-flying aircraft and spacecraft show many star-like objects and a few galaxies that are strong emitters between λ = 0.02 and 0.08 mm. In 1983 NASA's Infrared Astronomical Satellite (IRAS), cooled by liquid helium to 16 K, surveyed the whole sky in the band 0.02 to 0.3 mm, and discovered thousands of far-infrared sources.

The *masses of stars* are determined from motions of double stars, ranging from widely separated visual binaries whose relative motions can be photographed, to close spectroscopic and eclipsing binaries with orbits calculated from variations in radial velocity (observed Doppler shift). Among some 50 pairs, masses of individual stars are found from 0.08 to 20 solar masses, and there is less definite evidence of others as low as 0.03 and as high as 50 or 100. (One solar mass is 2×10^{33} gm.) Over most of this range the luminosity L is proportional to M^3.

Astrophysical theory has achieved considerable success in explaining the spectra of stars by theoretical models of the atmospheres, involving the surface temperature, surface gravity, abundances of chemical elements, turbulence, rotation, and magnetic fields. The strengths of absorption lines are found to fit a "curve of growth," the relation between measured line strengths and the strengths predicted by quantum theory for unit abundance of the one ion, atom, or molecule involved. The theory of stellar interiors further relates mass M, luminosity L, and radius R with chemical abundances, the opacity of the material, and the generation of energy by nuclear reactions. More spectacularly, it has explained stellar evolution in terms of changes due to nuclear reactions.

The theoretical models of *stellar interiors* are based on stability and two modes of transferring energy outward to the surface: radiative transfer and convective transfer. Radiative transfer, by repeated emission, absorption, and emission of light, implies a temperature gradient dependent on the opacity and on the flow of radiative energy, or L. After calculating the opacity of gaseous stellar material (about 60 per cent hydrogen, 35 per cent helium, and 5 per cent heavier elements, by weight) at various temperatures and densities, the astrophysicist can compute the temperature, density and pressure in shells at various depths inside a star, starting with a definite radius and surface temperature, and adding up the shell masses to get the total mass. At some level, the temperature and density are sufficiently high for nuclear reactions to take place, the simplest being conversion of hydrogen to helium generating 7×10^{18} ergs of energy per gram. The rate of energy generation over the whole inner core must match L. Calculations for convective transfer follow a similar pattern but depend upon matching the adiabatic gas law for over-all stability. A combined model may have a convective core surrounded by a radiative shell and that surrounded by an outer convective shell.

The successful fitting of nuclear energy generation into such gas-sphere models of stars by 1940 led to the idea of *stellar evolution*, the conversion of hydrogen to helium in its core causing a star to age. Direct evidence of this aging was first obtained from clusters of stars. The stars in one cluster, relatively close together in space, are assumed to have been formed at the same time, and the pattern of stellar characteristics differs from one cluster to another in a systematic way. The pattern is easily recognized on a Hertzsprung-Russell ("H-R") diagram of log L vs spectral type (or color) on which the vast majority of stars appear near a diagonal line, the "main sequence" (Fig. 3).

Several other classes of stars can be distinguished by location on the H-R diagram ("red giants," "white dwarfs," etc.) and theories of stellar evolution account for a change in location along an "evolutionary track" for any one star. The rate of such change will vary in general; for instance, the large-mass, high-L blue stars are expected to exhaust their hydrogen in a few million years, whereas yellow and red dwarfs remain for billions of years on the main sequence. H-R diagrams for clusters confirm the aging (also the theoretical star models and the assumption of cluster origin) and provide evidence of the age of each cluster.

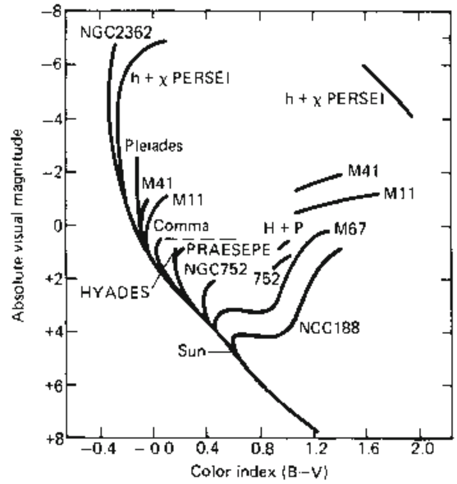

FIG. 3. This is the *H-R* diagram for galactic clusters used by Allan R. Sandage to estimate their relative ages. The turnoff from the age-zero main sequence (on which the sun is located) is lowest for the oldest clusters, NGC_188 and M67. The stars in the uppermost sequences, such as the red giants of the Perseus Double Cluster, are intrinsically some 10,000 or more times brighter than the sun. (From Thorton Page and Lou W. Page, eds. *The Evolution of Stars*, in *Sky & Telescope Library of Astronomy*. Copyright © 1967 by Macmillan Publishing Co.)

A large part of astrophysical research is devoted to filling in the details of stellar evolution and the variety of nuclear reactions involved. For example, after its hydrogen is exhausted, the core of a giant star contracts and heats up to a billion degrees; then helium combines to form carbon, providing a new intense source of energy, and gas is probably blown off the star. Later, a small white dwarf remains. The explosion driving off a large fraction of a star's mass probably accounts for *supernovae*, which are seen every 100 years or so in our Milky Way and in other galaxies. One that was seen to blow up in A.D. 1054 now has a large expanding cloud of ionized gas around it—the Crab Nebula in Taurus. Near the center is a peculiar small star thought to be the core of the supernova, possibly a *neutron star* with density (of pure neutrons) about 10^{15} gm/cm^3. Such supernova remnants (SMRs) are found in other galaxies such as the Large Magellanic Cloud (LMC).

In 1968 this was confirmed when astronomers in England discovered a rapidly pulsating radio source, the first of about 300 *pulsars* now known, one of which is near the center of the Crab Nebula. By 1970 it was fairly well agreed that pulsars are rapidly rotating neutron stars with strong magnetic fields that interact with surrounding gas to emit a radio pulse on each rotation. This pulse timing is accurately periodic—1.33730 sec for the first pulsar discovered—but the pulses measured in different radio frequencies (wavelengths) are out of step, an effect due to the ionized gas along the line of sight. In several cases, the period of the pulses (star rotation period) has been found to be increasing by 10^{-6} sec or so each year, showing the "braking" action of the surrounding gas. (see PULSARS).

The *formation of a star* starts with gravitational contraction of a large cloud ("nebula") of interstellar gas and dust, including matter ejected from previous generations of giant stars. The recycling of material back and forth from nebulae to stars involves changes in composition—the abundances of helium and heavy elements increasing with time. Since 1954, astrophysicists have therefore been concerned with *nucleogenesis*, the creation of the chemical elements in stars (or in an early stage of the evolving universe). Differences in composition of stars in various locations are now interpreted as evidence of past star making.

The *formation of the solar system* (sun, planets, asteroids, meteors, and comets) is one case of star formation studied in great detail by astrophysicists, geologists and chemists. Radioactive dating of minerals in the earth, moon, and meteorites places this event about five billion years ago when a slowly rotating nebula contracted, forming earth and planets, but losing a good deal of its mass in the process. Fractionation of chemical elements and compounds during the condensation is linked with astrophysical interpretation of chemical analyses of meteorites, and lunar and terrestrial minerals.

Interstellar material in the form of bright nebulae has been known since telescopes were first used. During the first two decades of this century, evidence was collected showing less obvious clouds of dust and interstellar gas in the plane of the Milky Way, based on the obscuring and color effects of dust and the spectral absorption lines of gas (primarily sodium and ionized calcium). In 1945 the polarization of starlight caused by the interstellar dust was discovered, and in 1950 the radio telescope added the emission by interstellar atomic hydrogen at 21-cm wavelength. This interstellar medium is now known to extend in a thin, flat slab centered in the Milky Way. When highly luminous blue stars are in or near it, the gas is ionized by ultraviolet radiation, and the resulting electrons produce emission lines of hydrogen, oxygen, helium and other elements by recombination or by electron excitation. In addition to such "H II regions," the dimensions of which depend on the temperature and luminosity of the exciting star and the density of the medium, astrophysicists have studied more complex nebulae in which the material density varies from one place to another. The interstellar medium is often denser near young clusters or individual blue stars, as expected from the theory of star formation

Since 1963, radio astronomers have detected over 50 different kinds of molecules in the intersteller medium, mostly in dark clouds of dust where light from stars cannot penetrate. These molecules consist of the most common atoms, H, C. N, and O; two include sulfur (S), and one silicon (Si). Absorption lines of CH and CN were discovered in optical spectra of stars about 1940, and H_2 in far-ultraviolet spectra taken from a rocket above the atmosphere in 1969. The study of these molecules is the new subject of *astrochemistry*, and involves such questions as how the interstellar molecules are formed, what other ones should be there, and the conditions (density, temperature, turbulent motions) of the gas. Preliminary estimates are that most of the 8 simple diatomic molecules may be formed by collisions in space; the more complex ones, such as H_2CO_2, CH_3CN, and NH_3CO, are probably formed on grains of interstellar dust in clouds where the concentration of hydrogen molecules (H_2) is 10^6/cm^3 or higher. These molecules leave the dust grains after combination, but other molecules stick to the dust until strong light "boils" them off. Hence dust grains can deplete the interstellar gas in large dark nebulae—another process going on in our Milky Way.

The molecular absorption lines are at slightly different wavelengths when heavy *isotopes* ^{13}C or ^{18}O are involved instead of ^{12}C or ^{16}O, and the line strengths show the relative abundances, or "isotope ratios," which are related to the source of the interstellar gas. Relative strengths of different spectral lines from the same molecule show that the excitation temperature in instellar clouds is very low—about 3 K, and the absolute strengths of the spectral lines show that the density of, for instance, CO is 20 molecules/cm^3. Two molecules, OH and H_2O, show maser interaction; i.e., these molecules are excited so as to "pump" energy into a few selected radio wavelengths, which may come out of the gas cloud in a single direction.

The whole *Milky Way system* of stars, nebulae and interstellar gas and dust is assumed to be in dynamic equilibrium; that is, the mass distribution can be calculated from individual motions under the gravitational attraction of the whole galaxy, another important part of modern astrophysics. Since 1920 the dimensions of the galaxy have been determined from distances of the large bright globular clusters and from the distances of nearer stars. The resulting model, a flat disk with a high-density nucleus (total mass about 10^{11} suns) also fits the average motions of stars within a few thousand light years' distance from the sun, and the radial motions of cold atomic hydrogen out to 50 000 light-years determined by Doppler shifts in the 21-cm radio emission line. The stellar motions are derived from statistics of Doppler shifts and changes in direction, allowing for random individual motions differing from the general circulation.

Most of the stars in the Milky Way share in a circular velocity, v_c, around the center of the galaxy, and the mass distribution is inferred from the observed change of v_c with distance from the center. The globular clusters and many other stars appear to move in orbits at high inclination to the Milky Way plane, forming a "halo" around the center having little or no angular momentum. It thus appears that there are two populations in the galaxy: "Population I" stars, nebulae, gas and dust in the outer parts of a thin rotating disk, and "Population II" stars in the nonrotating halo, probably formed at an earlier time. A large fraction of Population I in the disk is in the form of nonluminous interstellar dust and gas, although this interstellar material is only 10 to 15 percent of the total mass of the system. During the 1970s, after the "mass discrepancy" was recognized, several astrophysicists assumed the presence of much more nonluminous material in the halo. They found some evidence of such "dark haloes" in other galaxies (see below), and calculated that as much as half the mass of a galaxy is in its dark halo. Efforts have been largely successful in confirming this assumption for the Milky Way system.

There is a weak *magnetic field* between the disk stars which probably lines up the interstellar dust particles like small magnetic needles, and this pattern accounts for the polarization of starlight passing through. The field also deflects moving ions and electrons, and may account for the energy of very high-speed *cosmic rays*. Lower-speed cosmic rays are ejected by solar flares, and other stars probably do the same. It is possible that these ejected ions are accelerated to enormous speeds by the uneven magnetic field in the Milky Way system. Cosmic rays are studied above the atmosphere to determine the relative abundance of different ions, their energy spectrum, and source. Their energy flux is about the same as starlight, and they probably affect the temperature of the interstellar gas. They certainly produce x-rays and gamma rays by collisions with atoms and molecules.

The many *other galaxies* well outside our own are found to include some (classed as "spirals") very similar to our Milky Way galaxy in structure and internal motions. Others are strikingly different (classed as "ellipticals"), probably due to different conditions of formation. All the techniques of astrophysics are being applied to the study of these objects: measurement of their sizes, luminosities, colors and masses, their proportion of interstellar material, the formation and evolution of their stars, etc. These physical characteristics are fairly well correlated with morphological type; the spirals are similar to our Milky Way, but the ellipticals have almost no interstellar material, and are much more massive for their size and luminosity than the spirals.

The *evolution of galaxies* is due to the ageing of their member stars. This is a slow process, and no change can be observed during a man's lifetime, except for supernova explosions, and light variations in the nuclei of a few "active galaxies." But as we look to more distant (fainter) galaxies, we are looking back in time, seeing them at a younger age. This is because faint galaxies are hundreds of millions of lightyears away, and the light we see now left them hundreds of millions of years ago. By 1986, it may be possible to look back more than 5 billion years, using the new Space Telescope, launched into orbit then by Space Shuttle. Astrophysicists have traced galactic evolution backwards and expect that elliptical galaxies were very luminous 10 billion years ago, when their blue supergiant stars had just formed. They are eager to confirm this, and also to observe young spiral galaxies with Space Telescope.

The *mass* of a single galaxy can be measured from the rotational velocity, v_c, near the rim and the radius, R. Then $M = v_c^2R/G$, where G is the gravitational constant, and $v_c = v/\sin i$, where v is measured from the relative Doppler shift (rim to center), and i is the inclination of the disk to the line of sight. However, R is poorly determined because galaxies do not have sharp rims. Moreover, the observed change of v_c with distance from the nucleus r does not always follow the expected form of a rapid rise to a maximum and then a decrease ($v_c \propto 1/\sqrt{r}$) after r includes most of the galaxy's mass. During the 1970s many such velocity curves were measured for spiral galaxies, and several showed no peak; that is, v_c remained at its peak value out to r for the faintest rim stars observable. This is considered evidence of a spherical dark

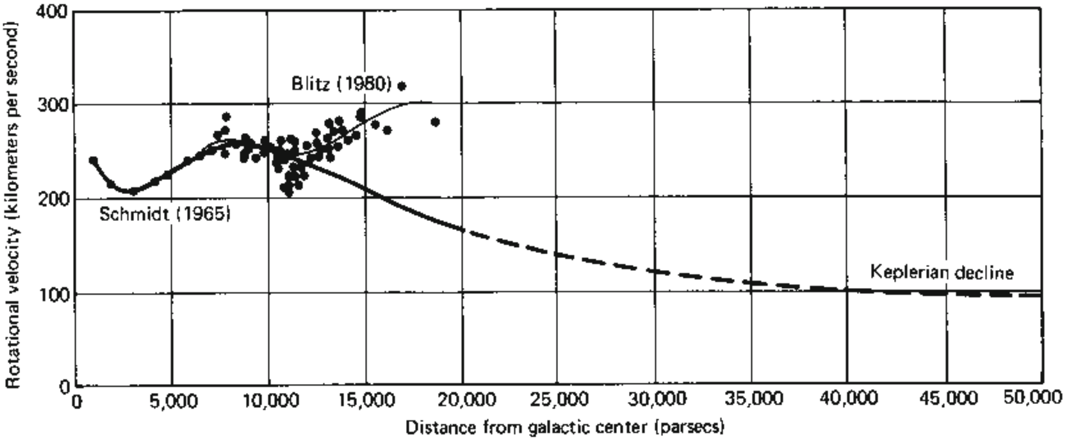

FIG. 4. Rotation curve graphs the circular velocity of matter in rotation about the center of the Milky Way. Here two such curves are drawn. A rotation curve plotted in 1965 by Maarten Schmidt of the Hale Observatories (*solid black line*) shows a circular velocity that declines toward the limit of the visible galaxy at 20,000 parsecs. If all the mass in the galaxy lay inside that limit, a test mass placed farther out would rotate at lower speed, in approximate obedience to a law first formulated (for the motion of the planets) by Johannes Kepler (*broken line*). Data analyzed by Leo Blitz and his colleagues at the University of California at Berkeley now yield a rotation curve (*light solid line*) that rises toward a value of 300 kilometers per second at 20,000 parsecs. The rise of the newer curve implies unseen mass in great quantity outside the visible limit of the galaxy. Each point in the newer data is the circular velocity of a cloud of hydrogen atoms. (From Bart J. Bok, "The Milky Way Galaxy," *Scientific American*, March 1981. Copyright © 1981 by Scientific American, Inc. All rights reserved.)

halo—nonluminous material extending almost to the edge of the luminous disk. Fig. 4 shows the velocity curve for the Milky Way system.

Another method can be used to measure the masses of the many galaxies in pairs, one orbiting around the other. In such a pair, $M_1 + M_2 = (v_1 - v_2)^2 S/G$, where S is the separation. However, the inclination of the orbit cannot be measured, and an average value of M must be obtained from statistics of many pairs. This method shows that the average spiral has $M_S = 4 \times 10^{10}$ suns $= 8 \times 10^{43}$ gm, while the average elliptical has 30 times this mass. The luminosity of either type is 10^{10} suns, on the average, so a spiral has about four times as much mass per watt of light output as the sun does, while an elliptical has over 100 times as much.

Except for the dark haloes, the mass of most galaxies seems to be concentrated in their nuclei, and several of these nuclei appear to be exploding. The most dramatic is the irregular galaxy, Messier 82, with jets coming out of the nucleus (Fig. 5). Doppler shifts in these jets show that they are moving outward at about 1000 km/sec. A few dozen *Seyfert galaxies* have active nuclei that vary in brightness and show strong, broad emission lines indicating explosive conditions. Both jets and Seyfert nuclei, as well as the superluminous quasistellar objects (QUASARS) are thought to be powered by black holes at the center. The power comes from mass falling into the black hole at rates of up to 1 solar mass (2×10^{33} gm) per year. Such black holes are estimated to have mass M_H, about 10^8 suns within a radius $R_H = 2GM_H/c^2 = 3 \times 10^{13}$ cm $= 3 \times 10^{-5}$ lightyear. (This "Schwarzschild radius" R_H comes from setting the velocity of escape v_e equal to the velocity of light c in the equation $\frac{1}{2}mv_e^2 = GmM/R$.) With such a small radius (0.01 lightday), the black hole in the nucleus can vary rapidly in brightness as gas falls into it.

Galaxies are observed in increasing numbers at larger and larger distances, roughly in uniform distribution, but with marked clustering. In 1981, a large void was found, about 1 billion lightyears from us in the direction of the constellation Bootes, where astrophysicists can detect no galaxies in a region 300 million light years across. There is some evidence that compact clusters contain a preponderance of ellipticals; the total number of galaxies in the Coma Cluster is about 500, of which only a dozen are spirals. The total mass of such clusters can be measured by the relative velocities of galaxies near the edge, and when this was done (first in 1932), astrophysicists were surprised to find that the cluster mass is 5 to 10 times larger than the sum of all galaxy masses in it. This *mass discrepancy* means that we see only 10 to 20 percent of the material in a large region of space—possibly in the rest of the observed universe, as well. The "missing mass" may be a thin intergalactic gas or discrete, nonluminous objects, or due to the fact that many galaxies have dark haloes and masses 10 times as large as the "average mass" used. Another possibility was brought out in 1980, when physicists

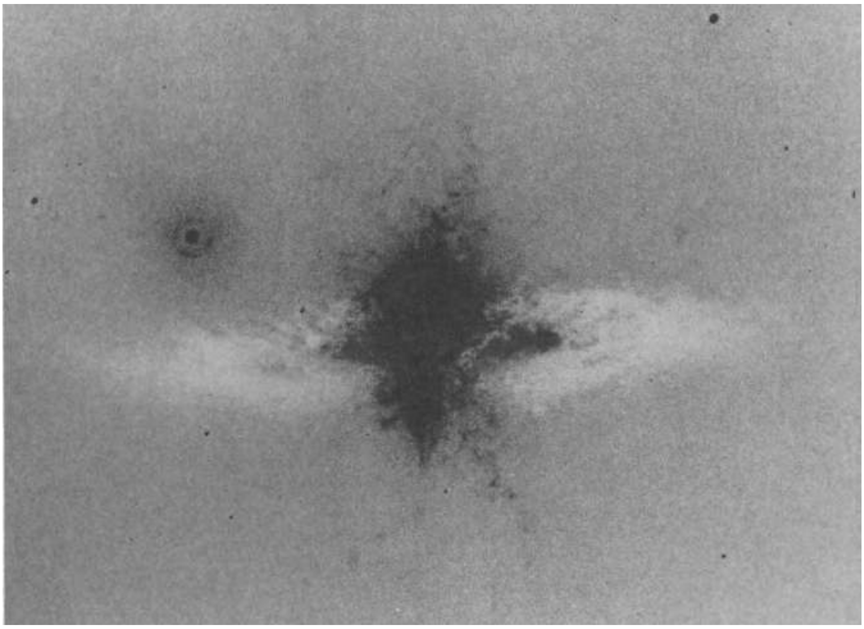

FIG. 5. The irregular galaxy Messier 82, photographed in red light of hydrogen with the 200-inch Palomar reflector. The enormous puff of luminous hydrogen gas escaping from the nucleus of this system stretches over 10,000 light years above and below the disk of the galaxy, which is about 20,000 light years across. (Palomar Observatory Photograph.)

found evidence that neutrinos have a small mass. Before then, neutrinos were considered to have a rest mass of zero. Nuclear reactions in the Sun's core are spewing out neutrinos at the rate of 10^{38} per second, and more luminous stars do so at even higher rates. Over the past 15 billion years, all space must have been filled with neutrinos, although their number levelled off as the density increased and neutrino pairing began to destroy them as fast as they are being created. Light as they are, the large numbers of neutrinos add up to a mass somewhat larger than all the visible galaxies, and provide a good part of the "missing mass" in the universe.

The spectra of distant galaxies all show large red shifts which, if interpreted as Doppler shifts, indicate a recessional velocity proportional to distance (Hubble's Law). In fact, the red shift is used to measure all distances (D) larger than about 40 million light-years by $D = v_R/H$, where H = 17 km/sec/million light years. Starting in 1958, radio astronomers began to survey the whole sky for faint radio sources, and found that many galaxies are strong radio emitters. The most puzzling were faint, starlike (quasi-stellar) objects, soon named *quasars*. In 1963 these were found to have very large red shifts, therefore very far away (up to 5 billion light-years) and about 100 times more luminous than the average galaxy. This large energy output is probably an enormous explosion, lasting but a brief fraction of a galaxy's life. At these large distances, we see now the quasars as they were 5 billion years ago, and it seems likely that many galaxies exploded at that time (see QUASARS).

Here astrophysics leads into COSMOLOGY, based on general RELATIVITY. Observations of the short-wave (3-mm) radio emission coming from all over the sky (isotropic) seems to confirm the "big-bang" cosmological model of the universe, and to disprove the steady-state theory which assumes continuous creation of matter. The *isotropic background radiation* with $I(\lambda)$ matching a black body at 3 K, is the remnant of the very hot explosion about 20 billion years ago that sent the galaxies moving outward to the great distances where we see them today. Astrophysical evidence for the missing mass in clusters of galaxies shows that the average density of matter in the universe is probably higher than 10^{-28} gm/cm^3 so that the space curvature predicted by general relativity fits the numbers of galaxies we count at different distances. For higher density of matter, the predicted curvature is larger, and at the extreme, space "wraps itself around" a large collapsed mass so that no light or radio waves can get in or out. This leaves a "*black hole*" which exerts gravitational attraction on distant masses, but cannot be seen—a possible explanation of the missing mass in clusters of galaxies.

ATOMIC AND MOLECULAR BEAMS

This field of research utilizes a collision-free stream of neutral atoms or molecules as they traverse a vacuum chamber. With 10^{-6} mm Hg pressure in a vacuum chamber, air molecules at room temperature travel on the average about 300 meters between collisions and move with an average speed of about 500 m/sec. Between collisions these molecules are essentially "free" and unperturbed by molecules of the residual gas or by atoms in the walls of the apparatus. The mathematical description of such isolated systems is much less complicated than for denser gases, liquids, or solids containing interacting particles.

Since 1911, when Dunoyer proved that a stream of neutral atoms would remain collimated in a vacuum, atomic- and molecular-beam research has become one of the most versatile, precise, and sensitive techniques for studying the properties of isolated atomic systems and interactions between such systems. Numerous fundamental discoveries in beam research have contributed to the present understanding of physical laws. The earliest experiments (1920) sought the molecular velocity distribution, which is important in the kinetic theory of gases. Atomic diameters (cross sections), van der Waals' interaction potentials, and polymer vapor composition were obtained after later refinements of technique. The Stern-Gerlach experiment (1924) demonstrated the validity of space quantization of angular momentum and established the electron spin as 1/2. This historic work placed quantum mechanics on a firmer foundation and initiated beam investigations of atomic and nuclear electromagnetic properties. Although many low-precision results appeared in subsequent years, high-precision spectroscopy began in 1937 with the introduction of the magnetic-resonance method by Rabi. In this method, transitions between quantum states separated by an energy $h\nu$ are induced by a radio-frequency field of frequency ν (h is Planck's constant). From the Heisenberg uncertainty principle, the width of the rf resonance is small, owing to the long lifetimes of the beam quantum states and to the ability to irradiate the beam with radio frequency for as long as a few milliseconds along its path.

Precision atomic-beam measurements have contributed to many theoretical and practical developments. The deuteron quadrupole moment (1939) pointed to the necessity of a tensor interaction in nuclear forces. The anomalous electron moment (1949) and the Lamb shift (1950) in the atomic-hydrogen fine structure were resolved by quantum electrodynamics. Nuclear spins (I) as well as magnetic-dipole (μ) and electric-quadrupole (Q) moments have been important in providing test information for the shell model (1949) and collective model (1953) of the nucleus. Atomic hyperfine-structure constants (dipole, a; quadrupole, b; and octupole, c), which describe the interaction between the electrons and the nucleus, as well as the numerous constants required to describe a molecule and its internal interactions, have contributed to the theory of atomic and molecular structure. The cesium "clock" or frequency standard (1952) represents a widespread practical application of beam technology by using the hyperfine-structure transition at 9192.631770 MHz (Ephemeris time) to regulate a quartz-crystal oscillator. Other frequency standards such as the thallium clock, ammonia maser (1954), and hydrogen maser (1960) also employ beam techniques for quantum-state selection. Very recent, high-energy nuclear accelerators have been equipped with atomic-beam sources to produce polarized protons.

Among nonresonant experiments, beams impinging on solid surfaces produce information on the wave nature of particles, work functions, and accomodation coefficients. Charge-exchange cross sections and interaction potentials are obtained from experiments with crossed beams, one neutral and one charged. Chemical reaction kinetics in isolated systems are studied in crossed beams of two reactants. Precision optical studies combine beam and laser techniques.

Four individuals have received Nobel Prizes for beam research: Otto Stern (1943) "for his contribution to the development of the molecular-ray method and for his discovery of the

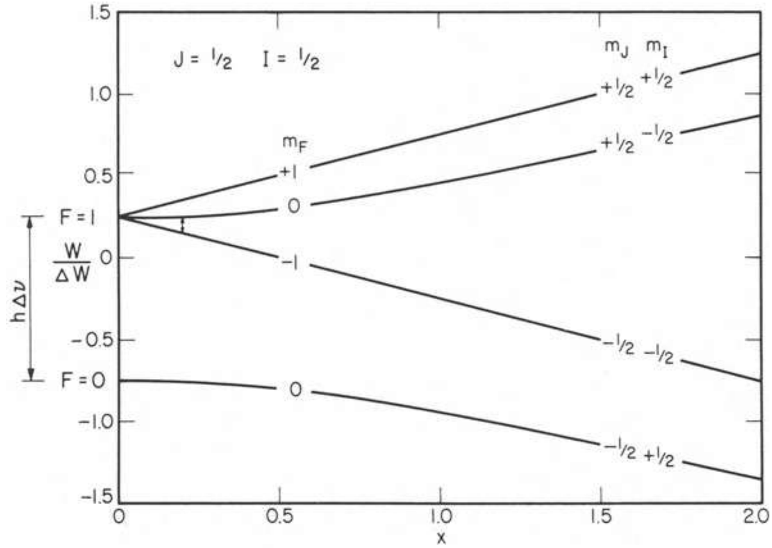

FIG. 1. Hyperfine-structure energies (ordinate) of an atom with $J = 1/2$ and $I = 1/2$ in an external magnetic field (abscissa).

magnetic moment of the proton"; I. I. Rabi (1944) "for his application of the resonance method to the measurement of the magnetic properties of atomic nuclei"; P. Kusch (1955) "for his precision determination of the magnetic moment of the electron"; and W. E. Lamb (1955) "for his discoveries concerning the fine structure of the hydrogen spectrum."

A discussion of the energy levels of a simple atom and of one particular apparatus will illustrate the magnetic-resonance technique. An isolated atom in an external field, H, has energy states which are calculable from the Hamiltonian

$$\mathcal{H}/h\ (\text{Hz}) = a\mathbf{I}\cdot\mathbf{J} + b\ (\text{quadrupole operator}) - g_J(\mu_0/h)\mathbf{J}\cdot\mathbf{H} - g_I(\mu_0/h)\mathbf{I}\cdot\mathbf{H},$$

where some symbols have been defined previously, $g_J = \mu_J/(J\mu_0)$, $g_I = \mu_I/(I\mu_0)$, and μ_0 is the magnitude of the Bohr magneton. The first two terms represent the dipole and quadrupole hyperfine-structure interactions between the electrons and nucleus; the last two terms express the interaction of the electron and nuclear magnetic moments with the external magnetic field. For the simple case of $I = 1/2$, $J = 1/2$, $b =$

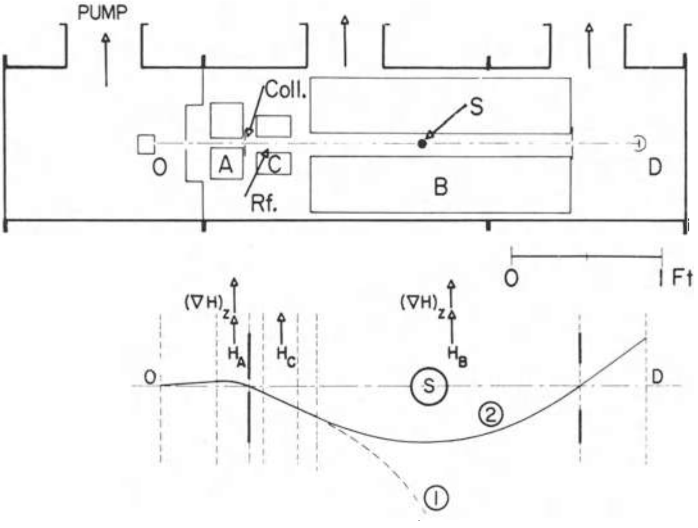

FIG. 2. Schematic of an atomic-beam, magnetic resonance apparatus.

0, as in the ground electronic state of atomic hydrogen, the energy levels that arise from different "relative orientations" of the nuclear (I) and electronic (J) spins are shown in Fig. 1 as a function of the magnetic-field parameter $X = [(-g_J + g_I)\mu_0 H]/\Delta W$. Here ΔW is the hyperfine-structure separation at $H = 0$. The levels are labeled by either the low-field quantum numbers (F, m_F) or by the high-field numbers (m_J, m_I), where $F = |I \pm J|$, and the m's are the projections of F, I, or J along the field direction.

Of the many magnetic or electric resonance apparatuses, one specialized type has proved valuable for measuring atomic properties of both stable and radioactive isotopes. In Fig. 2, the "oven" or source, O, may take one of many forms—a microwave discharge to dissociate gaseous diatomic molecules, a closed tantalum crucible (with an exit slit) heated by electron bombardment, or one of many other devices for evaporating atoms. The atoms pass between the poles of three separate electromagnets (denoted A, C, and B, successively, from oven to detector). The inhomogeneous A and B magnets have eccentric cylindrical pole tips which produce a field gradient, $\partial \mathbf{H}/\partial Z$. In this field, an atom experiences a force $\mathbf{F} = \mu_{\text{eff}}(\partial \mathbf{H}/\partial Z)$, where $\mu_{\text{eff}}(= -\partial W/\partial H)$ is the negative slope of an energy level in Fig. 1. Within the homogeneous C field, a superimposed rf field induces state changes. Thus an atom which remains in a single state [(1, 0) for example] is deflected similarly by the strong A and B magnets and follows trajectory 1 in Fig. 2. The stopwire, S, shields the detector from fast atoms and atoms with small deflections. If, in the C-field region, a transition occurs that causes the high-field slope $(-\mu_{\text{eff}})$ to change sign [e.g., $(1, 0) \rightarrow (1, -1)$], the A and B deflections are opposite, and the atom follows trajectory 2 to the detector D. A resonance is observed as an increase in beam intensity at the detector. Values of the constants in the Hamiltonian are deduced from the observed resonant frequencies of the atoms in known magnetic fields. Some detection methods in frequent use are:

(a) Deposition on a surface with subsequent assay by radioactive counting, neutron activation, or optical means (earliest detector).

(b) Ionization of alkali atoms on a hot tungsten wire, and measurement of the resulting ion current.

(c) Electron-bombardment ionization with subsequent mass analysis to discriminate against background gas ions. The beam ions are frequently counted by using electron multiplier tubes.

(d) Other detectors employing the principles of radiometers, pressure manometers, thermopiles, bolometers, laser fluorescence, and changes in space charge.

ATOMIC CLOCKS

Time Standards The concept of time has at least two distinct aspects: (1) duration (or time interval), and (2) date. Ordinary clocks can be used for either aspect, while stopwatches measure duration only. The concept of date includes not only the calendar day but finer subdivisions as well. For example, a date might be 10:27 AM EST, November 13, 1982. Both duration and date use the same set of units; that is days, hours, minutes, and seconds can refer to either date or duration.

Almost all clocks have three main parts: (1) A pendulum or other periodic phenomenon to control the clock rate; (2) a counting element to count the cycles of the periodic element just mentioned; and (3) a display mechanism to display the current count (i.e., time). Atomic clocks use natural resonances in atoms or molecules for the periodic part. It is possible to find natural resonances which are very insensitive to environmental conditions as well as being insensitive to the detailed construction of the clock. This allows independent laboratories to fabricate atomic clocks which agree in rate with other comparable clocks to within a few parts in ten to the 14th power.

The Early Atomic Clocks In 1949, Harold Lyons at the U.S. National Bureau of Standards announced the operation of the world's first atomic clock. This clock was based on microwave absorption in ammonia and was stable to about one part in a hundred million, which was roughly comparable to the best clocks of that time (pendulum and quartz).

In the 1950s and early '60s, scientists and engineers investigated various atomic and molecular resonances as well as various means of extracting the desired information to run a clock. In the mid 1940's, I. I. Rabi suggested using cesium in an atomic beam as a frequency standard. With innovations due to N. Ramsey, the essential design of the cesium beam clock was complete as we know it today, with, of course, numerous small refinements.

In the mid-'50s, C. H. Townes and others at Columbia University demonstrated the ammonia MASER (Microwave Amplification by Stimulated Emission of Radiation). In the early '60s, N. Ramsey and others developed the hydrogen maser. This maser is unique in that the hydrogen maser stores hydrogen atoms in a quartz bulb for periods of a second or so. This relatively long interaction time results in a very sharply defined resonance (i.e., a high Q). The hydrogen maser has demonstrated the highest frequency stability of any atomically controlled device for sampling periods out to a few hours. Even today, hydrogen masers are used in special applications where this high stability is needed. Because the hydrogen atoms collide with the walls of the quartz storage bulb, the hydrogen resonance is shifted. Various wall coatings have been used in attempts to avoid this and other problems, but so far the hydrogen maser has not been able to compete with the cesium beam device for absolute frequency accuracy.

Also in the '50s, scientists and engineers developed the rubidium gas cell. This device optically pumps rubidium atoms (contained in a sealed cell) to a higher energy state. A microwave signal relaxes the atoms to the lowest hyperfine level in the ground state provided this microwave signal is suitably close to the natural rubidium resonance. The resonance condition is sensed typically by monitoring the light from the optical pumping as a function of the microwave frequency. A buffer gas is added to the cell containing the rubidium vapor to reduce the effects of collisions with the cell walls. The commercial versions of rubidium devices are less expensive and less stable than cesium clocks, and typically display a systematic frequency drift. Still there are several thousand commercial rubidium cells in use today.

The Cesium Beam Atomic Clock In the mid-'50s commercial cesium beam clocks became available for the first time. The early versions were accurate and stable to about one part in ten to the tenth. Although expensive, several standards laboratories used them.

In a joint experiment between the US Naval Observatory (USNO) and the National Physical Laboratory (NPL) at Teddington, England, the frequency of the appropriate transition in cesium was measured in terms of the standard of the second as then defined (the Ephemeris Second). This experiment involved NPL's laboratory cesium frequency standard and USNO's determination of Ephemeris time. The experiment lasted about three years and resulted in a frequency value for cesium of 9,192,631,770 Hz. The accuracy was thought to be about one or two parts in ten to the ninth, due mostly to the difficulties in measuring Ephemeris time, not the cesium resonance.

In the '60s and '70s competing firms developed smaller and more advanced cesium beam models. Although the basic design remained about the same, the beam tube was made smaller and the electronics were reduced greatly in size with the advances in solid-state electronics. The performance of cesium clocks was close to the theoretical limits imposed by the granularity of the beam (i.e., "shot-noise"), and design limitations such as size, power, and reliability.

Several primary standards laboratories built laboratory versions of the cesium beam standard. The basic philosophy was to build a device which could allow the laboratory to measure any physical parameter which might possibly influence the frequency. Experiments were performed to test agreement of theory and performance of the standard. The laboratory then made a final accounting of uncertainties caused by such things as imperfect knowledge of the magnetic fields within the beam tube and many others. The resulting figure is an accuracy estimate of that laboratory's frequency standard. Historically, the individual accuracy estimates of the few primary frequency standards in existence have normally (but not always) been in accord with the measured differences between standards. Any disparity never has been really large.

On Friday, October 13, 1967, the General Conference of Weights and Measures (CGPM) announced a new definition of the second:

> The second is the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom. [13th General Conference of Weights and Measures (1967), Resolution 1.]

International Time Scales Historically, time has always been closely tied to the position of the sun in the sky. An ordinary sundial, for example, indicates apparent solar time. Keppler's laws allowed scientists to correct apparent solar time for the earth's elliptic orbit and the inclination of the earth's spin axis to the ecliptic plane (the plane of the earth's orbit). This correction is called the "Equation of Time," and can often be found engraved on sundials. These corrections amount to as much as plus or minus 15 minutes during the year. This corrected time is often called UT0, Universal Time, "zeroth" approximation.

Astronomers discovered that UT0 measurements at different observatories were not in agreement. This disagreement amounted to about ±30 milliseconds and was traced to the fact that the earth is not precisely fixed to its axis of rotation. That is, the pole wanders around within a circle of about 15 meters in diameter. Of course, the natural response was to correct time for the wandering of the pole. This new time was called UT1.

In the 1930s, scientists discovered that UT1 had periodic variations. Although corrections were applied to UT1 to get UT2, this latter time scale does not indicate the actual variations in the earth's rotation rate nor is it significantly more uniform than UT1. Today, one seldom hears of UT2.

Back near the turn of the century, Simon Newcombe, at the US Naval Observatory, computed a table of future positions of the sun, moon, and some of the principal planets for several years in advance. The computations were based on the best theories available. Such a table is called an "Ephemeris." Newcombe discovered, however, that the various celestial objects systematically departed from their predicted positions. He noticed that if the *time* were somehow in error, then the tables would be in good agreement for all of the objects. Newcombe correctly recognized that the earth's rate of rotation was not constant.

The natural response was to use the Ephemeris backwards. That is, when the sun reached its predicted position, the *time* was the value listed in the Ephemeris. Conceptually, this kind of time, called Ephemeris Time, is based on the orbital motion of the earth, and should be more uniform in its rate than the earth's rotation, since the earth can undergo geometrical changes that alter its rotational rate.

The definition of the second, the unit of measure in the International System (S.I.) of units, was defined as the fraction 1/86,400 of the mean solar day (24 X 60 X 60 = 86,400), prior to 1956. In 1956 the second was redefined as the fraction 1/31,556,925.9747 of the tropical year 1900. Since 1967, the definition of the second has been in terms of cesium, as noted above.

The definition of the International Atomic Time Scale (TAI) incorporates the definition of the second. The formal definition reads:

> International Atomic Time (TAI) is the time reference coordinate established by the Bureau International de l'Heure (BIH) on the basis of the readings of atomic clocks functioning in various establishments conforming to the definition of the second, the time unit of the International System of Units. [14th CGPM (1971), Resolution 1.]

International Atomic Time is a coordinate time scale. The reference elevation is mean sea level and frequency corrections are applied in transferring time measurements between laboratories. The largest gravitational "blue-shift" is 1. 8 parts in ten to the 13th for the National Bureau of Standards (elevation 1.7 km). Accurate and precise comparisons of time scales on an international basis now require relativistic corrections.

In spite of the importance of TAI, many operations require a time reference tied to earth position (i.e., UT1). Unfortunately, the earth is a poor clock compared to atomic clocks. Still, earth time is quite important. For example, small boat owners often use sextants for celestial navigation. For these purposes (and others), pure atomic time is not useful since it is not related to earth position. Beginning in 1972, nations agreed to a compromise time scale between the needs for atomic time and earth time. The compromise time scale, called Coordinated Universal Time (UTC), runs at precisely the same rate as TAI, but offset an integral number of seconds. When UT1 accumulates nearly an entire second error relative to UTC, the UTC clocks are reset one complete second, called a "leap second."

The rate of rotation of the earth is variable at a few parts in ten to the eighth. (Atomic clocks are almost a million times less erratic.) Unlike leap years, leap seconds are not predictable years in advance. Since 1972, eleven leap seconds have been added (Fall, 1982) to UTC; bringing the total time difference to 21 seconds. (TAI was set to agree with earth time January 1, 1958.)

The official time almost everywhere in the world is based on UTC, with an integral number of hours difference for the appropriate time zone.

Who Needs It? Many of the uses of precise time are related to distance measurements. In fact, a new definition of the meter is expected to be in terms of the distance traversed by a light wave in a specified fraction of a second. Thus, the cesium beam will be the standard for *both* the second and the meter. The speed of light then becomes a defined constant rather than a subject for measurement.

At this point, there are probably a few thousand commercial cesium beam devices in operation. They can be found in television stations, telephone control systems, NASA tracking stations, scientific laboratories, standards laboratories, and military systems, to name a few. The Department of Defense is currently developing a satellite navigation system, called the Global Positioning System (GPS), which is dependent on state-of-the-art timing systems. Atomic clocks are essential to the success of the GPS program.

Future Clocks For over 25 years now, the cesium beam frequency standard has surpassed all potential rivals. The accuracies specified by the national standards laboratories have steadily dropped to finer and finer tolerances. Today's standards (1982) quote accuracies of a very few parts in ten to the 14th. Still there are new potential rivals, as well as ideas to improve the cesium beam standard.

The leading candidate in several laboratories is trapped ions. The basic idea is to take a number of ions of some particular element and hold them in a Penning (or rf) trap. The trap can be arranged to cause only insignificant frequency shifts in the ions, and can hold the same set of ions for extended periods of time. This allows long interaction times with the interrogating signal and hence provides very narrow resonance linewidths.

A modification of the trapped ion method cools the ions to temperatures below one Kelvin. The cooling is accomplished by irradiating trapped ions with a laser set slightly below an optical transition frequency. The motion of warm ions will Doppler shift the laser radiation into resonance with the ion, and the ion will absorb a photon. At some time later, the ion will reradiate the photon in a random direction. The ions thus absorb photons with an energy bias below the ion's natural resonance frequency but reradiate photons with no such bias. The energy imbalance is supplied by the kinetic energy of the ions—thus cooling them.

In present atomic frequency standards, the motion of the atoms cause the primary limitations on improved accuracy. Although a lot of effort has been expended on attempts to cancel first order Doppler shifts, significant difficulties remain. Second order Doppler shifts are also significant. Laser cooling may solve both of these problems.

ATOMIC ENERGY

The terms "atomic energy" and "nuclear energy" are used interchangeably in the contemporary literature to mean energy that originates within the atomic nucleus. Events that release atomic energy involve basic changes in nuclear structure and result in the formation of one or more different nuclides, which may be isotopes of the original atom or altogether different elements. The release of atomic energy is thus a more fundamental process than the release of chemical energy, which merely involves a regrouping of intact atoms into different molecular forms.

To date, three basic atomic energy mechanisms have been exploited in practical applications: (1) the fission of certain heavy nuclides; (2) the fusion of certain light nuclides; and (3) the process of radioactive decay. These will be discussed in the order listed.

Fission In fission, a heavy nuclide splits into two lighter and predominantly unstable nuclides, commonly referred to as fission products, with the accompanying emission of several neutrons and the release of approximately 200 MeV of energy. Nuclides that readily undergo fission on interaction with low-energy or "slow" neutrons (< 0.5 eV) are referred to as fissile materials. There are three primary fissile materials:

(1) Uranium 235, which is a natural constituent of the uranium element and accounts for 0.71 per cent by weight of that element as found in nature.

(2) Plutonium 239, formed by neutron irradiation of uranium 238.

(3) Uranium 233, formed by neutron irradiation of thorium 232.

Uranium 238, which does not undergo fission on interaction with slow neutrons, does so on interaction with high-energy or "fast" neutrons (> 0.1 MeV). Table 1 lists representative fission energy distributions for the four nuclides cited.

A useful rule of thumb is that an energy release of 200 MeV per fissioning atom corresponds to an output of approximately one megawatt-day of thermal energy per gram of fissioned matter.

Practical applications of fission are based on the principle of a self-sustaining fission chain reaction, i.e., a reaction in which a neutron emitted by atom A triggers the fission of atom B, and one from atom B triggers the fission of atom C, and so on. For this to be achieved requires the assembly of a "critical mass" of fissile material, i.e., an amount sufficient to reduce the probability of neutron losses to a threshold value. The amount required depends on a number of factors, notably the concentration of the fissile material used and the composition and geometry of the reaction system.

There are two basic application concepts. One is the essentially instantaneous fission of a mass of highly concentrated fissile material in such a way as to generate an explosive force. This, of course, is what occurs in atomic weapons. Atomic explosives are also of interest in connection with peaceful uses such as large-scale excavation projects.

TABLE 1. ENERGY DISTRIBUTION IN FISSION

	Quantity of Energy (MeV)			
	Slow Fission			Fast Fission
Type of Energy	^{235}U	^{239}Pu	^{233}U	^{238}U
Kinetic energy of fission products	165	172	163	163
Kinetic energy of neutrons emitted	5	6	5	5
Instantaneous emission of gamma rays	8	7	7	7
Beta emission during fission product decay	9	9	9	9
Gamma emission during fission product decay	7	7	7	7
Total[a]:	194	201	191	191

[a] Exclusive of nonrecoverable energy associated with neutrino emission during fission product decay. All numbers are rounded to the nearest integer. It should be mentioned that 8 or 9 MeV of additional energy become available in a nuclear reactor as the result of neutron capture and subsequent gamma-decay phenomena.

The other application concept is that of the controlled and gradual fission of an atomic fuel in a nuclear reactor, which may be designed for one or more of the following principal purposes:

(1) To provide fluxes or beams of neutrons for experimental purposes. This category of use includes research and materials-testing reactors.

(2) To produce materials by neutron irradiation. Examples are reactors used primarily to produce plutonium for atomic weapon stockpiles or for the production of various radioisotopes for use in science and industry.

(3) To supply energy in the form of heat for such applications as the generation of electric power, the propulsion of ships or space vehicles, or the production of process steam.

The first demonstration of a fission chain reaction was achieved by E. Fermi and coworkers on December 2, 1942 when the world's first nuclear reactor (Chicago Pile No. 1) was successfully operated in a converted squash court beneath Stagg Field at the University of Chicago.

The most important application of fission promises to be in the electric power field. The basis for this expectation is that, if exploited efficiently, known and inferred deposits of atomic fuels represent a potential energy reserve many times larger than that of the fossil fuels (coal, oil and natural gas) on which the world's electric energy economy largely depends at present.

By the end of 1981 approximately 150,000 electrical megawatts of atomic power capacity were in operation, under construction, or planned for construction in the United States.

Fusion Fusion is a general term for reactions in which the nuclei of light elements combine to form heavier and more tightly bound nuclei with the simultaneous release of large amounts of energy. In order for this to occur the interacting nuclei must be brought sufficiently close together to permit short-range nuclear forces to become operative. This means that one or both nuclei must be accelerated ("heated") to velocities sufficient to overcome the strong electrostatic repulsion that exists between particles having the same electrical charge. The velocities required correspond to particle "temperatures" of the order of tens or hundreds of millions of degrees, which in turn correspond to particle energies of thousands or tens of thousands of electron volts. The term "thermonuclear" reactions is reserved for fusion reactions in which both nuclei are traveling at high velocity (as distinct from reactions between an accelerated projectile particle and a static target nucleus, as in particle accelerator experiments).

The only practical application of thermonuclear reactions developed to date is in thermonuclear weapons (so-called "hydrogen bombs") in which the energy released by a charge of fissile material serves to create the conditions required to bring about the reaction of "fusionable" materials. The first test of a thermonuclear weapon, which was the first demonstration of a man-made thermonuclear reaction, took place on October 31, 1952 at a U.S. testing site in the Marshall Islands. Peaceful uses of thermonuclear explosives are being studied and have the advantage, relative to straight fission-based explosives, that problems of radioactive contamination are greatly reduced. This reflects the fact that the nuclides formed by fusion are stable and hence, apart from neutron activation effects, the formation of radioactive substances is limited to the fission component of the explosive.

Research has been in progress for two decades on techniques for controlling the fusion process as a means of supplying energy for electric power generation. The thermonuclear reactions of primary interest in this context are the deuterium-tritium reaction:

$$D + T \rightarrow {}^{4}He + n + 17.6 \text{ MeV}$$

and the deuterium-deuterium reactions:

$$\mathrm{D} + \mathrm{D} \begin{array}{l} \nearrow {}^3\mathrm{He} + n + 3.2\ \mathrm{MeV} \\ \searrow \mathrm{T} + p + 4.0\ \mathrm{MeV} \end{array}$$

Deuterium is a stable isotope of hydrogen with a natural abundance of 0.0015 per cent. Tritium is an unstable hydrogen isotope with a radioactive half-life of 12.3 years and is produced from lithium 6 by the neutron-alpha reaction. The latter thus represents a relatively expensive "fuel" for thermonuclear reactions; however, the ignition temperature of the deuterium-tritium reaction is roughly an order of magnitude lower than that of the deuterium-deuterium reactions and the energy release is greater.

In most controlled fusion systems as presently conceived, the fuel is in the form of an ionized gas, or "plasma," confined by magnetic pressure within a high-vacuum apparatus. In effect, the plasma is held in a "magnetic bottle," thereby preventing fuel particles from dissipating heat in collisions with the physical walls of the apparatus. The objective is to achieve a situation in which an adequately hot plasma of adequate density can be magnetically confined for a long enough interval of time for the desired reaction to take place. One approach is to constrict and confine a high-current discharge of fuel ions and hold the resulting dense plasma in confinement while its temperature is raised by adiabatic compression or other methods. Another approach is to accelerate fuel ions to high energies and then trap them in a magnetic field, maintaining confinement long enough for a dense plasma to accumulate.

In experiments in various experimental devices, the time-temperature-density multiple has steadily been increased; however, there appears to be no conclusive evidence that true thermonuclear conditions have been achieved in any laboratory. Beyond laboratory demonstration of controlled fusion per se lies the problem of demonstrating that devices can be designed to produce more power than they consume and beyond that lies the problem of demonstrating the economic feasibility of practical thermonuclear power plants.

The chief incentive for thermonuclear power development is the promise of a virtually inexhaustible energy source, assuming the ultimate use of deuterium as the primary fuel.

Radioactive Decay As radioactive atoms undergo decay by alpha, beta or gamma emission, heat is generated by the interaction of the radiation with surrounding matter. Devices that utilize this heat to produce electricity are known as isotopic power generators. Research has been conducted on a range of such devices for specialized applications requiring from fractions of a watt to tens of watts of electricity. Thermoelectric or thermionic techniques are used to convert the heat to electricity. At present, isotopic power generators are being used on an experimental basis in a number of applications such as navigational satellites, automatic weather stations and coastal light buoys, all of which require a compact power source that can operate unattended for sustained periods (months or years). In the case of space applications, alpha-emitting radionuclides such as plutonium 238 or curium 244 are mainly used as the fuel. In terrestrial applications, the principal fuel used to date is strontium 90, a beta emitter.

ATOMIC PHYSICS

Throughout the twentieth century the study of atoms, their internal structure and their interaction with electromagnetic radiation and with other particles has played an important part in attempts to understand the physical world. The subject of atomic physics has been the testing ground of fundamental theories and at the same time the source of many applications.

The concept of an atom as an indivisible particle, the ultimate building block of bulk matter, is attributed to the ancient Greeks. During the nineteenth century such atoms, of which it was recognized that there had to be many different kinds, were identified with the chemical elements of the periodic table. But the era of modern atomic physics may be said to have begun with two discoveries, that of the electron and that of the nuclear atom. The idea of the indivisible atom was to be abandoned.

The first discovery was made in 1897 by J. J. Thomson, who was able to isolate an electrically charged particle, an electron, and to measure the ratio of its charge e to its mass m. Following his work it came to be believed that electrons were constituents of atoms. It was a little later that R. A. Millikan measured directly the electron charge itself: this charge e was the same for all electrons (by convention, it is taken to be negative). The two results taken together led to the conclusion, already guessed at, that the mass of the electron is only about 1/2000 of the mass of a hydrogen atom, the lightest element in the periodic table.

The second discovery was made by Sir Ernest Rutherford in 1911. At his instigation Geiger and Marsden carried out experiments in which alpha particles (which are positively charged) were scattered from thin foils. The result, very surprising at the time, that many alpha particles were scattered through large angles was explained quantitatively by Rutherford. He concluded that the mass of an atom of the foil is concentrated in a nucleus whose radius is of the order of 10^{-14} m, very much smaller than the radius of an atom, 10^{-10} m, and that the nucleus carries a positive charge Ze where Z, an integer, is the atomic number appropriate to the ordering of chemical elements in the periodic table. The model of a neutral atom, then, is that it consists of a small massive nucleus of positive charge Ze surrounded by Z electrons, each of negative charge e, filling a much larger volume. Electrostatic forces bind the whole thing together.

However, the nuclear atom, resembling a miniature solar system, would not be stable according to the laws of classical physics because the orbiting electrons, being charged, would emit electromagnetic radiation in a continuous spectrum of frequencies, lose energy and spiral into the nucleus. This does not happen: atoms are stable. It is true that they can emit radiation, but only when they are given enough energy, for example when free atoms are bombarded by electrons in a light source such as an electric arc. The emitted spectrum consists not of a continuous frequency distribution but rather of discrete frequencies characteristic of a particular atom. Spectroscopists working in the nineteenth century had studied these "spectral lines," many of which appear as light in the visible region, and had measured their frequencies with considerable precision. So more than one difficulty was raised by the model of the nuclear atom, and the problem was tackled in 1913 by Niels Bohr. He had at his disposal the concept of a "quantum" of energy of radiation which had arisen in Planck's treatment of blackbody radiation and in Einstein's theory of the photoelectric effect. A quantum of radiation has energy $E = h\nu$ where ν is the frequency of the radiation and h is a universal constant known as Planck's constant, having the value 6.626×10^{-34} J Hz^{-1}. Bohr developed a set of rules which required the angular momentum of the orbiting electron in hydrogen to be "quantized," that is, to have only integral values in units of $h/2\pi$. It followed that the energy of the atom was also quantized with the consequence that the frequency of emitted radiation had to satisfy the relation $h\nu = E_m - E_n$ where E_m and E_n are the discrete allowed energies of the mth and nth "energy levels" of the atom. Bohr's calculation of the allowed frequencies in the spectrum of atomic hydrogen, based on the mechanics of his model, agreed with precise spectroscopic measurements. This was a brilliant achievement.

Yet Bohr's calculations only worked well for hydrogen, the one-electron atom. Further, there was still no adequate explanation for the stability of the lowest energy level nor for the rate at which radiation would take place when an atom decayed from a higher level to a lower one. Even more difficult would be the attempt to predict in detail what would happen in an electron-atom or atom-atom collision. Whereas the idea had already been grasped that a light wave, through its quantum nature, can have the feature of a particle, namely localization in space, what was missing was the equally extraordinary idea that a particle, say an electron, can have the feature of a wave—a spreading-out in space. The latter idea was put forward by Louis de Broglie in 1924: he attributed to a particle of momentum p a wavelength $\lambda = h/p$. Planck's constant appears again in this relation and its size is crucial: electrons bound in atoms have momentum such that their de Broglie wavelength λ is of the order of the size of the atom. These electrons are only localized to the extent that they are somewhere inside the atom, which is now visualized as a nucleus surrounded by an electron charge cloud having no well defined boundary.

These quantum ideas were put into mathematical form in 1925. Schrödinger's wave mechanics of matter was soon generalized in the formal theory of quantum mechanics by Born, Heisenberg, Dirac and others. Quantum mechanics, which includes the famous Uncertainty Principle, is the basis for all calculations of physical problems in which the magnitude of Planck's constant cannot be considered to be negligible, and by this criterion the theory is certainly needed to describe atomic physics. The birth of quantum mechanics has been a revolution in the theory of physics, and this revolution has had in its turn a profound influence on philosophical thinking.

The hope that one now understands the principles of atomic physics is one thing, but the task of making quantitative predictions is another, for it involves making detailed calculations which are especially difficult in many-electron atoms. Fortunately, approximation methods can be used in treating the forces which govern atomic structure, at least in simple atoms with few electrons. The largest forces are the electrostatic attraction between nucleus and electrons, and the electrostatic repulsion between the electrons themselves. These are dealt with first. Electrons are found to have, in addition to their charge, an intrinsic angular momentum (called electron spin) together with an associated magnetic moment. The interaction between this magnetic moment and the magnetic field which an electron experiences within an atom is a small perturbation in our hierarchy of approximations. This effect leads to a "fine-structure" splitting of the energy levels of an atom. Even smaller is a "hyperfine-structure" splitting which arises from the interaction between the electron and the magnetic moment with which the nucleus is endowed (the nucleus, too, has the property of spin angular momentum).

On the theoretical side the aim has generally been to calculate the energies of excitation available to an atom in terms of all the interactions mentioned above, along with other properties such as the average lifetime of an excited atom before it decays to a lower energy state, emitting electromagnetic radiation (typical lifetimes are of the order of 10^{-8} s). In all this the role of the modern computer has been important, especially for many-electron atoms whose complexity would otherwise present intractable problems. On the experimental side there have been two main ways of approaching the study of atomic structure. One is by measuring the frequencies and intensities of spectral lines (spectroscopy) and the other is by causing collisions between atoms and particles—electrons or other atoms, for example. Whereas optical spectroscopy had been a traditional experimental discipline since the middle of the nineteenth century and collision physics began in the 1920s, both experimental approaches enjoyed the benefits of the enormous technical advances made during and after the Second World War.

The ever increasing precision of spectroscopic methods has had important consequences. One of these is exemplified by the Lamb-Rutherford experiment (1950) which is justly famous not only because it was a tour-de-force of experimental technique but also because it played a central part in an effort to develop a new and deeper understanding of physics—always the primary goal. Lamb adapted the methods of radio-frequency spectroscopy to measure the small separation between two energy levels in the lowest excited state of atomic hydrogen, a separation subsequently called the "Lamb shift." Even the sophisticated relativistic quantum mechanics developed by Dirac had not predicted a Lamb shift. The theory of quantum electrodynamics (also initiated by Dirac in 1927), in which electromagnetic fields were taken to be quantized, was needed to explain the Lamb shift, and it was Lamb's precise experiment which stimulated efforts to make accurate calculations from the theory. Quantum electrodynamics is regarded as a striking success because of its ability to achieve precise agreement (parts in 10^6) between theory and experiment in the interaction between radiation and matter. The theory is also the forerunner of more general quantum-field theories needed in the attempt to understand elementary particle physics.

The particular radio-frequency method to which Lamb's experiment is related is called atomic-beam magnetic resonance. This has been developed by I. I. Rabi and his co-workers, beginning in 1938, and has been very fruitful. The method ensures, in an especially elegant way, that the frequency of the peak of a spectral line can be measured accurately because the frequency bandwidth of the line is made very narrow. Moreover, the atoms, which are made to travel as a directed beam through a vacuum, do not collide with each other and so may be regarded as completely unperturbed by their neighbors: they interact only with the applied radio-frequency field. By this method a large number of measurements, particularly of hyperfine-structure splittings, have been made in nearly all the elements. Such work provided a body of data on nuclear spins and nuclear moments at a time when nuclear physicists could make good use of it in constructing models to describe the nucleus; the precise measurement of hyperfine structures also led to a better quantitative understanding of the behavior of the atomic electrons when they are close to the nucleus.

Technological developments soon followed. The hyperfine structure of the lowest energy level of cesium could be measured so precisely and reproducibly that a cesium atomic-beam apparatus was adopted as a time standard, that is, the second is now defined in terms of the frequency of an atomic clock:

$$\Delta\nu(\mathrm{Cs}) = 9\ 192\ 631\ 770\ \mathrm{Hz}.$$

During this period of prolific activity in the 1950s the maser was invented. The first maser was made to work by Townes and his colleagues in 1954 and subsequently many other workers contributed to the development of various kinds of maser. This device (the word is an acronym for *m*icrowave *a*mplification by *s*timulated *e*mission of *r*adiation) relies for its operation on the maintenance, in a dynamic equilibrium, of a population inversion in an assembly of atoms: this means that, given two energy levels of an atom, there are more atoms in the upper level than in the lower. In this way it is possible to make an oscillator tuned to the frequency of an atomic spectral line. A particular version, the hydrogen maser developed by Ramsey, has led to a measurement of the hyperfine structure in the lowest level of hydrogen which is utterly remarkable for its precision:

$$\Delta\nu(\mathrm{H}) = 1\ 420\ 405\ 751.7662 \pm 0.0030\ \mathrm{Hz}.$$

An optical analog of a maser, called a laser, was first made to work in 1960. It is not an overstatement to say that the laser, in its various forms, has brought about a revolution in optical technique. For example, the use of a dye laser, which is a tunable, nearly monochromatic, powerful light source, is now widespread in spectroscopic work. Many new experiments requiring high resolution and high power have been performed on atoms and molecules and many more are likely to be performed during the 1980s. Just one example of new work is that on very highly excited levels of neutral atoms. These so-called Rydberg atoms may be regarded as being very large in the sense that the outermost electron has a large "orbit" of the order of 10^{-6} m radius, and they are also fragile because only a tiny perturbation is required to ionize them.

The study of controlled bombardment of atoms (or molecules) by other particles, in particular electron-atom, atom-atom and ion-atom collisions, has had a development parallel to that of spectroscopy. The experiments have to be most carefully performed because, in obtaining quantitative results on the behavior of a variety of atoms undergoing collisions, it is necessary to distinguish one of several possible processes from another. For example, electrons used as bombarding particles may be scattered by atoms, they may excite them, they may ionize them and they may be captured by them. Reliable results on the probability of such events have to be achieved over a wide range of bombarding energies with good resolution. Only then can they be used both as a severe test of the quantum-mechanical description of atoms and as a means of understanding the collision processes occurring in more complicated environments.

Naturally, refinement of experimental technique has brought progress in many different directions. For example, as a result of the pioneering work of Dehmelt on ions trapped in electromagnetic fields it has become possible to study a single, isolated ion trapped for several hours on end—a remarkable feat. Some modern work has overlapped other fields: tests of fundamental symmetry principles and conservation laws, often regarded primarily as the concern of high-energy particle physicists, have been conducted by means of ingenious experiments on atoms; and close to the interests of nuclear physicists has been the study of "exotic atoms," those containing unstable particles playing the role of nucleus or electron, for example positronium, muonium, muonic and kaonic atoms.

Atomic physics is an applied science in the sense that in other branches of physics it is necessary to know about atoms. Obviously the astrophysicist needs to know about lifetimes and structures of excited states of atoms because he is trying to learn about a source of radiation (a star) which is in no way under his control! Similarly the study of atmospheres, both planetary and stellar, relies heavily on the results of collision physics and of spectroscopy conducted in the laboratory, as does work on plasmas associated with nuclear fusion. Solid-state physicists clearly must understand the atoms which are the components of their assemblies of interacting systems. None of these other fields can be thought of as divorced from atomic physics itself.

ATOMIC SPECTRA

Fundamental Facts Light from electric discharges in gases shows *line spectra* due to free atoms excited by electron collisions. Noble gases and metal vapors produce almost pure atomic spectra, while discharges in molecular gases show both molecular *band spectra* and atomic line spectra. Some spectral lines can also be observed in absorption when white light is made to pass through the gas into a spectroscope. Under high spectroscopic resolution, all lines are found to have nonzero width. This is due to random motion (DOPPLER EFFECT) and disturbing influences of neighboring atoms, molecules, ions or electrons (pressure broadening); but even after allowance for these effects, a spectral line has a definite, generally very small, width due to radiation damping (natural width). Precision measurement of wavelengths or resolution of very fine structures requires light sources giving narrow lines—discharges at low gas- and current-density and low temperature—or even atomic beams at right angles to the line of sight. *Continuous* atomic spectra are generally weak under laboratory conditions; in emission, they are due to recombination of an electron with a positive ion; in absorption, to the reverse process of *photoionization*.

The term atomic spectra includes positive ions, with the following terminology: spectrum of Na, *arc spectrum*, NaI; of Na^+, Na^{++}, · · · : first, second, · · · *spark spectrum*, or NaII, NaIII, · · · . Spectra of highly ionized or *stripped* atoms are important in astrophysics and occur in high-temperature plasmas. Systems with the same number of electrons, such as Na, Mg^+, Al^{++} show marked similarities and are called *iso-electronic* sequences.

In the ultraviolet, visible or infrared, the spectroscope, in the form of a grating or interferometer, measures primarily the wavelength (λ) of the spectral lines. It is generally expressed in angstrom units (Å) defined as 10^{-8} cm (10 nm) or, by recent international convention, the fraction 1/6056.12525 of the wavelength of a line of the isotope 86 of krypton, in air under standard conditions. The wave number ($\tilde{\nu}$ or σ), the reciprocal of the wavelength in vacuo, is measured in cm^{-1} or kayser (K), or in millikayser (mK). The frequency ν is derived by multiplying by c, the velocity of light in vacuo; in the range of microwaves and radio frequencies, ν is measured directly (1 mK = 29.9793 MHz).

In contrast to frequencies, intensities of lines are strongly dependent on experimental conditions, and special experiments are required for deriving quantities expressing the strength of a line as a characteristic constant of the atom. This can be defined in various forms; the *f*-value is a number giving the ratio of the absorptive or dispersive power of the line to that of the classical, harmonic electron oscillator of the same frequency; the transition probability or Einstein *A*-value is the probability, per second, of an excited atom emitting a light quantum.

Hydrogen-like Spectra The spectra of atoms containing one electron only (H, He^+, $Be^{++} \cdots$) are very simple if the fine structure is disregarded; they form the basis of the classification and theory of atomic spectra. Balmer's empirical discovery of a numerical relationship between the wavelengths of the visible hydrogen lines led to a formula expressing the wave numbers of all hydrogen-like spectra by one constant R, the charge number Z (=1 for H; =2 for He^+, $\cdots$) and two integral numbers, $n, n' > n$:

$$\tilde{\nu} = Z^2R(1/n^2 - 1/n'^2) = T_n - T_{n'} \qquad (1)$$

A *series* arising from a sequence of values n' is characterized by regularly decreasing spacings and intensities of the lines towards increasing wave numbers. Substitution of $n = 1, 2$ and 3 in Eq. (1) with $Z = 1$ gives the Lyman, Balmer and Paschen series, in the ultraviolet, visible and near infrared respectively. The wavelengths of the Balmer lines, H_α, H_β and H_γ ($n' = 3, 4, 5$) are 6562.8, 4861.3 and 4340.5 Å. The Lyman α line, the *resonance line* of hydrogen, has the wavelength 1215.7Å.

The relation of Eq. (1) can be derived theoretically by applying nonrelativistic quantum theory to a model consisting of a point electron of mass m and charge $-e$ and a fixed point nucleus of charge Ze. In the *Bohr-Sommerfeld* theory, this is done by imposing quantum conditions on the classical orbit of the electron; in the more rigorous Schrödinger theory, by solving the wave equation with the assumption of constant energy E. Provided $E < 0$ (bound state), it assumes discrete values, those of the stationary states of motion or the *eigenvalues* of the wave equation. Emission and absorption arise from transitions between two *energy levels* E_n, $E_{n'}$, with the frequency of the light given by

$$\nu_{n,n'} = (E_{n'} - E_n)/h \qquad (2)$$

where h is Planck's constant. Equation (1) is a special case of Eq. (2), with $E_n = -hZ^2Rc/n^2$. Allowance for the motion of the nucleus of finite mass M causes R to differ slightly for different M; it is given by $R_\infty/(1 + m/M)$ where $R_\infty = 109737.3\ cm^{-1}$.

The solution of the SCHRÖDINGER EQUATION for a mass point in space leads to 3 quantum numbers. In polar coordinates, with a force derived from a central potential $V(r)$, the quantum numbers n_r, μ and m give the numbers of nodes of the wave function in the range of the coordinates r, ϑ and φ. Introducing the *azimuthal quantum number* $l = |m| + \mu$ and the *principal quantum number* $n = n_r + l + 1$, we find the set n, l, m to have the following meaning: the z-component of the angular momentum is $L_z = m\hbar$, where $\hbar = h/2\pi$, the square of its absolute value is $|\mathbf{L}|^2 = l(l+1)\hbar^2$, and the energy E depends on n and l only. For the special case of the Coulomb field $V \sim 1/r$, E depends on n alone: $E_n = \text{constant}/n^2$. An energy level E_n has to be considered as consisting of a number g of *states* of different l and m. This situation is described as *degeneracy*, and g is the *statistical weight* of the level. The degeneracy in m is due to the central symmetry of the force field and occurs in all atoms in the absence of external fields. The degeneracy in l is peculiar to the Coulomb field in nonrelativistic treatment.

Alkali-like Spectra The spectra of the alkali atoms and their isoelectronic ions (Li, Na, $\cdots$, Be^+, Mg^+, $\cdots$) show lines arranged in series similar to those of hydrogen. Their wave numbers can be represented by empirical relations which are generalizations of Eq. (1). Series of term values T_n can be defined in such a way that $T_n \rightarrow 0$ for $n \rightarrow \infty$, and the observed wave numbers are equal to term differences $T_n - T_{n'}$ (Ritz combination principle). In contrast to Eq. (1), however, there are several series of terms, so that apart from n, a second index number l has to be introduced. The term values $T_{n,l}$ can then be identified with quantized values of $-E/ch$ and the index numbers n and l with quantum numbers, as implied by the letters chosen, if we assume that in these atoms one electron moves in a central force field different from a Coulomb field. This *valency* or *optical* electron has to be imagined as more loosely bound than the others and moving in the field of electrostatic attraction by the *core* consisting of the nucleus of charge Ze and the remaining $Z-1$ electrons. At large distances from the core, the field is like that caused by a single charge e as in hydrogen. At smaller distances, the optical electron penetrates into the electron cloud of the core and experiences an increased attraction. This picture leads to a qualitative understanding of the term diagrams and spectra of alkali atoms as exemplified for Na in Fig. 1, where terms with $l = 0, 1, 2, 3, 4, \cdots$ are conventionally described as $S, P, D, F, G, \cdots$ terms. For any given n, an energy level is the further below that of hydrogen (the term value the larger) the smaller l becomes, because a smaller angular momentum decreases the centrifugal force and brings the electron closer to the core. Emission or absorption of radiation according to Eq. (2) does not occur for all pairs of levels but is subject to the *selection rule* $\Delta l = \pm 1$. Transitions from P levels to the lowest S level form the *principal series.* Its lines can also be observed in absorption since the lower level is the ground level; the first member is the well-known yellow *resonance* line. Transitions from D or higher S levels to the lowest P level form the *diffuse* and *sharp* series, those from F levels to the lowest D level, the Bergmann or *fundamental* series.

A feature that cannot be explained by this model is the *doublet* structure, a doubling of all except the S levels. It is due to the fact that the electron possesses a *spin*, i.e., an intrinsic angular momentum $\mathbf{S}$ of fixed absolute value given by $|\mathbf{S}|^2 = s(s+1)\hbar^2$, where $s = \frac{1}{2}$, and connected with a magnetic dipole moment μ. The interaction of μ with the magnetic field due to the orbital motion, the *spin-orbit coupling*, causes any one energy level of given n and l (except for $l = 0$) to split into two levels. They are characterized by a new quantum number j associated with the total angular momentum resulting from vector addition of $\mathbf{L}$ and $\mathbf{S}$. It can have the two values $j = l \pm s = l \pm \frac{1}{2}$. Optical transitions are subject to the selection rule $\Delta j = \pm 1$ or 0. The width of the doublet splitting increases with core penetration and thus with decreasing l; it is most prominent in P terms. It decreases rapidly with increasing n and increases from Li to Cs. In the term symbol, j is written as suffix and the doublet character is indicated by superscript 2. For example, two transitions forming the yellow resonance doublet of Na are written $3^2S_{1/2} - 3^2P_{1/2}$ and $3^2S_{1/2} - 3^2P_{3/2}$. The absolute value of n (= 3 in this case) can be deduced by comparison with hydrogen (Fig. 1).

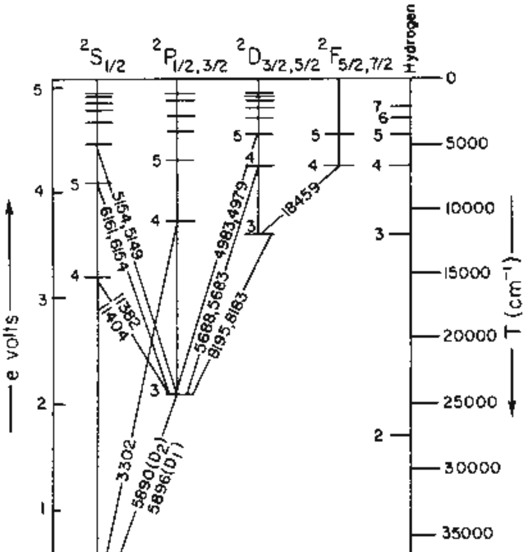

FIG. 1. Term diagram of Na. Approximate wavelengths in angstroms. The doublet splitting of the terms is not shown.

Since for all term values $T_n \to 0$ for $n \to \infty$, the extrapolation of a series $T_n - T_{n'}$ for $n' \to \infty$ gives the term value T_n. If this is the ground term, chT_n is the ionization energy of the atom. A convenient conversion formula is 8066 cm^{-1} = 1 eV.

Under high resolution, hydrogen-like spectra are found to have a rather complex structure known as *fine structure* (the same name is often applied to the much wider doublet or multiplet structures); it can be explained by a relativistic velocity dependence of the electron mass removing the degeneracy of states of different l, and by magnetic spin-orbit coupling causing a doublet splitting. In fact, these two effects are related since the spin itself is relativistic in origin. The theory gives the result that a hydrogen level of given n depends on j only, so that, e.g., $n = 2, l = 0, j = \frac{1}{2}$ should coincide with $n = 2, l = 1, j = \frac{1}{2}$. In fact, such terms show a small difference known as *Lamb shift.* Its existence can be explained by quantum electrodynamics.

A more complete description of the state of an alkali atom has to treat the core as a dynamical system of many particles. This cannot be done rigorously, but as a useful zero-order approximation, quantum numbers n and l can be assigned to individual electrons; in extension of the symbolism used before, values $l = 0, 1, 2 \cdots$ for individual electrons are described by small letters $s, p, d \cdots$, and the number of electrons of the same n and l, called *equivalent* electrons, by a superscript. Thus two $2p$-electrons ($n = 2, l = 1$) are said to form the *configuration* $2p^2$. The number of equivalent electrons in one atom is limited by the *Pauli principle* to $2(2l + 1)$, i.e., to 2 for s-electrons, 6 for p-electrons and 10 for d-electrons. When this limiting number is completed, a closed *subshell* is said to be formed. Thus the 10 electrons of the atom Ne form the three closed subshells $1s^2$, $2s^2$, and $2p^6$, and the entire atom contains the two closed shells $n = 1$ ($1s^2$) and $n = 2$ ($2s^2 2p^6$). The same applies to the 10 electrons forming the core of the atom of Na.

In a complete subshell or shell the orbital angular momenta of the electrons cancel one another out, as do the spins of the individual electrons; the total charge distribution has spherical symmetry. In an alkali atom the quantum numbers l and s of the outer electron therefore determine the orbital- and spin-angular momentum of the entire electron structure of the atom. The ground level of Na, e.g., can be described either as an s-level or an S-level, since $L = l = 0$.

The classical concept of the core as a *rigid* charge distribution is expressed by the assumption that the quantum numbers of the core electrons remain constant during the excitation of the outer electron.

Other Simple Spectra Helium, and also Li^+, Be^{++}, · · · , have two electrons, and the atoms in the second column of the periodic table Be, Mg (also B^+, Al^+, · · ·) have two electrons outside closed shells. The analysis of the spectra leads to two systems of terms, *singlets* and *triplets*, with only weak intercombinations; the S terms are single also in the triplet system. These facts can be formally described, in analogy to alkali spectra, by vector addition of the two spins to form the two possible resultant spin quantum numbers $S = 0$ and 1. The first alternative produces singlets ($j = l$), the second triplets ($j = l - 1$, l, $l + 1$) unless $l = 0$. This implies a strong interaction forming the resultant S of the two spins and a weaker interaction forming j. The latter interaction is the same magnetic spin-orbit interaction that causes doublet splitting in alkali atoms, but the former is, in a less obvious way, due to the *electrostatic repulsion* between the two electrons. In all the terms concerned, the symbol for the configuration shows only *one* electron to be excited, e.g., $1s2p$ in He, but owing to the identity of the electrons, it is not possible to attribute the excited state $2p$ to one particular electron. The situation is analogous to that of two identical, coupled, linear oscillators showing two normal modes of vibration, each involving both oscillators in a *symmetrical* and *antisymmetrical* way. Application of Pauli's principle to the wave mechanical description of this two-electron system leads to two energy states, one with parallel and one with anti-parallel spins, $S = 1$ and 0 respectively. Elements in the subgroup (Zn, Cd, Hg) show similar singlet and triplet spectra; in the heavier elements, however, the magnetic spin-orbit interaction is no longer weak compared with the electrostatic repulsion, and the division into singlet and triplet terms has a very restricted meaning.

In the elements of the third column, B, Al, Ga, In, Tl, the single electron outside a closed subshell produces doublet spectra, but in contrast to the alkali spectra, the ground term is a P term.

Complex Spectra The assumption that the quantum numbers n and l of only one of the electrons outside closed shells change in emission or absorption of a spectral line forms a good approximation for most of the strongest spectra in the optical range, from near infrared to near ultraviolet. Somewhat arbitrarily but conveniently one can define complex spectra as those in which more than one electron outside closed subshells assumes a value of $l > 0$. One then has to consider the interaction of more than two angular momentum vectors of orbits and spins, and a simple interpretation in terms of a vector model is meaningful only in certain limiting conditions. Very often, especially in low-lying levels, a description in terms of the Russell Saunders coupling scheme (L, S coupling) is possible because the electrostatic interaction predominates over the magnetic spin-orbit interaction. As a result, we can define *terms*, each of which is characterized by a set of values L, S (or a multiplicity $2S + 1$), and each term is split into *levels*, each characterized by a value of j, the highest of which is equal to $L + S$. The classification and terminology are obvious generalizations of those for two-electron spectra. For configurations of 3; 4; 5 electrons the possible multiplicities are respectively: doublets and quartets; singlets, triplets and quintets; doublets, quartets and sextets, etc. The strongest lines arise from transitions between terms of the same multiplicity. Such line multiplets are often recognizable by their characteristic groupings of the lines and their intensity ratios. The level spacings are governed by the *interval rule*: they are in the ratio of the j values, e.g., the levels of ${}^4D_{7/2,5/2,3/2,1/2}$ have spacings in the ratio 7:5:3:1.

Other, often much more complex forms of coupling occur, especially in the higher levels, and L and S then lose their meaning. One important property of any level which always remains well defined is the *parity*, and the *Laporte rule* states that even terms combine only with odd terms and vice versa. If the configuration is defined, a level is *even* or odd if Σl is even or *odd*. As one proceeds to higher levels or to heavier elements the concept of the configuration becomes less distinct. A given energy level may still be said to belong to a certain configuration, but a more accurate description often requires the inclusion of one or more other configurations of the same parity in the form of a *perturbation*. In other cases the *configuration interaction* is so strong that even the lowest approximation has to be based on the concept of mixed configurations.

Hyperfine Structure (hfs) and Isotope Shift These structures are usually of the order of fractions of 1 cm^{-1} and generally require interferometric methods for their study. Hyperfine structure is primarily due to the magnetic interaction of the nuclear magnetic moment μ_N with the field produced by spins and orbital motions of the electrons. A level of given j splits into hyperfine levels, each characterized by a quantum number F, where F can assume the values

$j+I, j+I-1, \cdots, |j-I|$. The nuclear spin I is a characteristic property of each nucleus and has integral or half-integral values for even or odd values of the atomic number. The structure of hyperfine multiplets is similar to that of fine structure multiplets, with F, I, j taking the place of j, S, L. However, there is often also an electrostatic interaction between the electrons and the nucleus if the nuclear charge distribution has no spherical symmetry. Deviations from the interval rule in hyperfine multiplets have led to the discovery of such nuclear deformations described mainly by the *quadrupole moment* Q. Hyperfine structures in ground states can be measured very accurately by methods of atomic beam resonance. Hyperfine structure studies lead to values of I, approximate values of μ_N and Q, and accurate values for the ratio of the two latter for different isotopes.

For different isotopes of an element the spectral lines, or the centers of gravity of their hyperfine multiplets, are often displaced against each other; this *isotope shift* has two quite different causes. The atomic nucleus, though heavy, does not stay at rest during the motion of the electrons, and its mass has a small influence on the energy levels, thus causing a *mass shift* between lines of different isotopes. For atoms with only *one* electron such as H or He$^+$, the effect is fully described by a factor $1/(1 + m/M)$ in the term values. For other spectra this factor, often referred to as normal mass shift, is at best a rough approximation; the influence of the other electrons is rarely negligible and not easy to calculate. All mass shifts, however, depend on M in a regular, monotonous way for any given spectral line, and are generally much *smaller* for heavier elements. These facts often allow them to be separated from the more important *field shifts* (or volume shifts) which markedly *increase* with atomic weight in the list of elements, a fact pointing to the nonzero size of the nucleus as a cause. Within the volume occupied by the nuclear charge, the electrostatic attraction acting on the electron is much smaller than that caused by a positive point charge. This raises the energy levels compared with their fictitious values for a point nucleus. For any two isotopes, the difference in neutron number and the resulting difference in nuclear size or shape leads to a difference of the *energy levels*. In the transition to another term, a *line shift* between the two isotopes is then observed, equal to the *difference* of the level differences. The field shift of levels is particularly large for *s*-electrons, ($l = 0$), on account of their high probability density near the center, and the observed line shift is therefore large in lines involving transitions of one or two electrons from their *s*-states. Studies of field shifts have provided valuable information on nuclear structure, especially the shapes and sizes of charge distribution and their dependence on the number of neutrons.

In the spectroscopy of hyperfine structures and isotope shifts, a limiting factor is often the Doppler width of spectral lines caused by the random motion of the atoms. Cooling of discharge tubes and the use of atomic beams for absorption or emission of light have often greatly reduced this effect but rarely quite eliminated it. The recent development of *tunable lasers*, in the form of *dye lasers*, has opened up new possibilities by providing the spectroscopist with a highly monochromatic source of continuously adjustable frequency and very high intensity. The possibility of selective and powerful excitation offers obvious advantages for emission spectroscopy, but the less obvious advantages for absorption spectroscopy are best explained by two examples. The absorption spectrum is scanned by means of the laser whose spectral width determines the spectroscopic resolving power. If, instead of the transmitted beam, the fluorescent light is focused on the detector, the recorded signal is proportional to the beam intensity, and the great radiation density of the laser beam allows the study of *very weak* absorption lines. In this way absorption lines due to *two-photon transitions* have been observed. These can occur between two atomic levels of equal parity, of energy E and E', at exactly half the frequency corresponding to the level difference,

$$\nu = \tfrac{1}{2}(E' - E)/h$$

with a probability proportional to the *square* of the light intensity, in accordance with the concept of the simultaneous absorption of two photons. In the case of Na (see Fig. 1). Laser light of wavelength 6022.3 Å has been found to cause transitions from the ground state $3\ {}^2S_{1/2}$ to $5\ {}^2S_{1/2}$ which were detected by fluorescence of wavelength 6161 Å ($5\ {}^2S_{1/2} - 3\ {}^2P_{3/2}$). The *virtual* energy level introduced by the theory of this process half-way between E and E' is then slightly below $3\ {}^2P_{3/2}$. Its closeness to this level accounts in the theory for the comparative ease of observing the two-photon absorption. If the atomic vapor is exposed to two laser beams traveling in opposite directions, e.g., by being placed inside the laser cavity, the spectrum shows a very sharp, virtually *Doppler-free* peak caused by two photons of opposite direction, flanked by much weaker wings of full Doppler width due to photon pairs of the same direction.

Of probably wider application is the technique of crossing a laser beam with an *atomic beam* at right angles. In contrast to earlier work it is now possible to use atomic beams of much lower density and therefore of much higher collimation, since the probability of an atom getting excited during its passage through the laser beam is close to 1. Such methods of Doppler-free spectroscopy are proving to be of great value in work on isotope shift and hyperfine structure.

Magnetic and Electric Effects The effects caused by magnetic fields play a great part in research on atomic spectra, particularly in magnetic resonance methods. An external magnetic field removes the degeneracy due to the spherical symmetry of atomic force fields and causes the energy to depend on the magnetic quantum number m. This leads to the formation of the *Lorentz triplet* or *normal Zeeman effect* in singlet spectra and to the more complex structures of *anomalous Zeeman effects* in multiplet lines. Zeeman effects in hyperfine structures are especially important for the determination of nuclear spins. The *Stark effect*, due to electric fields, is of somewhat less importance. It causes the energy to depend on $|m|$ only, thus not removing the degeneracy completely. While magnetic splittings are proportional to the field strength, Stark splittings are generally proportional to the square of the electric field.

Direct Measurement of Hyperfine Structures. The optical spectroscopy of hyperfine structures aims at the determination of a very small quantity (a level difference in an atom) by means of measuring the difference between two much larger quantities (wavenumbers or frequencies). If, instead of these, the small level difference can be measured directly, as a single, low frequency, one can expect a gain in accuracy on general grounds; more specifically, since the Doppler width is proportional to the frequency, such direct measurements are virtually *Doppler-free*. Many hyperfine structures, and also some other small, spectroscopic effects such as *Lamb-shifts*, have been measured in this way to an accuracy beyond that of optical methods. It has to be remembered that *isotope shifts* can *not* be measured by such direct methods because they are not due to a level difference in *one* atom.

Radiofrequency Methods. All hyperfine levels and magnetic sublevels within a given configuration have the same parity, and electric dipole transitions between them are forbidden. An electromagnetic wave can, however, act through its *magnetic* field on the spin and orbital motions and their precession about the direction of an external field B. Whenever the frequency of the radiation field equals the Larmor frequency ($1/h$ times the spacing of the energy levels), transitions $m \rightleftarrows m \pm 1$ can occur, with equal probability in both directions, and are described as *magnetic resonances*. A change of m implies a change of the component of angular momentum and magnetic moment along the direction of B. This field is described as weak, intermediate, or strong according to its effect as compared with the hyperfine structure splitting. Each resonance point is found by scanning B at constant frequency. In weak fields, transitions between the magnetic levels of each hyperfine level are measured separately and allow the nuclear spin I to be determined; measurements in intermediate fields involve all values of F of the term and yield an accurate value of the hyperfine splitting for $B = 0$. The various techniques differ mainly in their methods of *detecting* resonances.

In the *atomic beam resonance* method (see ATOMIC AND MOLECULAR BEAMS) the beam passes through two strong, magnetic fields having *gradients* of *opposite* directions, one before and the other after passage through the resonance region with a *homogeneous* field; the fields are all in the same direction. Though the quantization is different in weak and strong fields, the total component of the angular momenta of the atom remains the same during its passage ($m_F = m_j + m_I$), unless resonance occurs, and the two deflections cancel out. A resulting deflection can thus be used for the *detection* of resonance.

In the methods of *double resonance* and *optical pumping*, changes of intensity or polarization of light in emission or absorption are used for the detection of resonances. These phenomena depend on the *population* of sublevels of different m within a large assembly of atoms. Since the *Boltzmann* factor is close to 1, all these levels have normally the same population, and resonance transitions between them have statistically no effect. Absorption of polarized light in a resonance line, however, causes an anomalous population in the excited state, as shown by the polarization of the fluorescent light. When a radiofrequency field is applied, resonances in the excited state tend to restore normal population and can thus be detected by the resulting *depolarization* of the fluorescence. The method is known as *double resonance*. If *circularly* polarized light is used in the fluorescence experiment, the optical transition always increases (or decreases) the value of m to $m + 1$ (or $m - 1$), according to the sense of polarization and produces a state of partial *orientation* in the *excited* state. The reemission, in accordance with the selection rules, then shifts the population in the *ground* state in the same sense. A state of partial orientation of the angular momenta and the magnetic moments has thus been produced solely by the action of light, a process known as *optical pumping*. Such a state can be remarkably long-lived; it can easily be monitored by the strength of absorption in the resonance line. Resonances in the *ground* state can then be produced and detected in the same way.

Level Crossing and Quantum Beats. A group of methods for measuring hyperfine structures and radiative lifetimes of excited states is based on the properties of atomic systems in or close to a condition of *degeneracy*. A plot of the energy levels of different m, of any hyperfine state, as function of B shows $2F + 1$ lines crossing one another at $B = 0$. Some of the levels arising from different values of F and differing m also cross at *intermediate* fields. Any such crossing point represents a *degenerate* system; a transition from this to the ground state "corresponds" to a classical, *isotropic* oscillator. It responds to a light wave by oscillating in the direction of the electric vector, emitting light waves of the appropriate direction and polarization. Slow changes of B from 0 or from its value at other crossing points remove the degeneracy and cause precessional motions of the oscillator, thereby changing or destroying the polarization of the fluorescence. This change takes place when the frequency of precession $(E_m - E_{m\pm1})/h$ is equal to the reciprocal of the *radiative lifetime* of the excited state which can thus be measured. For zero-field crossing, these phenomena, known as the *Hanle effect*, are often used for measuring radiative lifetimes. More information is gained from crossings at intermediate fields. The exact value of B for any crossing point can be determined by the very distinct change of polarization, and this allows the width of the field-free hyperfine splitting to be derived; this is known as the method of *level crossing*.

In the emission of light from two closely adjacent levels excited by the same source, the atom passes through a stage during the radiative lifetime τ when it can be described by a mixture of two time-dependent functions. This causes a light emission with an intensity modulation superimposed on the exponential radiative decay. The emission from different atoms having different velocities is *not* optically coherent but contains common *Fourier* components of the *beat frequency*. In excitation by pulses of duration $\ll\tau$ these *beats* can be synchronized and thus made observable, e.g., on an oscilloscope; they are known as *quantum beats*. This *time-resolved* spectroscopy has been applied to different kinds of close level structures, also in *beam-foil* spectroscopy where the foil produces the sudden excitation and the beam provides the time resolution.

Far Ultraviolet and X-ray Spectra Atomic spectra of frequencies about 1000 times those of optical spectra have long been known as *characteristic* x-ray spectra (see ENERGY LEVELS). Though generally observed in condensed matter, they are characteristic of the constituent atoms, only slightly modified by chemical bonds or crystal structure. They are due to the inner electrons of the atom which are very tightly bound by the strong attraction of the nuclear charge, only partly screened by the other electrons of the same or lower n. The energy of the inner electrons depends primarily on n, as in hydrogen-like spectra, and in x-ray terminology one classifies electrons and shells by the value of n as K-, L-, M, $\cdots$ electrons and shells for $n = 1, 2, 3, \cdots$. Since the inner shells are filled in atoms of not too small Z, the absorption spectrum shows mainly continuous bands, due to the removal of an electron from one of these shells. The photoionization energies for electrons of $n = 1, 2, \cdots$ mark the low-frequency edges of the K-, L-$\cdots$ bands. The state of an atom with a "hole" in one of the inner shells, caused by x-ray absorption or electron bombardment, represents a highly excited state of the atomic ion. It leads to emission of the x-ray line spectra by transition of an electron from a higher shell to the vacant state of the inner shell.

Spectra in the gap between x-rays and the near ultraviolet have recently received increasing attention, partly owing to their importance to astrophysics. Work in this *far* and *extreme* ultraviolet requires vacuum spectrographs, usually with gratings used at grazing incidence. *Emission* spectra of highly ionized atoms (*stripped* atoms) can be observed in the solar corona and in stellar nebulae, and in the laboratory in condensed sparks and high-temperature plasmas. Their strongest lines are in the extreme ultraviolet; e.g., in work ranging down to about 20 Å, all the spectra of the isoelectronic sequence from NaI ($Z = 11$) to Cu XIX ($Z = 29$) are known. The study of *absorption* spectra of neutral atoms has been extended into the extreme ultraviolet, partly by the use of the continuous background radiation from synchrotrons. Such spectra are mainly due to two kinds of processes: either the excitation of one of the electrons in closed shells, e.g., of one of the electrons $1s$, $2s$, or $2p$ in Na, or the simultaneous excitation of two electrons. A simple example of the second type is the absorption series $1s^2\ {}^1S - 2snp\ {}^1P$ in He between 206 and 165 Å. In both types of absorption spectra, many lines show a peculiar, strongly asymmetric profile known as *Fano profile*. It can be explained by configuration interaction in the following way. The same energy as that of the two-electron excitation state $2snp\ {}^1P$ can be reached from the normal atom by removal of a single electron with excess kinetic energy, i.e., the absorption line falls in the range of the continuous absorption extending towards higher frequencies from the limit $n = \infty$ of the absorption series $1s^2\ {}^1S - 1snp\ {}^1P$. Configuration interaction between the discrete state and the continuous state of the same energy and parity causes the anomalous line profile by a kind of interference effect. The absorption of light within this line leads either to re-emission of the same frequency or to nonradiative transition to the ionized state, a process known as *autoionization*. In x-ray spectroscopy, the analogous process had been detected by the appearance of fast, free electrons and is known as *Auger* effect (see AUGER EFFECT). The process of autoionization is closely related to the inverse process of *resonance capture* of electrons by ions.

Particle accelerators normally used in nuclear structure research have been successfully applied to the optical spectroscopy of multiply ionized atoms. In a technique known as *beam-foil method*, the high-speed ion beam is made to pass through a very thin foil (usually of carbon) and the spectrum is observed at different distances from the foil. The rate of decrease of intensity allows life times of excited states to be determined. In spite of difficulties due to cascading processes numerous transition probabilities could be measured in this way. Modulation structures superimposed on the exponential decay are sometimes observed and are known as *quantum beats*. They are due to finer level structures and can be understood in the way indicated above.

AUGER EFFECT

Definition and History The Auger effect is the filling of an electronic vacancy in the atom by one electron from a less tightly bound state, with the simultaneous emission not of a photon but of a second electron from another less tightly bound state.

Following experiments by Barkla (1909) and Sadler (1917) in which the number of characteristic K x-rays emitted by material absorbing higher-energy x-rays appeared to be substantially less than the number of x-rays absorbed in the K shell, Kossel (1923) suggested that the remaining vacancies might be filled by a radiationless transfer of the excess energy to an emitted electron. This interpretation was reiterated by Barkla and Dallas (1924), who observed an increase in the number of electrons emitted when x-rays were absorbed. Wilson (1923) had observed in a cloud chamber, simultaneous ejection of two electrons from the same atom. It remained for Auger (1925, 1926) to make systematic investigations of this phenomenon in argon. The effect has since been called the Auger effect, and the ejected electrons have been called Auger electrons.

Principal Features Auger showed that:

(1) The photoelectron and its Auger electron arise at the same point.

(2) The Auger-electron track length is independent of the wavelength of the primary x-rays, but the photoelectron track length increases with x-ray energy.

(3) The direction of ejection of the Auger electron is independent of that of the photoelectron.

(4) Not all photoelectron tracks show a coincident Auger track.

Filling of vacancies by the Auger effect can occur for any vacancy for which there are two electrons in the atom sufficiently less tightly bound that a net positive energy is available for the ejected Auger electron. Because photon emission is more easily detected and has played such an important role in the development of quantum theory, it is not generally realized that Auger emission is much more probable. Only for vacancies in the K shell in atoms with atomic number above 32 and in vacancies in the outer two electron states of an atom does photon emission dominate. The Auger effect also occurs after capture of a negative meson by an atom. As the meson changes energy levels in approaching the nucleus, the energy released may be either emitted as a photon or transferred directly to an electron which is emitted as a fairly high-energy Auger electron (keV for hydrogen, MeV for heavy elements). Finally we note that each Auger process increases the positive ionization of the atom by changing one initial vacancy into two final vacancies.

Energy Spectra of Auger Electrons Auger spectroscopy is the measurement of the number, energy, and intensity of lines present. The spectrum of Auger electrons resulting from a given vacancy is more complex than the corresponding photon spectrum. The energy of the Auger electron resulting from the filling of a vacancy V of energy $E(V)$ by production of vacancies X_i and Y_j of energies $E(X_i)$ and $E(Y_j)$ is $E(V - X_iY_j) = E(V) - E(X_i) - E(Y_j) - \Delta Ex_iy_j$, where ΔEx_iy_j can be interpreted as either the increase in binding energy of the Y_j electron due to an X_i vacancy, or vice versa. Experimental energy determination in Auger spectra then consists of determining ΔEx_iy_j for each transition. Exact calculation of the number of possible Auger transitions, their energies, and their relative probabilities necessitates the use of a relativistic intermediate-coupling theory. In the above notation, X and Y refer to the total quantum number of a group of levels, and i and j to the individual substates within the group.

At low resolution the Auger spectrum from a vacancy with initial total quantum number n always consists of at least three well separated groups which can be characterized by vacancies as $n \rightarrow (n+1)\,(n+1)$, $n \rightarrow (n+1)\,(n+m)$, and $n \rightarrow (n+m)\,(n+m)$, where $(n+m)$ represents all final vacancies with total quantum numbers greater than or equal to $(n + 2)$. Thus for an initial K vacancy we have K-LL, K-LX, and K-XY groups where X and Y stand for all vacancies with quantum numbers equal to or greater than $n + 2$ (in this case 3). Similarly, for an L_3 primary vacancy we have L_3-MM, L_3-MX, and L_3-XY, and similarly for L_1 and L_2. But for the L shell the groups do not appear well separated because the L_1 and L_2 groups overlap each other and the L_3 groups.

When a higher resolution is used each band is seen to be composed of numerous lines of which many are ordinary lines resulting from a single initial vacancy and others are satellites resulting from multiple initial vacancies, multiple Auger processes, and other complex phenomena.

Complete interpretation of the ordinary lines necessitates relativistic-intermediate coupling which is a combination of L-S coupling (small binding energies) and j-j coupling (very large binding energies). As an example of these interpretations we show in Table 1 the designations for the K-LL group.

Auger spectra also enable the relative intensities of the lines or groups of lines to be determined. At high resolution the K-LL intensities of all the ordinary lines can be accurately measured. No theoretical calculation gives the correct relative intensities for all values of atomic number but relativistic j-j coupling gives quite good agreement above 80. K-LX and K-XY lines are less well resolved and theories are less developed. For L-MM spectra the experimental intensities are much less precise due to the much lower energies and the overlapping of the bands. Nonrelativistic L-S and j-j coupling theoretical intensities have been calculated, and crude agreement is obtained with the former for low atomic numbers and with the latter for high atomic numbers. Very little good data exist for L-MN and L-NN spectra. Considerable medium resolution data exist for M and N Auger spectra.

While the global K-Auger intensity is easy to obtain by integrating under the spectrum, the total L_1, L_2, and L_3 intensities are difficult to obtain because of the overlap of the three bands.

Relative Probability of Auger and X-ray Emission The evaluation of the relative probability of x-ray and Auger emission for different initial vacancies, and the determination of the relative intensities of various Auger lines constitute one of the most important aspects of Auger effect research.

The fluorescence yield, ω_i, for any initial vacancy i is defined as the fraction of vacancies filled by emission of photons. The Auger yield is defined correspondingly as the fraction filled by emission of Auger electrons. The Auger yield is divided into two parts, one (denoted by a_i) which transfers the vacancy to a level with a higher total quantum number, and the other (denoted by f_{ij}) which transfers the vacancy to a lower-energy vacancy with the same total quantum number. The latter process is called the Coster-Kronig effect.

For the K shell the following equation holds

$$1 = \omega_K + a_K.$$

Although in principle $\omega_K(Z)$ should be readily calculable, the number of (frequently relativistic) electron wave functions which must be known for each Z, and the number of permutations and combinations of these functions which must be handled in order to calculate the individual probability of every line and, by summing, the total K-Auger probability per unit time, present a formidable problem even with the aid of a sophisticated computer. The K fluorescence yield is therefore normally

TABLE 1

L-S Coupling (light elements)	Intermediate Coupling	j-j Coupling (heavy elements)
$K - 2s2s\ {}^1S_0$	K-$L_1L_1\ {}^1S_0$	K-L_1L_1
${}^1P_1$	K-$L_1L_2\ {}^1P_1$	K-L_1L_2
$K - 2s2p$	K-$L_1L_2\ {}^3P_0$	
${}^3P_{0,1,2}$	K-$L_1L_3\ {}^3P_2$	K-L_1L_3
	K-$L_1L_3\ {}^3P_2$	
${}^1S_0$	K-$L_2L_2\ {}^1S_0$	K-L_2L_2
${}^1D_2$	K-$L_2L_3\ {}^1D_2$	K-L_2L_3
$K - 2p2p$	K-$L_2L_3\ {}^3P_1$ parity forbidden	
${}^3P_{0,1,2}$	K-$L_3L_3\ {}^3P_0$	K-L_3L_3
	K-$L_3L_3\ {}^3P_2$	

For K-Auger electrons, measurements and comparison with theory are extensive.

found by fitting theoretical expressions for ω_K containing empirical constants to the experimental values. For $20 < z < 55$, ω_K is given to a few per cent by

$$\omega_K = (1 + 7.8 \times 10^5 Z^{-4})^{-1}$$

and somewhat less accurately for $10 < z < 20$. For $z < 10$ the experimental errors are large because of solid state and molecular effects, and the theoretical estimates may also be considerably in error.

For $Z > 50$ it is better to estimate a_K since relativity has an important effect on a_K but not on ω_K which is very close to unity. The following equation probably predicts a_K to 10 to 15 per cent and hence ω_K to a per cent or better for $z > 50$:

$$a_K = [1 - (1 + 7.8 \times 10^5)^{-1}](1 + 3.5 \times 10^{-5} Z^2 + 3 \times 10^{-8} Z^4).$$

For the L shell in the *j-j* coupling limit the following equations hold:

$$1 = \omega_3 + a_3$$
$$1 = \omega_2 + a_2 + f_{23}$$
$$1 = \omega_1 + a_1 + f_{12} + f_{13}.$$

In addition, the average L-fluorescence yield $\overline{\omega}_L$ for an atom with an L vacancy, having probability n_1, n_2, and n_3 of being in each of the three subshells, is

$$\overline{\omega}_L = 1 - \overline{a}_L = n_1(\omega_1 + f_{12}\omega_2 + f_{13}\omega_3 + f_{12}f_{23}\omega_3) + n_2(\omega_2 + f_{23}\omega_3) + n_3\omega_3.$$

The values of the nine L-shell constants are much less well known than the two constants for the K shell. Below atomic number 50 the ω_i are all less than 6 per cent and appear to be less than 50 per cent for all elements. ω_3 is given reasonably accurately by

$$\omega_3 = (1 + 0.82 \times 10^8 Z^{-4})^{-1} \qquad Z > 65$$
$$\omega_3 = (1 + 1.08 \times 10^8 Z^{-4})^{-1} \qquad Z > 50.$$

ω_2 is much less accurately known but the agreement between theory and experiment is fairly good. The knowledge of ω_1 is relatively poor. The Coster-Kronig yields go through sudden changes in value as certain transitions become energetically possible or impossible. For example, $L_2 - L_3 M$ transitions are forbidden for Z from 50 to 73. Experimental values for f_{13} and f_{23} have precisions ranging from 5 to 20 per cent, while f_{12} has only a precision of about 30 per cent. Agreement with theory is not very good. The $\overline{\omega}_L$ and $\overline{a}_L$ clearly depend on the type of excitation.

Although initial interest in the Auger effect arose through creation of vacancies by ejection of photoelectrons by x-rays, there has been a strong recent upsurge in interest in several other types of experimental work which involve Auger spectra closely:

(1) Vacancies created in radioactive decay.

(2) Vacancies created in electron-ion and ion-ion collisions in gases.

(3) Auger electrons emitted from the surface layers of solid targets in ultrahigh vacuum when the surface is bombarded by electrons up to 3 keV and sometimes by ions.

When radioactive decay occurs, internal conversion, shake-off, accompanying beta-decay, and electron capture all create vacancies. In fact, the only method of studying the relative probability of orbital capture in the various shells and subshells of a nuclide involves the study of the x-ray or Auger spectrum of the product nuclide. The interpretation of these spectra necessitates the knowledge of the constants discussed above.

The importance of the Auger effect for radioactive nuclei, as well as the almost 100 per cent probability of Auger and Coster-Kronig emission for the M and higher levels, is indicated by measurement of the total charge accumulated by certain radioactive nuclei. For example, a vacancy produced in xenon 131*m* by internal conversion gives rise in some cases to as many as 21 Auger processes, leaving a xenon ion with a charge of $-22e$.

The highest-resolution Auger spectra are those from vacancies created in gaseous atoms or molecules at low pressure by bombardment by electrons or other ions. Such spectra are particularly rich in lines (satellites) arising from multiple vacancies, and their interpretation has contributed to our understanding of the processes which take place in such collisions.

Since about 1967 there has been great interest in the study of surface impurities by means of the Auger spectra of solid surfaces in ultrahigh vacuum bombarded by low energy, up to 3 keV, electrons. The experiments are usually done by modifying a Low Energy Electron Diffraction (LEED) apparatus to provide it with a retarding grid. By varying the retarding voltage, an integral spectrum of the scattered and secondary electrons is obtained. By applying a small alternating voltage to this grid and tuning the detector amplifier to twice the frequency, a very sharp differential line spectrum of scattered and Auger electrons is obtained. Impurity detection of better than $\frac{1}{50}$ of a monolayer is claimed in some cases. Although it can be shown that a deflection-type spectrometer with an alternating voltage on the detector has in principle a better signal-to-noise ratio than the retarding grid, the combination of the latter with electron diffraction studies of the same surface constitutes an extremely powerful tool for the study of surface physics and chemistry.

AURORA

The earliest auroral descriptions date back to the Old Testament and early Chinese chronologies. Up until the Renaissance period, there was little scientific understanding and most reports involved superstitious, prognostic, or religious interpretations. The metaphor "aurora borealis" seems to have been first used by Galileo, and many famous 17th–19th Century scientists (including Halley, Descartes, Celsius, Dalton, Biot, and Ångström) speculated on the nature of the phenomenon. However, little real progress in understanding was made until the era of polar exploration resulted in systematic data gathering from high latitude regions.

The general term "aurora" (*aurora borealis* or northern lights in the northern hemisphere, *aurora australis* or southern lights in the southern hemisphere) refers to the luminous emissions commonly seen in the night sky in polar regions. The aurora is much brighter than airglow (see AIRGLOW), which is a uniform, subvisual luminosity and is worldwide in occurrence.

Auroral forms typically take the shape of arcs or bands that align along parallels of geomagnetic latitude (see Fig. 1), and often exhibit a vertical striated structure (rays) that align along the local direction of the earth's magnetic field (see Fig. 2). The height of the aurora may be as low as ~80 km and as high as 300–500 km, but most auroras occur around 110 km. Because the extent of auroras commonly exceed the limited field of view from a ground station, many of the auroral forms reported from the ground (arcs, bands, coronas, etc.) are only apparent shapes, distorted by perspective effects.

The aurora occurs in two oval-shaped (nearly circular) bands encircling the north and south geomagnetic poles, locating about 25° of latitude from these poles on the night side of the earth, and about 12° from the poles on the dayside (see Fig. 3). This instantaneous auroral distribution is called the "auroral oval." As the aurora is typically brighter near local midnight, the region of highest probability of seeing an aurora is the projection of the midnight sector of the auroral oval onto the rotating earth; this is a circular region about 25° latitude from the geomagnetic poles, called the "auroral zone." During periods of geomagnetic storms (see GEOPHYSICS) the auroral oval shifts to lower latitudes (see Fig. 4) and at rare times is seen over the tropics.

(b)

FIG. 1. (a) Wide angle photograph showing typical appearance of an auroral arc as seen from the ground. (b) Pictures of an auroral arc as seen from space (*Spacelab*) (R. H. Eather).

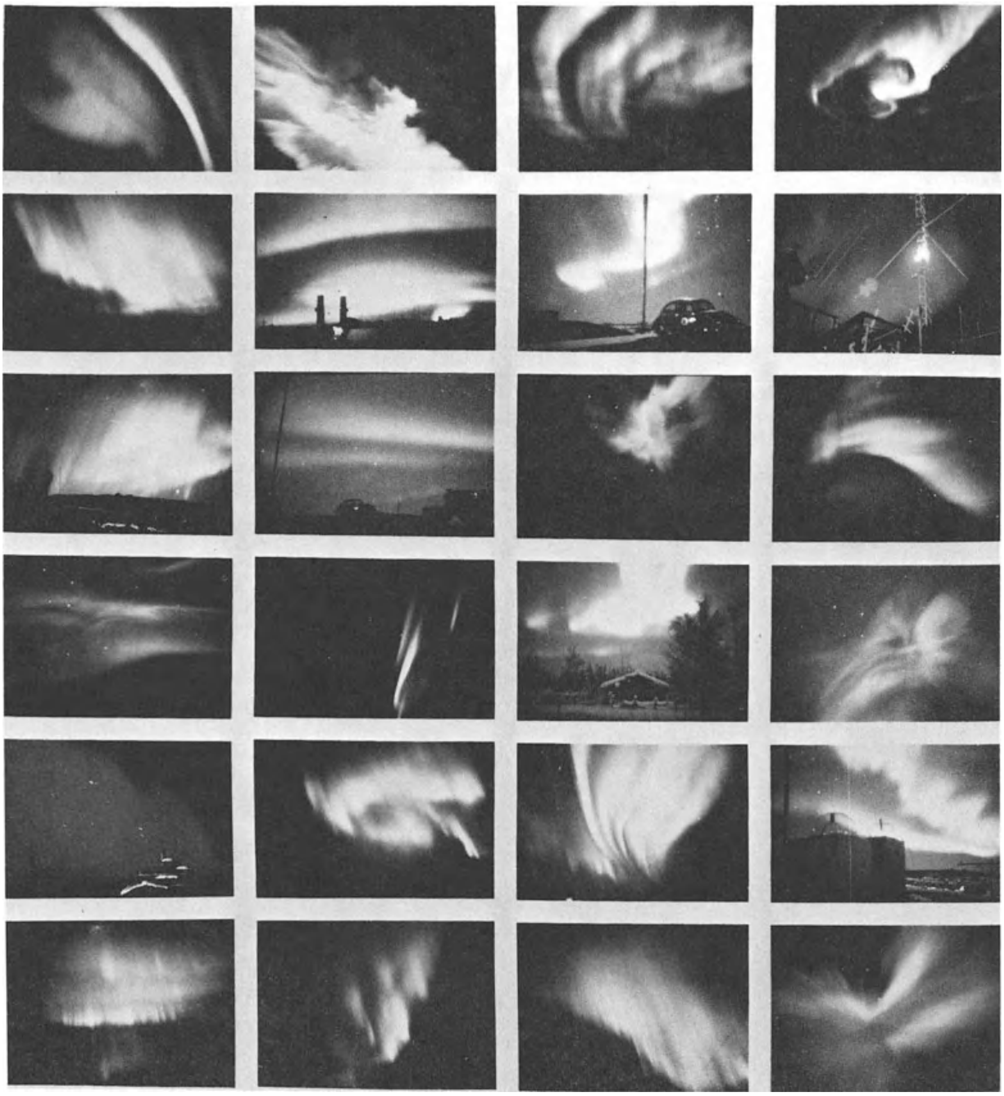

FIG. 2. An illustration of the variety of auroral structures (NASA).

Auroras are observed to occur simultaneously in the northern and southern hemispheres, showing remarkably similar shapes and radiances at opposite ends of the same magnetic field line. Such auroras are said to be magnetically conjugate (see Fig. 5).

The auroral light arises from spectral emissions by atmospheric gases in atomic, molecular and ionized states. The most important auroral emissions, and approximate relative radiances, are listed in Table 1. The strongest emission is the yellow-green line of atomic oxygen.

The total integrated radiance of the aurora may vary over many orders of magnitude, and is often classified on a scale of 1 to 4 called the International Brightness Coefficient (see Table 2).

The auroral light is produced by bombardment of the upper atmosphere by energetic electrons and protons in the energy range of about one-tenth to tens of keV, with electrons normally being the dominant energy source. The energy of the particles determines how far they penetrate into the atmosphere, and so determines auroral height. Because atmospheric composition changes significantly with height above the turbopause, the relative importance of various spectral features (Table 1), and hence auroral color, also are functions of height. If auroral radiance does not exceed the color

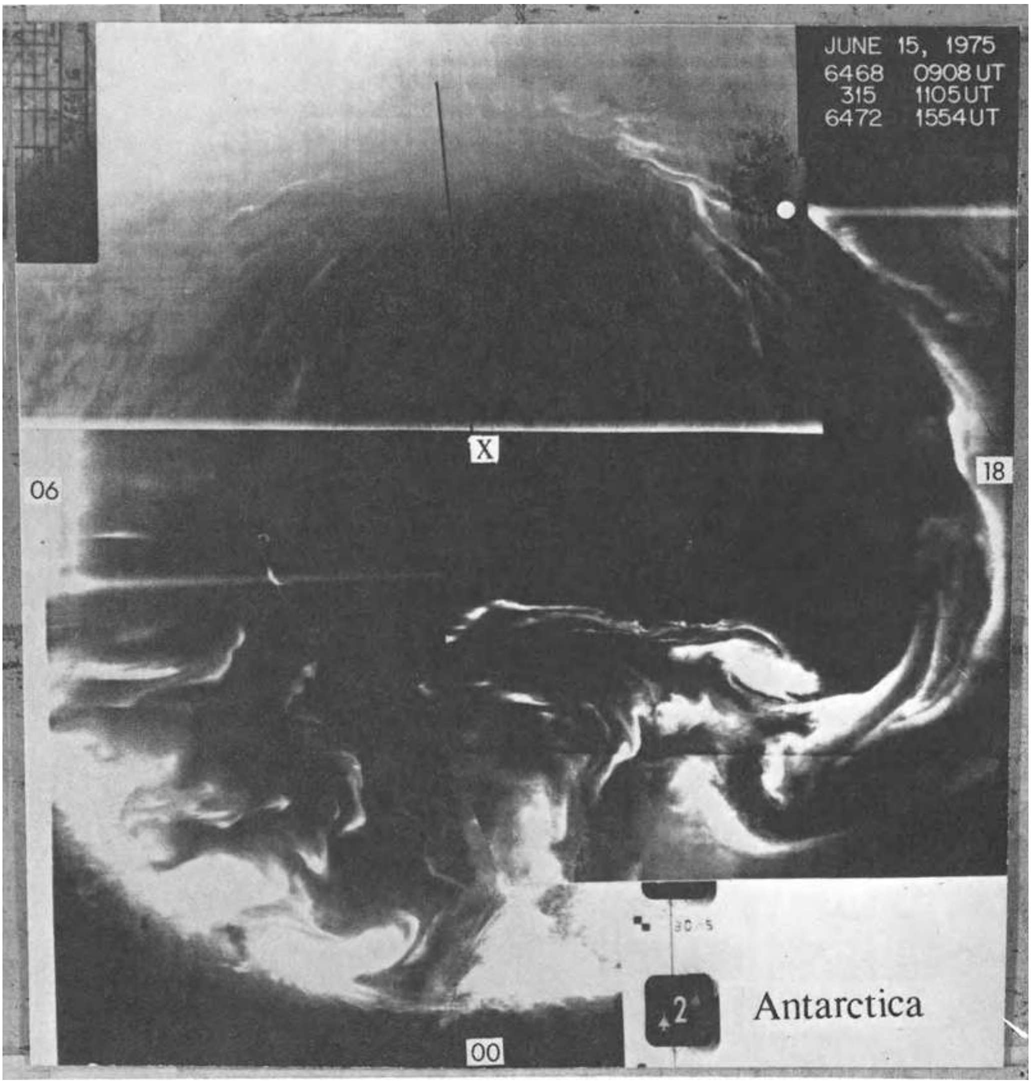

FIG. 3. A composite of satellite pictures taken over Antarctica near midwinter. The geomagnetic south pole is marked with an X, and the geographic south pole with ●. Local time is indicated around the edges of the picture. The active bright nightside aurora is illustrative of a intense substorm; the dayside aurora is much less intense, and shows a common fanning out of structures from near midday (S. I. Akasafu).

threshold of the eye (~IBC 2, see Table 2), the aurora appears whitish in color. When this threshold is exceeded (scotopic vision), the strong auroral emissions in the blue, green and red regions of the spectrum (Table 1) can combine to give a wide range of hues. Typically, however, bright auroras appear yellowish-green (557.7OI), sometimes with blue- (N_2^+) or red (N_2, O_2^+) lower borders, and sometimes with red upper regions (630.0/636.4 OI). The auroras seen at low latitudes during large magnetic storms are often excited by lower energy electrons, giving high red auroras.

The energetic electrons (and protons) that generate the aurora have their primary source in the solar wind (see MAGNETOSPHERIC RADIATION BELTS and Fig. 6). (A secondary probable source of auroral particles is the earth's upper ionosphere.) Details of the mechanism whereby solar wind particles gain entry to the magnetosphere are not clear but probably involve merging of the earth's magnetic field with the interplanetary magnetic field imbedded in the solar wind. It is likely that particles entering the magnetosphere through the dayside cusp regions have fairly direct access to the dayside

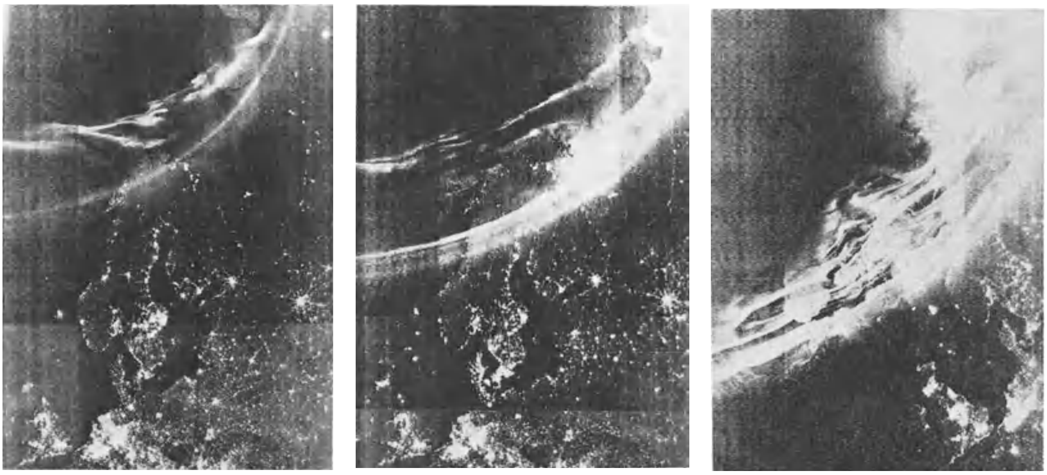

FIG. 4. Satellite pictures showing the location of the auroral oval over western Europe for different levels of magnetic activity. For quiet conditions (left panel) the aurora locates north of the northern coast of Scandinavia. For weak magnetic activity (center panel), the aurora is seen over central Scandinavia. During moderate disturbances, auroras are seen from southern Scandinavia (right panel) (Air Force Geophysics Lab, R. H. Eather).

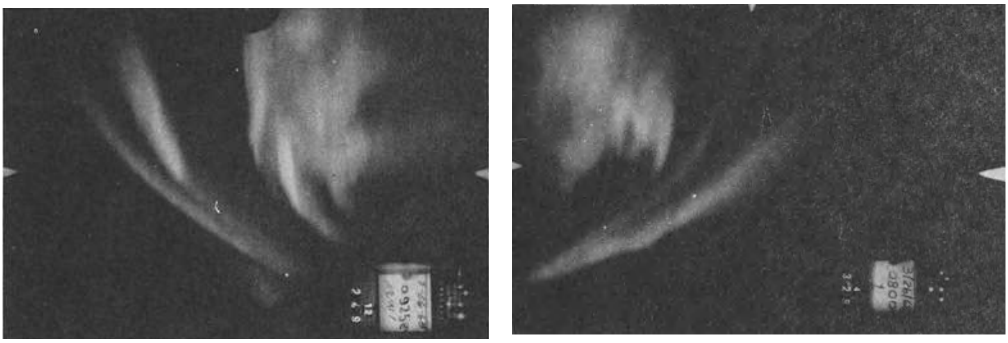

FIG. 5. Photographs taken from aircraft flying under the same magnetic field line in the northern hemisphere (over Alaska) and the southern hemisphere (between New Zealand and Antarctica). The pictures are mirror images of each other (auroral conjugacy) (T. Neil Davis).

TABLE 1. Main Auroral Emissions in Visible Region.

Emission	Spectral Region (nm)	Approx. Height	Relative Radiance*
OI	557.7 yellow-green	110 km	1.
	630.0/636.4 red	175 km	.1 → 10
N_2+ 1st neg	391.4 violet	110 km	.6
	427.8 blue	110 km	.2
N_2 1st pos	red	90-100 km	.5
N_2 2nd pos	violet	90-100 km	1.
O_2+ 1st neg	yellow-red	90-100 km	.1
H Balmer	486.1 H, 656.3 H	120 km	.1

*Radiance refers to an emitting surface and is not strictly the correct term in this context. Auroral "radiance" is actually an integrated column emission rate, and is often quoted in units of Rayleighs, where 1 R = 10^{10} photons m^{-2} (column) sec.

TABLE 2. Auroral Radiance* Classification.

International Brightness Coefficient	557.7 OI Column Emission Rate (kR)*	Description of Brightness	Approximate Luminance (ft Lamberts)
1	1	Milky Way	10^{-4}
2	10	thin moonlit cirrus	10^{-3}
3	100	moonlit cumulus	10^{-2}
4	1000	provides ground illumination similar to full moonlight	10^{-1}

*See note at bottom of Table 1.

NOTE: Approximate photographic exposure required (fl.4 lens, ASA 400) is 1-2 secs for IBC 3 aurora.

ionosphere and generate dayside aurora. These precipitating particles are typically low energy (0.1-1 keV) and generate weak, reddish aurora (often subvisual) at heights of $\gtrsim 150$ km. The particles generating the more intense nightime aurora have higher energies (~1-10s keV) and a source region in the plasma sheet. The acceleration mechanism required to energize the solar wind particles to keV energies have not been definitively identified. Some energization probably occurs by magnetospheric electric fields that drive particles from the flanks of the magnetosphere to the plasma sheet region, and additional (possibly primary) energization by field aligned electric fields has been discovered at low altitudes (10-15,000 km) above the auroral ovals.

The auroral oval displays considerable dynamic behavior on a time scale of the order of hours (Fig. 7). Periodically, intense auroral

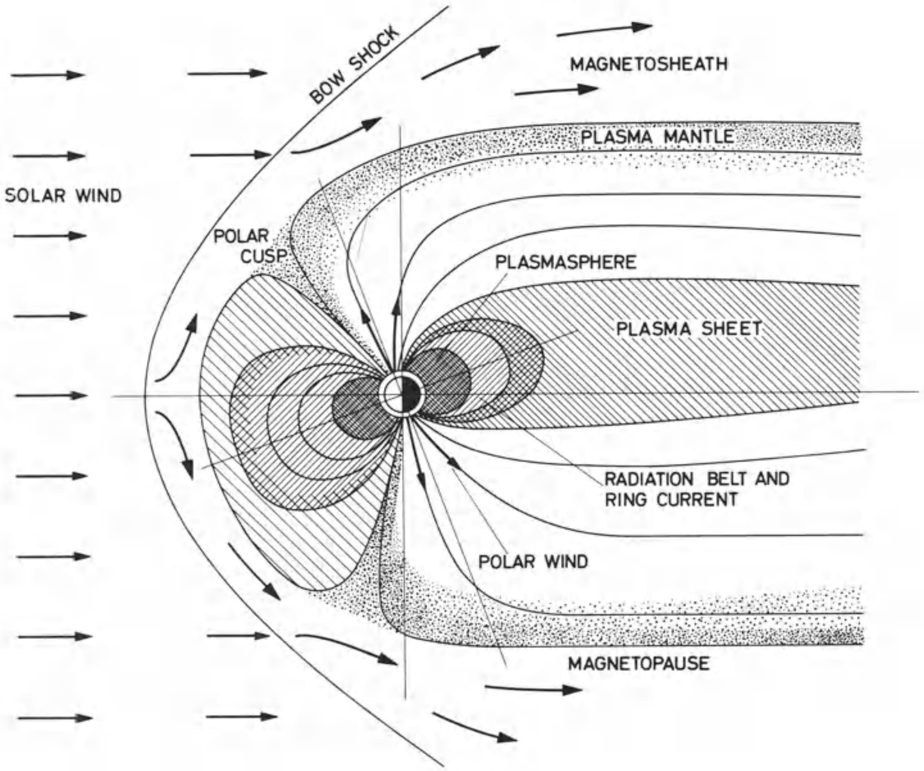

FIG. 6. Sketch showing the main particle region in the magnetosphere. The nighttime aurora occurs at the base of magnetic field lines that thread the plasma sheet. Dayside auroras occur at the base of the polar cusp field line (G. Paschman).

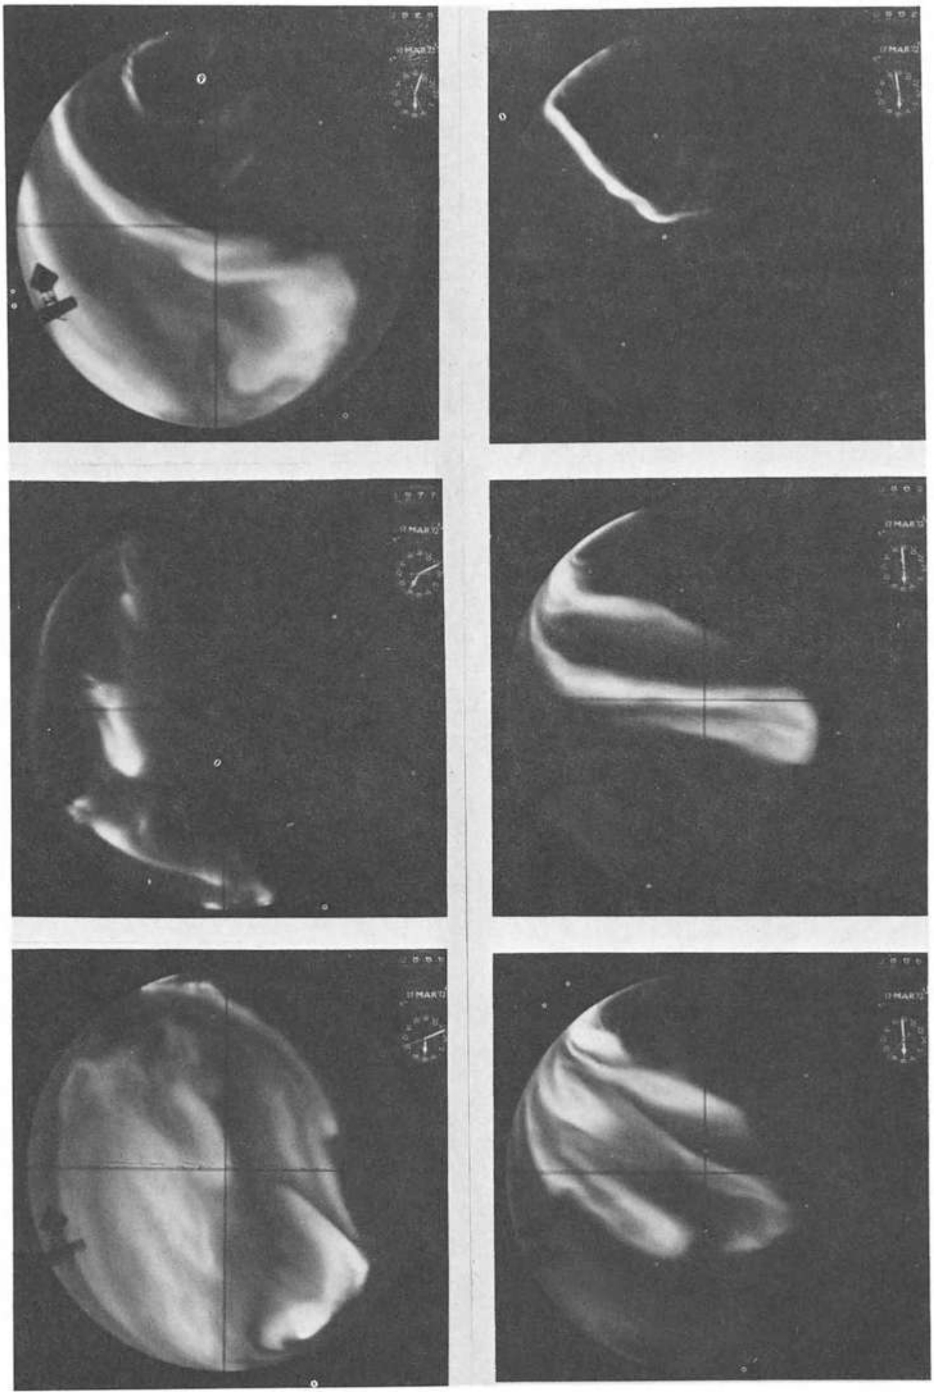

FIG. 7. These fisheye pictures show the complete sky, and illustrate how auroral forms may rapidly change during a substorm. This sequence shows changes over a 10 min. period of substorm development (R. H. Eather).

brightenings appear in the midnight region, followed by a characteristic poleward expansion in the midnight sector, westward travelling surges in the evening sector, pulsating forms in the morning sector, and equatorward shifts of dayside aurora. This sequence of events, lasting $\frac{1}{2}$-1 hour, is called an auroral substorm. The frequency and intensity of substorms increases during worldwide magnetic storms. The triggering process that initiates this substorm sequence is not yet identified. The uncertainties concern whether it is an internal (to the magnetosphere) relaxation process that suddenly releases stored energy in the tail, or whether the process is externally driven by fluctuations in the solar wind.

There are many phenomena associated with the aurora other than the visible light. The auroral ovals carry large electric currents (the auroral electrojet) that represent closure paths for large-scale magnetospheric current systems. These currents have strong magnetic effects at ground level. Ionization in the aurora results in radio-wave reflections at lower frequencies and absorption and scintillations at higher frequencies. Electromagnetic emissions from the aurora include x-ray, ultraviolet and infrared, vlf, radiowave, and ulf emissions. Auroral heating leads to a wide variety of chemical changes.

The aurora is the only visible manifestation of the dynamic electromagnetic environment around the earth. This facilitates coordinated experiments between ground-based and satellite based detectors. It is such coordinated experiments, between ground station arrays and multiple satellites both inside and outside the magnetosphere, that will eventually result in definitive answers to three very important unanswered questions—what is the entry mechanism(s) for solar wind particles into the magnetosphere; what is the acceleration mechanism(s) inside the magnetosphere; and what triggers and drives the substorm process?

B

BETATRON

A betatron is a particle accelerator which uses a sustained induced voltage to accelerate charged particles to full energy during the whole period of acceleration of the particle. Since this method of acceleration seemed most applicable to electrons, the name *betatron* was used to indicate that it was the agency for producing high-speed electrons. The accelerating action in a betatron is similar to the action of an electrical *transformer* in which a high-voltage winding of many turns is used. In a transformer, the voltage can be stepped up from a primary voltage V_1 to the secondary voltage V_2,

$$V_2 = V_1 N_2 / N_1$$

where N_2 is the large number of turns of the secondary coil and N_1 is the small number of turns in the primary winding. For example, diagnostic x-ray transformers producing high voltage, such as 100 000 volts, have very many turns of fine wire and consequently raise the primary voltage by a large factor.

The accelerating or voltage generating structure of a betatron is really a transformer; particle guiding, or focusing, magnets are arranged around the transformer core where a secondary winding might be put. A toroidal vacuum vessel is placed between the poles of the focusing magnets so that electrons can travel hundreds of thousands of times around the core. Each time the electron circulates around the core it acquires an energy equivalent to the voltage which would have been induced in one turn of wire at that instant. The very long path requires magnetic and electrostatic field errors to be small, particularly when the particles are starting at low speed and are perturbed by small magnitude field errors.

In order to guide the electrons the focusing magnet can be such that its magnetic field decreases with increasing radius. Then the lines of force going from pole to pole bulge outwardly across the orbital plane. This provides forces, which are always perpendicular to the field line, which have a component directed back toward the orbital plane in case the particle strays away from this plane. This bulging field is also used for vertical focusing cyclotrons. However, it is necessary that the magnetic field decrease less rapidly than $1/r$, where r is the radius of the orbit. If this latter requirement is met, the radial focusing will be insured; the required centripetal force to hold the particle in the circle going around the core decreases as $1/r$. Consequently, if the magnetic force decreases less rapidly than this, it will be too strong at large radii to permit the orbit to remain circulating at a large radius, and it will be too weak at small radii to maintain the particle circulating at a small radius. The particle thus will oscillate about the so-called *equilibrium orbit radius* when the magnetic force has the right value to supply the required centripetal force. The axial or radial oscillations of the particle about the equilibrium orbit are called betatron oscillations, and this name appears in the scientific literature referring to particle motions and focusing in other accelerators.

It is possible to use "strong focusing" magnets with much more rapid variation of magnetic field with radius to provide axial and radial focusing. In this case a succession of strong focusing and defocusing magnets must be used which alternately focus vertical (axial) and radial motion. The net result is a focusing action, just as for optical lenses. Such magnets are called *alternate gradient focusing magnets*, and their value is that they can limit the amplitude of oscillation of a particle about the equilibrium orbit to a very small size. This makes possible very large circumference high energy accelerators without immense magnetic guide field spaces. For example, the magnets for the large synchrotrons at CERN and at the Fermi National Accelerator Laboratory providing energies of several hundred GeV are such alternate gradient magnets; but in these accelerators the acceleration is not done by a continuously rising betatron flux within the orbit. Instead, small transformer cores which operate at radio frequencies link the orbit so that whenever the particle returns to the vicinity of the core the flux is rising in the direction to accelerate the particle. Thus the extremely large iron core of a betatron is not needed.

The usual betatron has a focusing magnetic field which rises proportionately with the increase in the transformer's magnetic flux within the orbit. Thus the guiding field increases proportionately with the momentum gained by

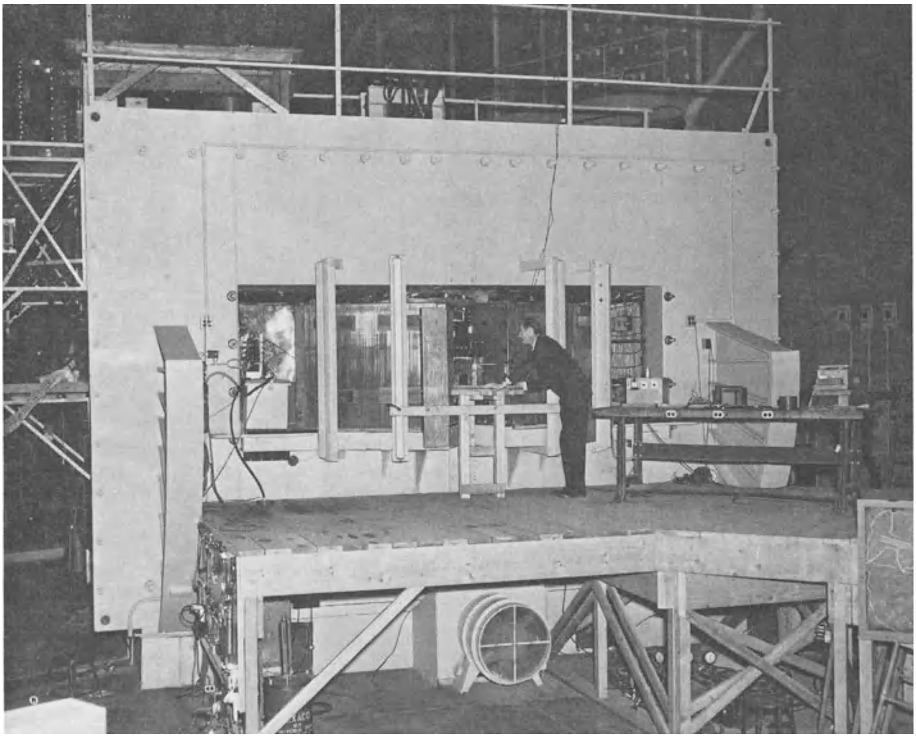

FIG. 1. The 320 MeV betatron at the University of Illinois near completion. The six guide field magnets placed around the central leg of the big accelerating core would form a synchrotron if a radiofrequency accelerating cavity were used for acceleration instead of the transformer. 5 watts of x-rays were produced by this accelerator. The light radiation loss from the revolving 320 MeV electrons was nine percent, which had to be made up by extra flux driven through the core. The original 2-MeV typewriter-size betatron, if made in the image of this 320 MeV betatron and biased, would be the size of a match box.

the transformer action, and it provides sufficient magnetic force to hold the particle at a constant radius.

The first betatron of this type produced 2 MeV and radiation equivalent to 2 grams of radium. It is now in the Smithsonian Museum in Washington, D.C. This accelerator is the size of a typewriter. The largest betatron (see Fig. 1) could generate beams of 320 MeV. The x-rays and electrons from it were used for experiments to produce mesons and numerous nuclear disintegrations. At such energies circulating electrons radiate an important fraction of their energy as light. This is a limitation on the use of betatron action for very high energy electrons, but synchrotrons are better able to make up this energy loss. The most commonly used betatrons are for 25 to 35 MeV. These provide x-rays of maximum penetration in iron for industrial radiography, and they provide x-rays and electrons with optimum depth dose characteristics for x-ray or electron beam therapy of the human body.

The intensity of radiation from the medical or industrial betatrons is of the order of 100 to 200 roentgens/min at a meter from the target for x-rays. With the extracted electron beam, the ionization doses would depend on how widely the electrons are spread at the point of treatment, but comparable doses are obtained. The large 320-MeV betatron at the University of Illinois, which is shown in the figure, produced intensities of the order of 20 000 roentgens/min at a meter or other terms, of the order of 5 watts.

There are possibilities for increasing the intensity of radiation from betatrons. One is the fixed-field alternating-gradient betatron (FFAG betatron). In this case, the focusing field is constant in time, and the particle orbit can be caused to spiral either outwardly or inwardly with increasing energy to the high field region of the direct current magnet or permanent magnet poles. The electrons can thus be injected and accepted by the guide field continuously; and with a transformer accelerating core with a sinusoidal flux variation a beam of x-rays could be produced about 20 percent of the time.

Betatrons with time-varying focusing fields just give one pulse every cycle of the transformer core, and the pulses are only of the order of a microsecond duration. Because of the large duty factor available with FFAG betatrons, it should be possible to achieve intensities of 10 000 watts of electrons. Although FFAG combination betatrons and synchrotrons have been made, full advantage has not been taken of a large duty factor achievable by incorporating a full-size transformer core within the betatron orbit.

Another possibility for increased intensity is operation at a higher frequency or loading each cycle with more electrons. Medical and industrial betatrons are filled to approximately their space-charge limit at the injection energy of about 60 000 volts. But as the energy increases the space-charge limit rises because the beam's rising current magnetic pinching of itself counteracts its space-charge repulsion. At relativistic energies the limit on current is very high—hence injection at higher energy allows much more current to be held in the guide field. Some attempts at holding high currents in large aperture guide fields have been made.

In the case of the conventional betatron with constant orbit radius, the relation between the strength of guiding field and total flux change within the orbit can be found as follows:

The momentum of the particle in the orbit

$$P = \frac{e}{c} BR$$

while the rate of change of momentum

$$\frac{dp}{dt} = eE$$

where e is the charge of the electron, c is the velocity of light, B is the magnetic field in gauss, R is the radius in centimeters, and E is the electric field in electrostatic units.

$$2\pi RE = \frac{1}{c}\frac{d\Phi}{dt}$$

is the electrostatic volts per turn, where Φ is the flux linking the orbit. Combining the last two equations

$$\frac{dp}{dt} = \frac{e}{2\pi RC}\frac{d\Phi}{dt}.$$

Thus, after a lapse of time

$$p = \frac{e}{2\pi RC}(\Phi_2 - \Phi_1).$$

Combining this with the first equation yields

$$2\pi R^2 B = \Phi_2 - \Phi_1.$$

Thus the flux change within the orbit during acceleration is twice as big as the flux would be if the flux density B were uniform within the orbit. Therefore, the transformer core must be adjusted so the proper excess flux provided within the orbit meets the conditions of this last relation if the orbit is to be at a constant radius, the assumption made in the above derivation.

The flux condition allows the core of the transformer to be biased with Φ_1, reversed compared with Φ_2. Thus the iron in the transformer can be started at −16 000 gauss and reversed to +16 000 gauss while the orbit field B goes from zero to its maximum value. Biased betatrons are thus much smaller than unbiased betatrons.

BIOMEDICAL INSTRUMENTATION

This article is restricted to examples of physical measurements on humans which are useful in the diagnosis and management of disease. It ignores measurements of physiologic variables for research purposes, measurements in other animal species or in plants (for crop management, for example), and measurements based primarily on chemical processes. It also excludes devices to augment patient function, such as artificial organs, limbs, and other prostheses.

Many measurements involve the use of a transducer to convert some physical variable into another variable more easily sensed by the observer. Often the transduction process involves an electrical signal as an intermediate stage, because of the ease with which such signals can be processed (amplified, filtered, etc.). An electrical intermediary is not always required: blood pressure is measured with a cuff and stethoscope, and x-rays blacken a photographic film.

Measurable mechanical quantities which may be useful are displacement, velocity, acceleration, force or pressure. Pressure within the eye is measured (tonometry) by determining the force required to flatten a defined area of the cornea. The blood pressure maximum (systole) and minimum (diastole) can be measured with the familiar cuff and stethoscope. Measurements of blood pressure as a function of time are usually made with catheters inserted in an artery. These either have a small pressure transducer at their tip or contain fluid which transmits the pressure to an external transducer. Recently, schemes have been developed which measure the blood pressure changes noninvasively by applying a time-varying external pressure which unloads the arterial wall (Wesseling; Yamakoshi).

The classical instrument for measuring respiratory flow is the water spirometer. A bell jar, balanced by a counterweight and closed at its lower, open end by a water seal or bellows, moves up and down as the patient breathes into the space it encloses. Movement of the bell jar can be related to volume changes in the lung by using the gas law. Flow rate is the time derivative of the lung volume. Pneumotachometers measure flow directly. Some pneumotachometers use a small turbine in the air stream; others measure the pressure drop across a section which offers a fixed resistance to the air flow. Still other models measure the convective cooling of a hot wire by the flowing air.

Thermal and dye dilution techniques are used to measure cardiac output. For thermal dilution, catheters are threaded through a vein into the right atrium and the pulmonary artery. A known amount of cool liquid injected into the right atrium warms up as it passes through the right ventricle into the pulmonary artery. The time constant for warming can be related to the flow rate from the heart. Cardiac output can be determined by a similar mathematical analysis when a dye or a radioactive isotope spreads after it is injected.

The most obvious application of acoustics is in the diagnosis of hearing disorders. Audiograms show the threshold of sensitivity of the ear to tone bursts of different frequencies. Measurements of the acoustic compliance of the ear drum as external air pressure is changed (tympanogram) can be used to distinguish different problems in the middle ear. *Evoked response audiometry* or *auditory brainstem response* records small electrical signals from the scalp due to audible stimuli. Because these signals have an amplitude of about 100 nV and are masked by other signals of about 50 μV, the signal must be extracted by averaging over many stimuli. The amplitude and time delay of the various components of this signal provide diagnostic information (Thornton).

Ultrasound is used extensively as a diagnostic tool. The basic pulse-echo technique detects discontinuities in acoustic impedance at anatomical features and locates them by the time required for the echo to return to the transducer. Two-dimensional maps are made by recording the direction in which the transducer points along with the echo time. By pointing the ultrasound beam at the heart, motion of the heart wall and valve leaflets can be recorded as a function of time. The Doppler effect is also exploited in ultrasonic diagnostic to measure the velocity of the reflecting surface. Detecting only moving interfaces improves the signal-to-noise ratio for monitoring fetal heart or lung movement. The magnitude of the frequency shift when ultrasound is scattered from red cells is used to measure blood flow. Details of various ultrasound techniques can be found in the references by Wells.

One frequently measures directly the electrical potential difference between two points on the body. Various kinds of measurements are shown in Table 1. These potentials arise because the interior of a cell is normally at a potential of 70–90 mV less than the outside. As a nerve cell conducts or a muscle cell prepares to contract, the cell depolarizes and the interior becomes more positive than the outside. The resulting currents flowing in the body give rise to potential differences at the surface. (These currents also produce magnetic fields which can be measured with SQUID magnetometers (Wikswo; Geselowitz)).

The measurement of these potentials requires great care in the design of the electrodes. It is necessary to minimize battery effects (polariza-

TABLE 1. Measurements of Electrical Potential Difference Between Points on the Body.

Measurement	Source or Stimulus	Measurement	Amplitude	Frequency Response
Electroencephalogram	nerve activity in the brain	electrodes on scalp	10–100 μV	0–100 Hz
Electrocardiogram	muscle activity in the heart	surface electrodes on the limbs and chest	1 mV	0–100 Hz
Electromyogram	electrical activity in skeletal muscles during contraction; motor and sensory nerve conduction	needle electrodes surface electrodes	1 mV 50 μV	10 Hz–3 kHz
Electroretinogram	flash of light periodically moving pattern	cornea to lid	200–500 μV 10 μV	1–600 Hz 0.5–100 Hz
Electrooculogram	eye movement	skin on nose and temples, or corners of eye	1 μV	0–10 Hz
Visual evoked response	flash of light; changing pattern	scalp electrodes over visual (occipital) cortex	1 μV	1–600 Hz
Auditory brainstem response	sound stimulus	scalp	100 nV	50 Hz–2 kHz

tion) and spurious signals which can be generated in the outer layers of the epidermis (Webster; Plonsey).

The principles of geometrical optics are used in ophthalmology to examine the eye and determine errors of refraction. The ophthalmoscope works on the principle that an object at the focus of a lens produces a beam of parallel rays. If both the patient and examiner have normal vision and the patient's retina is illuminated, the parallel beam of light emerging from the patient's eye will be focused on the retina of the examiner. A laser, used as a flying-spot scanner, has been used to produce raster images of the retina (Webb). Total internal reflection has made possible fiber optic endoscopes which are quite flexible and which can be used to examine the patient's colon, stomach, lungs, urinary bladder, etc., with much less discomfort than with the old rigid-tube instruments. Moiré patterns have been used to record body surface contours.

The most widespread use of lasers in medicine has been for photocoagulation, which is outside the scope of this article. Speckle patterns have been used for refracting the eye. Holographic techniques have been suggested for the diagnosis and quantification of glaucoma.

The use of x-rays, nuclear radioactivity, and ultrasound for diagnosing and treating patients is called *medical physics* in the United States. Conventional radiography measures anatomical features by using a point source to cast a shadow of the patient on a sheet of film. X-ray photons of 60–80 keV are used so that the photoelectric effect, which depends strongly on atomic number, will help separate bone from soft tissue. It is often necessary to introduce contrast agents of high atomic number into the esophagus, stomach, bowel, kidneys, blood vessels, or hepatobiliary tree, in order to visualize the anatomical features.

Tomography (Greek *tomos*: a cut or section) has been used to blur all but one plane within the body by pivoting both the camera and the film around a point in the plane of interest. Computed tomography produces genuine sections by reconstructing a function $f(x, y)$ from a series of projections $F(x) = \int f(x, y)\,dy$ taken at many angles through the body (Fig. 1). In transmission tomography, the attenuation of a pencil beam of x-rays is measured, and the function $f(x, y)$ is the x-ray attenuation coefficient (Pullan). Emission tomography measures the γ-rays emitted by a radioactive pharmaceutical agent distributed along a line through the body, and $f(x, y)$ is the concentration of the radioactive substance.

Ultrasonic tomography is also being developed. For ultrasound $f(x, y)$ can be the reciprocal of the velocity (if $F(x)$ corresponds to the propagation delay of a pulse) or $f(x, y)$ can be the ultrasonic attenuation coefficient. The analysis is complicated by the fact that ray optics is not a good approximation to the propagation of the ultrasound.

Digital radiography uses electronic detectors similar to those used in computed tomography to record a two-dimensional projected image similar to that of a conventional x-ray. In addition to providing greater dynamic range than film, this technique allows images to be made by digital subtraction. For example, a recording without an intravenous contrast agent, sub-

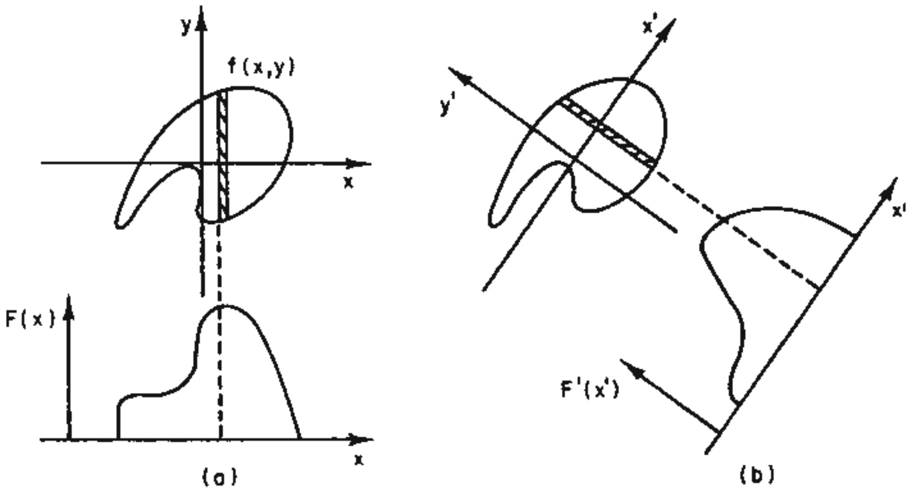

FIG. 1. Computed tomography reconstructs a function $f(x, y)$ from a series of projections $F(x)$, $F'(x')$, etc. (From Hobbie; reproduced by permission of John Wiley & Sons, Inc.)

tracted from one with the agent, provides an image of the vascular system. Similar images in the past usually required an intra-arterial injection of larger amounts of the contrast material, with greater discomfort and risk for the patient.

A single scan of a limb with a monoenergetic photon source and a scintillation detector allows quantitative determination of bone mineral content. The source for this small, desk-top machine is a radioactive nucleus which emits a gamma ray photon (Cameron, 1963).

X-ray fluorescence is used to measure the concentration of heavy metals such as lead or mercury in the body. When the x-ray fluorescence lines are favorably situated this method is sensitive to 10–20 ppm (Bloch).

Nuclear medicine measures the γ-ray emission of radioactive pharmaceuticals taken up in various organs of the body. Detectors range from a small unit placed over the organ of interest to a large disk of scintillator viewed by many photomultiplier tubes, which can record a plane-projected image of the body. Emission tomography, mentioned above, uses an array of detectors surrounding the patient (Brownell). X-ray and nuclear medicine techniques provide complementary information. X-ray pictures typically have resolutions of 1 mm and measure anatomical features; the resolution of a nuclear medicine image may be a factor of 10 worse, but since the radioactive pharmaceutical has been selectively taken up by some organ, the nuclear medicine image shows the physiological function of different parts of the organ (MacIntyre).

Neutron activation analysis is used to measure specific elements in the body. A neutron source such as ^{252}Cf irradiates the region of interest. Some of the nuclei in the body are made radioactive; the excited nuclei emit γ-rays of characteristic energy, the intensity of which is proportional to the concentration of the element being measured.

Nuclear magnetic resonance measures the absorption and emission of radiofrequency photons as a nuclear spin magnetic moment changes orientation in an external magnetic field. The photon frequency is proportional to both the external magnetic field and the nuclear magnetic moment. The strength of the signal is proportional to the concentration of the nuclei for which the apparatus is tuned. Studies are most often made of protons (hydrogen), although other atoms such as ^{31}P also possess a nuclear magnetic moment. Pulsed NMR also allows measurement of relaxation times, during which the excess nuclear orientation energy is exchanged with the surrounding lattice or with neighboring nuclei. Since the NMR resonance frequency is proportional to the external magnetic field, it is possible to image either hydrogen concentrations or relaxation times by varying the magnetic field across the patient. The reconstruction techniques are similar to those in computed tomography (Brownell; Lai).

NMR is also used to measure blood flow. The measurement relies on the fact that once the nuclei have been aligned, the RF resonance field misaligns them even as it produces a measurable signal. If the fluid is flowing, new aligned nuclei are brought into the sensitive volume at a rate proportional to the flow, and the signal is increased (Battocletti).

An article this short can only survey the field of biomedical instrumentation. The references which follow will provide the reader with more detailed information about any topic mentioned. Topics which do not have specific references above are discussed in the books by Cameron (1978), Cobbold, and Webster.

BIONICS

Bionics is defined as the branch of knowledge pertaining to the functioning of living systems and the development of nonliving systems which function in a manner characteristic of, or resembling, living systems. The definition of bionics infers the use of scientific skills and techniques from biological, physical, mathematical, and applied sciences in carrying out research in which: (1) the functions of chosen biological components and systems are studied and analyzed to determine underlying principles and processes that may lead to methods for improving physical components or systems, and (2) the theories and techniques of chemistry, physics, and mathematics are applied to advance our knowledge of the principles upon which these functions are based.

Bionics research depends on the acceptance of certain postulates. These postulates are of two types—one essentially operational, the other essentially technical. The important operational postulates are: (1) Common experience shows that biological systems perform operations that no nonbiological system can now perform efficiently, e.g., operations such as pattern recognition and identification, discrimination, and learning; (2) biological components perform such functions as detection, filtering, and information transfer more efficiently and with greater certainty over broader bandwidths than do present nonbiological components; (3) intensive study, analysis, and application of the principles that make superior biological performance possible can lead to nonbiological systems that equal or may, in some cases, exceed biological systems capabilities. The technical postulates are: (1) The functional advantages of biological systems are implied in the unique methods for information transfer, memory storage, and retrieval, united with unique ways of correlating and integrating data from many sensors or sensor systems. These unique methods depend mainly on: (a) many converging and diverging information transfer channels and many connections between channels, and (b) the special properties of biological components at the points where these channels are interconnected. (2) The superior capabilities of biological components or particular elements of the components (e.g., receptor cells or nerve muscle junctions) are derived from specific ways of interconnection and probably as well from specific molecular properties. (3) The relevant data describing biological systems that will represent major improvements over existing physical and engineering hardware are analyzed and studied. (4) The present rapid advances in microminiaturization techniques suggest that, for the first time, the possibility exists for the development of physical components or systems that incorporate these superior biological principles and processes.

The definition of bionics suggests the methodology of procedure. We design, grow, or in some way obtain nonbiological systems that function in a way "resembling" living systems. The physical component simulates the biological way of doing or carrying out its function. To obtain this objective, we first choose the biological components that perform the desired function; second, we compile the descriptive biological data; third, we translate these data into engineering terms; and fourth, we apply the translated data for the physical simulation of the function.

This process requires application of relevant mathematics to describe clearly, and as rigorously as possible, the biological function by some mathematical theory or model. This process may also require various techniques from the physical sciences to arrive at the necessary data defining the biological function of interest.

While the bionics research procedure requires the description, mathematically, of the function to be performed by the nonbiological system, it may also require mathematical and physical descriptions of the properties of the materials used to construct the nonbiological analog.

Gaining enough data to describe the given biological function may require study of the biological component or one of its elements at the molecular level. Similarly, solid-state or molecular techniques may be required to construct the physical system that is the appropriate simulation of the desired biological function.

Successful bionics activity may be modified by several factors. These include the complexity of the biological functions; the kind, quality, and quantity of data available to describe the functions; and the existence of relevant mathematical and physical techniques essential to the simulation of the functions.

In terms of the bionics objectives, the scope of the work must include research on the following components and/or systems: (a) receptors or sensors; (b) receptor systems–including central interconnections and interconnections among receptor systems; (c) central nervous system networks and the interconnections among parts of the nerve network; (d) effectors and actuators; (e) effector systems–including the feed-back and feed-forward connectors to and from the central processor; (f) the integrated system made up of sensors and their input channels, the central correlating, control, and computing networks, and the channels from the central system to the effectors and actuators.

This complete research program will extend over a long period of time. However, progress has been made. Data have been acquired, analyzed, and put into engineering terms to provide a set of specifications for the functional properties of several types of neurons. The neuron is presumed to be that physiological component underlying observed psychological parameters such as learning and adaptation. Therefore, the construction of a network of artificial neurons should, to some extent, simulate these observed behavioral parameters. In contrast, data have been acquired and analyzed from the field of experimental psychology on functions such as learning. These data can be translated into engineering and can suggest types of components which can simulate the learning function directly. This example illustrates a procedure which is common in bionics research. One can start at the operational level with an observed set of functional parameters and attempt to synthesize the class of mechanisms that could simulate these functions, or one can start with the biological component which is presumed to give rise to these functions and attempt to simulate this component. The choice of one method over the other depends greatly on the assurance one has of the validity of the data at one level or the other.

Applications, using the former (functional simulation) type of component, have been successfully made to flight control systems, variable geometry jet engine control, radar detection and search problems, and various industrial process control problems such as nondestructive materials inspection techniques. The functional simulation type of component has been successfully realized in both microcomputer and LSI (large scale integrated circuit) forms.

At the biological component level of simulation a somewhat different approach has been initiated, mostly by the work of Dr. A. H. Klopf (see references).

Heretofore goals for adaptive networks were presumed specified at the systems level or at most at the subsystem level; rarely at the individual component level. Dr. Klopf's work has been exploring the possibilities of goal seeking systems realized with goal seeking components. The goals for the components may be of several types, but the emphasis has been on designing the components so as to maximize certain parameters associated with signal propagation. There is evidence that similar processes may occur in physiological neurons. A preliminary extensive assessment (circa 1980) has been made. A few of the relevant papers are listed in the references under Applications.

BIOPHYSICS

Biophysics is a very broad field with poorly defined boundaries. It encompasses all applications of the principles of physical science to the functioning of living organisms. It has considerable overlap with areas of biomedicine, bioengineering, biochemistry, and physiology, as well as strong connections to space medicine, sports medicine, fluid dynamics, psychology of perception, molecular biology, membrane physiology and other related topics. This article will provide a very brief summary of some selected topics; it will neither cover all areas nor discuss those chosen in great depth.

In a strict sense, biophysics is as old as science itself. In Western intellectual history, those who made significant contributions to physical science also had important roles in the biological sciences. Aristotle wrote extensively (often incorrectly) about human and animal functioning, Newton and Galileo studied many aspects of human physiology, and René Descartes made significant contributions to our understanding. Thomas Young, a physician who described optical interference and translated the Rosetta Stone, provided a theory of color vision that has a significant remnant in modern theories of this most difficult subject. Galvani's discovery of bioelectricity was another important event in the history of biophysics.

More modern progress has resulted from surprising and unrelated discoveries. The work of Becquerel and Roentgen provided X-ray methods that produced an incredible amount of new knowledge, even up to the application of the diffraction technique of Bragg for the analysis of the structure of DNA. Arrhenius and other chemists provided quantitative descriptions of the behavior of ions in solution. Coupled with advances in fluid dynamics, these discoveries induced further progress in understanding the behavior of biological fluids. The organic chemists provided information about metabolism and other processes leading to understanding of amino acids and proteins and modern achievements such as Sanger's synthesis of insulin.

Contemporary biophysics contains very many diverse areas of investigation. Some of these are extensions of older subjects while others represent completely new areas of investigation. A small number of topics from each of these categories is discussed below.

One of the oldest subjects in biophysics is the study of energy expenditure, conservation, and conversion in the performance of physiological functions. Ordinary mechanics can be used to calculate the optimum performance expected from human athletes in a variety of events. The results of these studies compare favorably with Olympic records, thereby supporting the hypothesis that mechanical action for men and machines follow the same rules. For example, equating the potential energy at the top of a jumper's trajectory h to the work done by the leg muscles in accelerating the body upward by distance s gives $Fs = mgh$ where F is the average muscular force. For humans, s is about $\frac{1}{2}$ meter and the maximum force F is about mg, suggesting that we can raise our center of gravity about $\frac{1}{2}$ meter by jumping. This is supported by experience. In another example, we find that the peak power output of a human athlete is about 3600 W whether running at maximum speed (10 m/sec), throwing a 1 kg football 50 meters or a 7 kg shotput 16 meters, or broad jumping 3.5 meters. Each of these calculations is based on certain idealized but sensible models of the body, in accordance with the practice of physicists trying to understand nature.

The food requirement, energy and oxygen consumption, and metabolism changes for these activities are now well documented. Studies of animal motion are now showing that there are many different ways to use the metabolic energy available from the food supply to move about, conserve water, escape from predators, etc.

Measurements and studies of energy consumption in the ordinary processes of life have provided considerable knowledge about physiological functions as well as the basis for a wide variety of diagnostic tools and methods for the practice of modern medicine. The power required to keep warm, maintain respiration and circulation, and provide necessary chemical gradients constitute the basal metabolism rate (BMR). Control of the flow of this energy between storage areas and external reservoirs is the subject of a major field of study. Elementary aspects of feedback control are apparent in some processes; others are so very complicated that they haven't been unravelled. There are many pathological circumstances that can be traced to improper or inadequate control of energy exchange.

On the microscopic scale, many aspects of energy transfer are still not known. We know that mitochondria are the power plants of cells, converting the energy of metabolism into a phosphor bond in ATP, the basic fuel for life. The ATP transports stored energy for muscle contraction, Na^+ expulsion, etc., but many details of the process are not understood. Activity and progress in the study of energy in biological progress spans the range from how horses run to the phosphorylization of ATP.

Another very important subject in biophysics is sensory perception. The discussion in this article will deal primarily with vision and hearing because both the stimuli and the responses are more amenable to quantitative description than are taste, smell, and kinesthesis (touch). The sciences of optics and acoustics are very highly developed and as such allow careful study of animal response to light and sound.

We begin with the optics of the human eye. The $f/4$ (approximately) system has a resolution limited to a few μm on the retina by diffraction, and this is remarkably close to the size of the receptor cells (this near agreement is startling). Measurements of visual acuity reveal that our angular resolution of detail is indeed equal to this 10^{-4} radian limit. But the naive notion of point-to-point transmission of images from eye to brain that would allow connection of these two facts is shattered by the additional information that 10^8 cells 2 μm in diameter cover the retinal surface, but there are only 10^6 individual neurons in the optic nerve. This 100 : 1 reduction is the most elementary of many pieces of information that demand a more sophisticated description of human vision.

The Nobel prize winning work of H. K. Hartline (1967) and of D. Hubel and T. Weisel (1981) have shown that lateral inhibition (LI) among receptor cells plays an indispensible role in our visual process. LI arises when the response of a particular receptor cell to a fixed stimulus is reduced by the stimulation of an adjacent cell. It provides a mechanism for enhancing contrast and increasing sensitivity to edges and boundaries. Furthermore, there are higher levels of LI that result in considerable data processing, leading many scientists to the feeling that the retina is an extension of the brain.

It has long been known that there are many ways nerves can form junctions (synaptic junctions) and that some of them are inhibitory. That is, if two axons feed into a single ganglion cell, it is possible that the ganglion's response to a fixed stimulus from one of the axons could be reduced by a stimulus from the other axon. In this case we say that the other axon has an inhibitory effect.

In order to understand how inhibition affects perception, we consider an array of receptors as shown in Fig. 1. Suppose that each cell in the array could inhibit the response of its nearest neighbor, but only by some fixed fraction of the original cell's response. If the array is subject to a nonuniform stimulus that has a maximum located at one of the cells, that cell will exert a stronger inhibitory effect on its neighbors than they will exert on it, resulting in an enhancement of its relative strength. In the numerical example of Fig. 1, we assume each cell can inhibit the response of its neighbors by 25%. The cell whose uninhibited response would be 80 is reduced by 25% of 50 (= 12.5) and 25% of 100 (= 25) so that its net response is only 42.5 (similarly for the other cells). We notice that the center cell that had enjoyed only a 25% higher level of response to distinguish it as being at the maximum before inhibitory effects is now elevated to a 40% higher level over its neighbor. Inhibition can act in this way to sharpen sensory perceptions.

Resolution of detail in a biological optical system is not as simple as a discussion of ideal components with well understood physical limits. Indeed, the system is subject to all the irregularities of biological growth as well as the effects of the scattering of light from impurities in ocular fluids. The problem of information retrieval from severely distorted images by a system of limited resolution is a fertile area for physical study.

The visual system provides much more information than simply the image in the field of view: one of its most striking capabilities is color

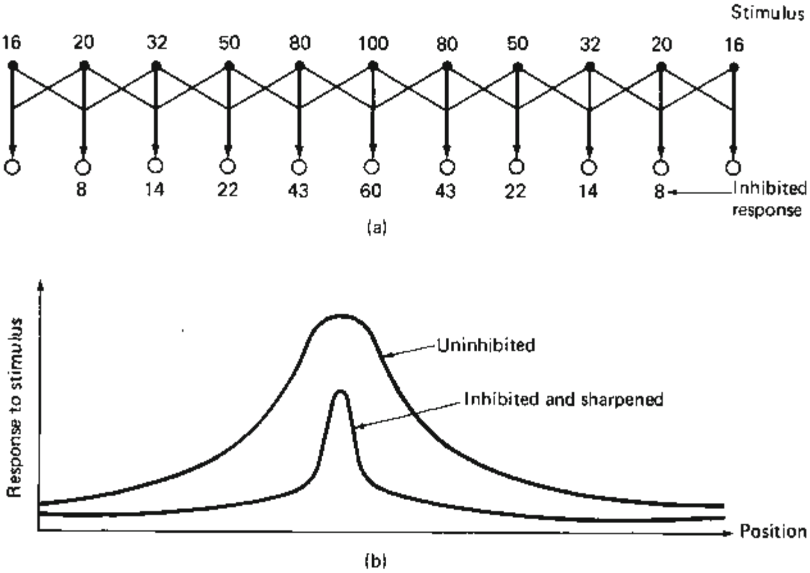

FIG. 1.

perception. Although different wavelengths of light are perceived as different colors, it has been conclusively demonstrated that different color perceptions can be achieved with the same wavelength, and the same color perception with different wavelengths. There is an extraordinarily large body of data on color vision, but no single, clear, simple theory has emerged. The role of LI in the process is probably as important as it is in detail perception.

Our hearing process, particularly tonal discrimination, is also enhanced by LI. The Nobel prize winning work of G. von Bekesy (1961) showed that tonal discrimination over a large region of the spectrum of audible sound stems from excitation of spatially distinct regions of the basilar membrane, a thin sliver of tissue curled up in the cochlea in the inner ear. But tones having small frequency differences can excite overlapping regions of the membrane, resulting in limits to our ability to distinguish between slightly different tones. The detection of vibration of the basilar membrane is also subject to LI, much like image detection, in a system that functions to enhance discrimination. The ability of trained musicians to sense off-key notes to a precision of less than 1% attests to the capability of the system.

Another area of major interest in biophysics is transport. This includes the gross transport of fluids through the circulatory system for the purpose of distributing heat and nutrients, as well as the microscopic transport of molecules through membranes and fluids. The most obvious example of fluid transport in human physiology is blood flow. Classical fluid dynamics can be used to describe flow when friction can be ignored ($P + \rho gh + \rho v^2/2$ = constant—Bernoulli's equation) and also when viscous friction plays a dominant role ($Q = \pi R^4 \Delta P/8\eta L$—Poiseuille's equation). Each of these equations describes ideal fluids (continuous, homogeneous, incompressible, etc.) flowing under ideal conditions (smooth straight pipe with rigid walls, no turbulence, steady flow, etc.). Application of these models to human circulation must be done with the greatest of care because blood contains both rigid and deformable bodies of various sizes, flows in vessels with elastic walls that bend and divide, and is pumped into an elastic aorta by a cyclic heart that produces pulsatile flow.

Ventricular contraction produces a rapid injection of blood into the aorta. Since resistance to flow in the peripheral circulatory system is rather high, the elastic walls of the aorta expand to accommodate the extra volume: the kinetic energy of the blood is briefly stored as potential energy in the aortic walls and then slowly returned as the collapsing aorta squeezes the blood through the rest of the system. The flow is very fast at first (Reynolds number $\cong$ 2000) and then slows as the dominant pumping comes from the aortic walls. A good electrical analogy is a capacitor ripple filter on an ac current source. Classical fluid dynamics may apply instantaneously to some parts of this sequence of events, but the boundary conditions are changing so rapidly that quantitatively accurate descriptions are not available.

Flow in the peripheral arteries is somewhat simpler, but branches and elastic walls still provide difficulties. The simple relationship between radius R and pressure difference ΔP for an elastic tube of wall thickness t ($R/R_0 = 1/(1 - x)$, $x = R_0 \Delta P/Yt < 1$) that might be used in Poiseuille's equations is inapplicable because the Young's modulus Y is not necessarily constant—arterial walls contain both elastin and collagen, resulting in a nonlinear stress-strain relation.

Flow in the smallest vessels is complicated by the presence of blood cells. An average viscosity is no longer a tenable description, and very complicated conditions can arise. Some capillary vessels are so narrow that the cells must deform to squeeze through them. Sometimes a few red cells can join into larger objects called rouleaux, further complicating the problem by producing a rather large distribution of cell sizes. In some circumstances there is a tendency for the cells to concentrate in the central core of flow leaving a layer of liquid adjacent to the vessel walls, and thus producing a *decrease* in the apparent viscosity (Fahreus-Lindquist effect).

For these and other reasons, a physicist approaches the problem of blood flow with some trepidation. The models must be carefully thought out, applied in the proper domains, and the results must be interpreted with the proper limitations in mind.

The other meaning of transport in biophysics applies to movement of molecules, ions, and dissolved gases across membranes and fluid boundaries. This problem has very many facets, only some of which will be described here. To begin, the transport of solutes across concentration gradients in the usual kinetic sense (osmosis, diffusion, etc.) is very important in many circumstances. There are several distinct phenomena involved in various examples, but they can most readily be divided into the two categories of kinetic and carrier-mediated diffusion. Kinetic diffusion is the usual topic described by the random walk process. The techniques of statistical analysis provide a quantitative description called Fick's laws, whose equations are familiar to many physicists. Carrier-mediated diffusion is not significantly different in some concentration domains, but the transported substance may reach concentrations that saturate the capabilities of the carriers, resulting in a nonlinearity that doesn't appear in Fick's equations. Nevertheless, a differential equation similar to that of catalyzed chemical reactions describes the process.

One of the most important areas of current study is transport through membranes. This process may be suitably described by kinetic methods for substances soluble in the membrane's lipids, but this is usually not the case. In the more usual case, transport occurs through pores or channels that are either large or comparably sized with the solute molecule, and different conditions prevail in these cases. Sometimes channel transport is carrier mediated, sometimes the walls of the channel or the nature of the solute molecule dictate the dominant process of transport, and sometimes the properties of the channel depend on time or on the chemical environment. Transport against a concentration gradient, called active transport, is most well-known for the "sodium pump" that maintains a lower Na^+ concentration inside electrically active cells (nerve and muscle). The details of this process are not yet completely understood.

The uptake of nutrients, the exchange of O_2 and CO_2 in the lungs, the response to chemical transmitters of nervous information, and many other processes involve membrane transport. Each of them has special characteristics and mitigating circumstances that are amenable to a physicist's model-making approach to nature. A great deal of understanding of many of these processes has been achieved by the application of physical methods to biological problems; many others are under active investigation.

This article has presented a brief summary of some restricted aspects of three major topics in biophysics. The interested reader is referred to the references which follow and the work cited in them for further information on these topics as well as discussions on very many others.

BOLTZMANN'S DISTRIBUTION

Boltzmann considered a gas of identical molecules, able to exchange energy upon colliding, but otherwise independent of each other. Such a system, in which the interactions between the molecules between collisions is neglected, is applicable to real gases which are sufficiently rarefied, for in that case the molecules are almost always sufficiently far apart for the interaction force between them to be negligible. An individual molecule of such a gas moves freely between collisions, but experiences abrupt random changes in velocity in each collision, so that no exact statements can be made concerning its state at a particular time. However, when the gas comes to equilibrium at some fixed temperature, predictions can be made concerning the average fraction of molecules which are in a given single state, or equivalently, the fraction of time spent by one molecule in that state. (The concept of a single state will be described below.) Since these average fractions are equivalent to probabilities, one can say that predictions can be made for the probability distribution for a molecule over its possible single states. To describe this distribution, let the set of energies available to each molecule be denoted by ϵ_j. If l and m stand for two single states of a molecule and ϵ_l and ϵ_m the energies of the molecule when it is in these states, then the ratio of the probability P_l of finding a molecule in the single state l to the probability P_m of finding a molecule in the single state m is

$$\frac{P_l}{P_m} = \frac{\exp(-\epsilon_l/kT)}{\exp(-\epsilon_m/kT)} \tag{1}$$

This distribution of molecules over different states is called *Boltzmann's distribution*, after the founder of statistical mechanics, Ludwig Boltzmann (1844-1906). Equation (1) indicates that the ratio of probabilities for a molecule to be in two selected states depends only on the energies of these two states and on the thermal energy kT, which is proportional to the equilibrium temperature T. When T is measured in kelvin ($T = 273.16$ K at the triple point of water) then the universal constant k, called *Boltzmann's constant*, has the value 1.38041×10^{-23} joules/kelvin.

Using the fact that the sum of the probability P_l over all accessible states for a molecule must be unity leads to an alternative form of Eq. (1):

$$P_l = \frac{\exp(-\epsilon_l/kT)}{\sum_j \exp(-\epsilon_j/kT)}. \tag{2}$$

Equation (2) indicates that the probability for a molecule to be in a single state l varies exponentially with the negative of the energy in the state, divided by kT. The exponential $\exp(-\epsilon_l/kT)$ is called the *Boltzmann factor*. The sum of the Boltzmann factor over all single states for the molecule which appears in the denominator of Eq. (2) is called the *partition function* for the molecule. This alternative form of Boltzmann's distribution indicates that the probability of finding the molecule in a single state l is smaller, the larger is the energy ϵ_l, and that the rate of decrease of probability with increasing energy is faster, the smaller is the temperature T.

Boltzmann's original derivation of the probability distribution described by Eqs. (1) and (2) was restricted to the molecules of a gas. Subsequently, Gibbs (Josiah Willard Gibbs, 1839–1903) recast the reasoning to show that the Boltzmann distribution holds not only for a molecule, but also for an arbitrary system in thermal equilibrium with a much larger system, the reservoir, with which it can only exchange energy. The combination of system plus reservoir forms a closed system, insulated from all external influences. With this greatly extended applicability, the Boltzmann distribution is of vast utility in analyzing the equilibrium behavior of a wide range of both classical and quantum systems. In such applications, it is essential to understand the meaning of the concept of single state used above. This is simpler to describe for quantum systems, and will lead to a somewhat different but related description for classical systems, which can be regarded as limiting cases of quantum systems.

Quantum mechanics asserts that a complete description of a physical system is given in terms of probability amplitudes and provides a method for calculating these amplitudes. The probability amplitudes describe the state of the system, for using them one can predict the probabilities for the result of measurement of a set of compatible dynamical variables of the system, such as the three Cartesian components of momentum for a free particle, p_x, p_y, and p_z, or alternatively, its three coordinates x, y, and z. Special importance is attached to states, called *eigenstates*, for which measurements of particular dynamical variables yield one unique result, rather than a range of possibilities. The special values of the dynamical variable corresponding to each eigenstate are called the *eigenvalues* for that dynamical variable. For our present purposes we are interested in the eigenvalues of the energy for a system, corresponding to the ϵ_l in Eqs. (1) and (2), and its corresponding eigenstate. Confined systems, like a gas of molecules in a container have a discrete set of energy eigenvalues. It may be that a particular one of these discrete energy eigenvalues ϵ_l corresponds to not one, but rather several linearly independent probability amplitudes, each of which describes the system with the same energy ϵ_l. Each of these linearly independent probability amplitudes represents what we previously called a single state. One says that such an energy level ϵ_l is *degenerate*, and a g_l-fold degenerate energy level is one which is equally well described by g_l linearly independent eigenstates (single states). As an example, take the physical system to be a single structureless particle of mass m freely moving in a container, which is a rectangular box with length a, breadth b, and height c. The energy eigenvalues for this system are

$$\epsilon_{n_x, n_y, n_z} = \frac{h^2}{8m}\left(\frac{n_x^2}{a^2} + \frac{n_y^2}{b^2} + \frac{n_z^2}{c^2}\right) \tag{3}$$

where h is Planck's constant, $h = 6.6256 \times 10^{-34}$ joule-seconds, and n_x, n_y, and n_z are independent integers, positive or zero, which are called *quantum numbers*. The probability amplitude, or energy eigenstate ψ is the following function of particle coordinates x, y, and z:

$$\psi_{n_x, n_y, n_z}(x, y, z) = \left(\frac{8}{abc}\right)^{1/2} \sin\frac{n_x \pi x}{a} \cdot \sin\frac{n_y \pi y}{b} \sin\frac{n_z \pi z}{c}. \tag{4}$$

In the case that no two dimensions a, b, c of the box are in a ratio of integers, the energy levels corresponding to various sets of values of the three quantum numbers are all different, with one and only one probability amplitude ψ associated with each. Energy levels of this type are *nondegenerate*. If, however, any pair of a, b, c are in a ratio of integers, there will occur certain values of the energy $\epsilon_{n_{\hat{x}}, n_{\hat{y}}, n_{\hat{z}}}$ corresponding to two or more distinct sets of values of the three quantum numbers n_x, n_y, and n_z, and to two or more independent probability amplitudes ψ. This is the case of a degenerate energy level. For example, if the container is a cubical box with $a = b = c$, most of the energy levels will be degenerate, since all eigenstates with $n^2{}_x + n^2{}_y + n^2{}_z = q$, a fixed integer, have the same energy, $\epsilon_q = h^2 q/8ma^2$. Say $q = 30$, then any of the six assignments of integers 1, 5, and 2 to n_x, n_y, and n_z yield the same energy, but correspond to different amplitudes ψ. This example illustrates the connection between degeneracy and geometrical symmetry—for the cubical box the directions x, y, and z are all equivalent.

It may often be more suitable to express the Boltzmann distribution in terms of probabilities $P(\epsilon_l)$ for a system to have a given energy ϵ_l, rather than P_l, the probability for the system to be in a single state. In that event, the ratio of probabilities for finding the system in two energy levels will include the degeneracy factors g for each level, and Eq. (1) will become:

$$\frac{P(\epsilon_l)}{P(\epsilon_m)} = \frac{g_l \exp(-\epsilon_l/kT)}{g_m \exp(-\epsilon_m/kT)}. \tag{5}$$

For example, if the difference in the two energies $\epsilon_l - \epsilon_m$ is much less than the thermal energy kT, the probability ratio will just be the ratio of the degeneracy factors for these two energy levels.

Atoms and molecules are properly described in terms of quantum mechanics, but a description in terms of classical mechanics may sometimes be a useful approximation. We now consider the concept of *single state* in classical mechanics. Here the state of a single particle is completely described in terms of its position coordinates x, y, and z, and corresponding momenta p_x, p_y, and p_z. The specification is complete, since the laws of classical mechanics are such that knowledge of position and momentum at any one time permits prediction of these variables at any other time. Specification of the state of the particle is then equivalent to specifying a point in the six-dimensional Cartesian space spanned by three coordinate axes x, y, z and three momentum axes p_x, p_y, p_z. As the position and momentum of the particle change with time, its representative point moves through this space, which is called the *phase space*. The particle has three degrees of freedom, and is represented in a six-dimensional phase space. In general, a system with f degrees of freedom has its state described by f coordinates and f conjugate momenta, and is represented by a point in this $2f$-dimensional phase space.

Connection between the classical description of a state with its continuously changing coordinates and momenta and the quantum mechanical description in terms of discrete states for dynamical variables labelled by quantum numbers is made by considering the classical limit of quantum systems. In this limit, the discrete eigenvalues of dynamical variables change by only a very slight fractional amount with small changes in the quantum numbers which determine them. For example, the classical limit for the particle in a box, with quantized energies given by Eq. (3) is achieved for large energies, or large quantum numbers n_x, n_y, and n_z, when energy levels become very closely spaced. Consider the case of a cubical container with volume a^3 and energies $\epsilon_n = h^2n^2/8ma^2$, with $n^2 = n^2{}_x + n^2{}_y + n^2{}_z$. For large values of the quantum numbers n_x, n_y, and n_z, small changes in these numbers will produce a change Δn in n, and a corresponding change $\Delta\epsilon_n$ in energy, such that $\Delta\epsilon_n/\epsilon_n = 2\Delta n/n$ is smaller, the larger is n. Then the number of quantum states for which n lies between n and $n + \Delta n$ will be the volume V of one octant of a spherical shell in n_x, n_y, n_z space with radius n and thickness Δn, or $V = 4\pi n^2 \Delta n/8$. In this classical limit, we expect the particle energy to depend on momentum as $\epsilon_n = p_n{}^2/2m$, with $p^2 = p_x{}^2 + p_y{}^2 + p_z{}^2$. Comparing the two expressions for the energy gives $p_n = nh/2a$. Then the number of quantum states for which the particle momentum lies between p and $p + \Delta p$ is just $(2a/h)^3$ times the volume in n_x, n_y, n_z space, or $a^3 4\pi p^2 \Delta p/h^3$. One now sees that this number of states, which is the phase space volume $a^3 4\pi p^2 \Delta p$ divided by h^3, could also have been obtained by dividing the six-dimensional phase space into cells of size h^3, then counting the number of cells which lie in that region of phase space which corresponds to the spatial volume a^3 and the region between p and $p + \Delta p$ in the momentum space. This result implies that each quantum state for the particle occupies a volume h^3 in the classical phase space. It is an example of a general result: for a system with f degrees of freedom, each of its quantum states occupies a volume h^f in the $2f$-dimensional phase space in the classical limit. We may remark that the finite size h for a cell in the phase space x, p_x of a particle with one degree of freedom corresponds to Heisenberg's uncertainty principle, according to which the position and momentum of a particle cannot be more exactly defined than is consistent with the relation $\Delta x \Delta p_x \approx h$ between products of their uncertainties. In view of this relation, it would be meaningless to make a finer division of the phase space, as it is impossible to decide by experiment in which of these cells a particle lies.

We can now apply Boltzmann's distribution law to find the momentum distribution for a free particle in a cubical container in thermal equilibrium at temperature T, in the classical limit. The particle has a (kinetic) energy $\epsilon = (p_x{}^2 + p_y{}^2 + p_z{}^2)/2m$. Suppose we want the probability $P(p_x, p_y, p_z)\, dp_x dp_y dp_z$ to find its momenta in the range between p_x and $p_x + dp_x$, p_y and dp_y, p_z and dp_z. Corresponding to this specification are a number of quantum states equal to $a^3 dp_x dp_y dp_z/h^3$. Multiplying this number of states (degeneracy factor) by the Boltzmann factor $e^{-\epsilon/kT}$ and dividing by the integral over all states gives the desired probability as

$$P(p_x, p_y, p_z)\, dp_x dp_y dp_z = \frac{\exp\left(-\dfrac{p_x{}^2 + p_y{}^2 + p_z{}^2}{2mkT}\right) dp_x dp_y dp_z}{\displaystyle\iiint_{-\infty}^{\infty} \exp\left(-\dfrac{p_x{}^2 + p_y{}^2 + p_z{}^2}{2mkT}\right) dp_x dp_y dp_z} \tag{6}$$

Equation (6) is called *Maxwell's distribution*, after James Clerk Maxwell (1831–79), who obtained it in 1860 before Boltzmann's more general derivation in 1871. We may note that this probability distribution is the product of three independent factors, each of which defines the probability distribution for a separate component p_x, p_y, or p_z of the momentum. The probability distribution for momenta given by Eq. (6) is applicable to the translational motion of the molecules of a gas, and in fact does not depend at all on the type or strength of the interactions between the molecules in the classical limit.

For systems of weakly interacting indistinguishable constituent elements such as atoms, molecules, electrons, and photons, the Boltzmann distribution properly describes how such elements are distributed among their own individual states only when the average number of elements or particles in every single state is considerably less than unity. Physically this case corresponds to the gas of particles being sufficiently rarefield. When this condition is not satisfied, quantum mechanical symmetry requirements on probability amplitudes for the system under exchange or any two identical particles lead to two new distribution laws. Particles with integral intrinsic spin, like photons, are described by the *Bose-Einstein distribution*. This distribution is applicable, for example, to the treatment of electromagnetic radiation, described as photons, in a hollow enclosure which has come to thermal equilibrium. It leads to the Planck radiation law for the density of radiant energy from a black body. Particles with half-integral intrinsic spin, like protons, neutrons, and electrons, are described by the *Fermi-Dirac distribution*. This distribution is applicable to the treatment of conduction electrons in metals and to dense stellar interiors.

An interesting physical system which involves both the Boltzmann and the Bose-Einstein or Planck distributions consists of a rarefield gas of atoms which absorb or emit electromagnetic radiation. The radiation may be considered as a gas of noninteracting photons. When thermal equilibrium is established between the gas of atoms and the gas of photons, the atoms of the rarefield gas will be distributed among their individual energy states according to the Boltzmann distribution, while the photons are distributed among their individual energy states according to the Bose-Einstein or Planck distribution. The physical consistency of this result was first proved by Einstein in 1917, for slowly moving atoms, and generalized by Dirac in 1927 to the case of atoms with arbitrary speeds.

BOND, CHEMICAL

Every atom consists of a relatively compact nucleus bearing positive charge, surrounded by a cloud of electrons in sufficient number exactly to balance the nuclear charge by their negative charge. Being thus electrically neutral, atoms might be expected to exert among themselves only the negligibly weak gravitational forces predictable for such low mass. However, there are two principal means by which more significant interatomic attractions can occur, and these are largely responsible for the existence and properties of chemical substances.

One is the result of the fact that the electrons surround the nucleus in an easily deformable cloud. Although opposite charges tend to distribute themselves if possible so that their centers coincide, when two atoms come near to one another, the repulsion between the two negatively charged electronic clouds results in mutually induced distortions of the clouds so that the charge centers no longer coincide, creating atomic dipoles. Although these dipoles oscillate rapidly, their net effect is to create an electrostatic attraction between the atoms. Such attractions are known as *van der Waals forces*. Although such forces become very significant as exerted between molecules consisting of many atoms, they are so slight per atom pair that at ordinary temperatures the attractions among small molecules are usually completely overcome by the disruptive forces of kinetic energy, making them gaseous. They are insufficient to hold atoms or small molecules together in a condensed state, liquid or solid, unless most of the kinetic energy has been removed by cooling. However, large molecules do cluster together at ordinary temperatures as a consequence of these intermolecular attractions, commonly so strongly that decomposition occurs before the temperature is high enough for melting or vaporization.

In contrast, much stronger per atom pair is the interatomic force known as the *chemical bond*. This depends on the electronic structure of each atom, described by quantum theory as based on occupancy by electrons of certain energy regions of limited number and availability. In atoms of only six of the chemical elements, helium, neon, argon, krypton, xenon, and radon, this electronic configuration, with two outermost electrons in helium, eight in all the others, results in a sufficiently thorough covering up of the nuclear charge that no region of the atom remains within which an electron from another atom might be stably accommodated. In atoms of all the other chemical elements, all of which have fewer than eight outermost electrons, however, there remain regions, called *orbitals*, within which an electron from elsewhere would, despite repulsions by the other electrons, experience a net electrostatic attraction between itself and the effective positive charge of the nucleus. Each such orbital can accommodate two electrons only, and there are four outermost orbitals in all atoms beyond helium in atomic number. Vacancies exist wherever the number of outermost electrons is less than eight, this being the maximum that the outermost shell can hold in any isolated atom. (For more on the effective nuclear charge that can be sensed in such vacancies, see PERIODIC TABLE AND PERIODIC LAW.) The presence of outermost vacancies provides the possibility that outer electrons from another atom may be accommodated, these electrons now being held by both nuclei. Thus the atoms are held together by simultaneous attraction of both nuclei for the same electrons. All chemical bonding is essentially of this nature.

There are four ways by which vacancies may be utilized to form chemical bonds:

(1) If the atoms have more outermost vacancies than electrons, then the outermost electrons of each can spread out into the vacancies of the others, resulting in what is called *delocalized* or *metallic bonding*.

(2) If each atom provides one outermost orbital that is half-filled, the single electron of each can be accommodated within the vacancy of the other so that a pair of electrons is shared between the two atoms, the atoms being held together because both nuclei are attracted to the same bonding electrons. This is called a *covalent bond*. The shared electrons are essentially concentrated within the internuclear region, and thus localized. If additional half-filled orbitals are available on each atom, multiple bonds between the same two atoms may form.

(3) If one atom has an outermost vacant orbital and the other an outermost filled orbital, or electron pair, this pair may be accommodated within the vacant orbital to provide electron-pair sharing, termed *coordinate covalence*.

(4) If each atom has the requisites for forming a covalent bond but one attracts electrons much more strongly than the other, the former may acquire essentially all the bonding electrons, thus gaining a unit negative charge at the expense of the other atom left with unit positive charge. The electrostatic attraction between the opposite charges will hold the atoms together in what is commonly called an *ionic bond*. The existence of truly ionic bonds is in serious question, most so-called ionic bonds being partly covalent and therefore more accurately described as *polar covalent*.

All substances derive their special physical and chemical properties from the nature of the atoms that compose them and the way in which these atoms are attached to one another. An understanding of chemical bonds is therefore at the very heart of understanding chemistry. All substances except the six elements mentioned above normally exist in the form of atoms bonded together. Therefore all chemical reaction involves the breaking of existing bonds and the formation of new ones. At ordinary temperatures the usually dominant tendency is for bonds to be broken in favor of forming new, stronger bonds. Therefore a knowledge of bond strength and the origin of this strength is also essential to understanding chemistry.

Chemical bonds occur between atoms of all the chemical elements except the six previously mentioned, and in all chemical compounds. If the atoms linked together are all alike, the substances is a *chemical element*, but if the substance contains bonds between unlike atoms (different elements), it is a *chemical compound*.

The following qualities of chemical bonds are of special interest: number of bonds an atom can form, multiplicity, bond length, bond angle, and bond strength. Under most circumstances, atoms tend to form the maximum number of bonds of which they are capable. They can form one covalent bond for each outermost half-filled orbital they can supply. The number of single bonds or their equivalent in multiple bonds that an atom can form is usually called its *valence*. A two-electron bond is called *single*, a four-electron bond *double*, and a six-electron bond *triple*. Bond length is important because bond energy is greater at shorter internuclear distances. It is measured experimentally as the distance between the two nuclei. When an atom forms more than one bond, the angle between bonds is important in determining the geometry of the molecule. In general, electron locations in the exterior of an atom consist of bonds or lone pairs. These locations tend to follow the laws of like charge repulsions and be separated as far from one another as possible. If all outermost electrons are in two locations, these must be at opposite sides of the atom, and if in bonds, the bond angle is 180°. If all electrons are in three locations, these are at the corners of an equilateral triangle planar with the nucleus, and any bond angles are 120°. If all the electrons are in four locations, these are at the corners of a regular tetrahedron, corresponding to bond angles close to 109°28′. Five bonds usually assume a trigonal bipyramid structure, two trigonal pyramids having a common base. Six bonds most commonly are directed toward the corners of a regular octahedron. Most molecular structure or geometry can be satisfactorily rationalized through this simple type of reasoning. As for bond strength, to be discussed in detail presently, chemical bonds exhibit a wide range of strength, but even the weakest are recognized as bonds if they are sufficiently stable to allow experimental studies of the combined atoms. In general, chemical bonds are far stronger, per atom pair, than the van der Waals forces described previously, and quite able to persist at ordinary temperatures despite the kinetic energy which threatens their disruption. Although all bonds tend to break at sufficiently elevated temperatures, some persist even at several thousand degrees C.

Chemical bonds may join atoms together into finite molecules or into indefinitely extensive three-dimensional arrays of atoms in solids, called *nonmolecular.* Molecular substances themselves may become solid, if sufficient kinetic energy is removed, through van der Waals forces which hold the molecules together in crystalline array. In molecular substances, each molecule contains the same whole number of each kind of atom, and thus can be assigned a molecular formula which indicates its exact composition but does not necessarily reveal the exact arrangement of the atoms in the molecule. For nonmolecular substances, all of which are solid, the composition is commonly accurately representable by definite chemical formulas, but many examples exist wherein the composition is slightly variable and the formulas cannot represent the composition accurately in exactly whole numbers of atoms. These differences are indicated by calling the exact molecular compositions or nonmolecular compositions *stoichiometric* and the inexact compositions of certain nonmolecular compounds *nonstoichiometric*. Only in the solid state, and then only for certain combinations of elements, is nonstoichiometry possible in what are called *pure compounds*. Most naturally occurring substances are mixtures of different chemical substances, to which assignment of specific chemical formulas would be meaningless and misleading.

Covalent bonds involve bonding electrons localized within the internuclear region, but bonding electrons spread out if they can. Their delocalization in metals, not possible in nonmetals where there are no extra vacancies into which the electrons can spread out, removes the limitation of valence imposed by the number of available orbitals. Regardless of the number of normal valence electrons, the atoms of metals tend most commonly to pack together as closely as is possible for like sized spheres, which gives each interior atom 12 closest neighbors, or in other close packing wherein each interior atom has 8 direct neighbors and 6 more just a little farther away. The special properties of the metallic state, good conductivity of heat and electricity, malleability, and ductility, are the consequences of the delocalization of electrons, allowing them to flow among the atoms without affecting the bonding, and allowing the rearrangement of atoms without the breaking of specific localized bonds. Atoms of metal may usefully be regarded as positive ions held together by the negative electron glue (bonding electrons) that fills the interstitial space.

The exact description of chemical bonds or the molecules or nonmolecular solids which they hold together has been the unrealized, and probably unrealizable, goal, of theoretical chemists applying quantum mechanics for more than half a century. (See PHYSICAL CHEMISTRY.) The immense complexity of mathematical calculations involved requires the extensive use of computers even for approximations, and so far defies efforts to obtain exact results. One cause lies in the difficulty inherent in problems involving, as do atoms, many-particle interactions. Another, with respect to chemical bonds, lies in the fact that the energies of interactions among atoms are generally very much smaller than the total energies of these atoms. For example, the total energy of a molecule of potassium bromide, KBr, is more than 8 million kJ per mole but differs from that of the separate atoms by only about 370 kJ. To evaluate the bond energy as the difference between the total energies of the separated atoms and the molecule is to determine accurately a small difference between very large numbers, in practice impossible.

Nevertheless by far the major effort has been directed toward quantum mechanical applications, even though these require numerous simplifying assumptions and approximations. Two ways of looking at a covalent bond that have received most attention are: (1) the atomic orbital, or valence bond approach, according to which electron sharing is visualized as permitted through the overlap of bonding orbitals on each atom so that they occupy a region in common within which the bonding electrons are attracted to both nuclei; and (2) the molecular orbital approach, according to which, ideally, all the electrons of a molecule belong to all the nuclei, occupying molecular orbitals which are the equivalent of atomic orbitals in atoms. Wave equations for these molecular orbitals are usually obtained as a *linear combination of atomic orbitals* (LCAO). For a diatomic molecule, coalescence of two bonding atomic orbitals is pictured as forming two new molecular orbitals, one concentrating the electrons within the internuclear region and called a *bonding orbital*, and the other dispersing them away from the internuclear region and called an *antibonding orbital.* Each electron within a bonding orbital serves to hold the atom together and each electron within an antibonding orbital cancels the bonding effect of one bonding electron.

It is the molecular orbital approach which receives most current attention, and numerous molecular properties are studied in this way. However, not surprisingly, far less complicated, more empirical studies have led to a more practical understanding of chemical bonds. In particular, a simple concept of covalence allows a practical method of calculating bond energies from atomic properties which produce accurate results for most molecular species and for many nonmolecular solids as well. Thus it allows an understanding of the origins of the heats of formation and reaction compiled by thermochemists, and the prediction of the strengths of bonds and the direction of chemical reactions.

The concept is based largely on that of electronegativity, which is a measure of the attractive force between a bonding electron and the effective nuclear charge acting over the distance of the covalent radius. Atoms of different elements differ in their electronegativity, or ability to attract bonding electrons. Consequently the only chemical bonds in which the bonding electrons are evenly shared are between like atoms. In all compounds, the bonds involve uneven sharing of electrons, which results in acquisition of a partial charge by each atom. The initially more electronegative atoms acquire more than half share of the bonding electrons, leaving the initially less electronegative atoms with a partial positive charge and themselves acquiring partial negative charge. This uneven sharing results in an equalization of electronegativity within the compound, since atoms initially low in attraction for electrons become partially positive, thus increasing the attraction for electrons, while atoms initially high in attraction for electrons become less so as the result of acquiring partial negative charge. Thus each bond between unlike atoms is polar covalent, meaning that electrons are unevenly shared. The energy of such a bond is considered to consist of two contributions. One is the nonpolar covalent energy E_c which would result if the two electrons were evenly shared at the observed bond length. This is easily evaluated as the geometric mean of the two homonuclear bond energies, corrected for any difference between the sum of the nonpolar covalent radii and the actual bond length. The other is the ionic energy E_i which would result if one atom monopolized these two electrons creating a positive and a negative ion. The ionic energy replaces a part of the total possible covalent energy, but the ionic contribution is always larger than the part of the covalent energy which it replaces, so that polarity always strengthens the bond. For this reason, chemical change tends to occur in the direction of forming more polar bonds, and the earth's matter exists primarily as compounds having polar bonds rather than pure elements held together by nonpolar bonds.

A polar covalent bond is thus pictured as a blend of a covalent and an ionic contribution, both based on hypothetical extremes. The blending coefficients are easily evaluated from the partial charges, the ionic coefficient t_i being half the difference between the two charges, and the sum of the ionic coefficient and the covalent coefficient t_c being 1.00. In turn the partial charges are evaluated from the initial electronegativities. The electronegativity in the compound is evaluated as the geometric mean of all the initial atomic electronegativities. The change in electronegativity corresponding to acquisition of unit charge is a constant times the square root of the atomic electronegativity. The partial charge is the ratio of the actual change in electronegativity in forming the compound to the change corresponding to unit charge.

The energy E of a polar covalent bond, in kJ per mole, when bond length and radii are expressed in picometers, is

$$E = t_c E_c + t_i E_i = t_c R_c (E_{\mathrm{AA}} E_{\mathrm{BB}})^{1/2}/R_0 + 138909 t_i/R_0$$

where R_c is the sum of the nonpolar covalent radii and R_0 the bond length.

The homonuclear single covalent bond energies (E_{AA} and E_{BB}) are determined directly or indirectly from experiment. Here a very important anomaly is recognized. Normally, as the electronegativity increases and the radius decreases from left to right across the major groups, one expects the homonuclear single bond energy to increase steadily also. From M1 to M4 (e.g., Li–C) it does. Beyond M4, however, there are two changes. The outermost shell now acquires its first lone pair of electrons, having five to be accommodated within only four orbitals. At the same time, the homonuclear bond energy decreases. It is assumed that the lone pair somehow weakens the bond, so the effect is called the *lone pair bond weakening effect* (LPBWE). The effect is very large in nitrogen, oxygen, and fluorine, and significant but much smaller in the heavier elements of these groups. It is halved when the atom forms a double bond and eliminated when a triple bond is formed. Similar reduction of this weakening is also observed in certain single bonds. Although not yet thoroughly understood, the LPBWE provides quantitative explanation of many common and important chemical facts, such as the existence of nitrogen, oxygen, and carbon dioxide as gases instead of solids like phosphorus, sulfur, and silicon dioxide.

The bond energy equation given below, with appropriate modification for solids, has been successfully applied to thousands of different bonds in hundreds of compounds, including most of the common functional types of organic molecules, with results agreeing usually within 1–2% of the experimental values.

The bond energy obtained in this way is the *contributing bond energy* (CBE), defined as that part of the total atomization energy which this bond provides. Only for diatomic molecules is this the same as the *bond dissociation energy* (BDE). When breaking a bond liberates a fragment—*free radical*—which consists of more than one atom, the liberated bonding electron may either decrease or increase the strength of the remaining bonds. If it decreases the remaining bond strength, extra energy must be absorbed when the original bond is broken, making it that much more difficult to break and increasing the bond dissociation energy. If breaking the bond increases the remaining bond strength, energy so liberated will permit the original bond to be broken that much more readily, decreasing the bond dissociation energy. This energy of readjustment may be termed the *reorganizational energy* of the radical. It is applicable whenever that particular is liberated by a bond dissociation. For example, all bonds to the phenyl group, C_6H_5-, require about 50 kJ per mole more to break than would be expected from the contributing bond energy, this being the reorganizational energy of the phenyl radical. Such values can be very useful in organic chemistry, especially in understanding free radical reactions.

Finally, no discussion of bonds, however brief, should omit mention of the special bonding exhibited in compounds of hydrogen. Since an atom of hydrogen has only one electron, used in its bonding, the nucleus remains quite unprotected when the hydrogen bears partial positive charge. If a small atom on another molecule bears partial negative charge and a lone pair of outer electrons, a substantial attraction can occur between the positive hydrogen of one molecule and this electron pair, bridging the two molecules together. Commonly termed a *hydrogen bond* but better called a *protonic bridge*, this kind of bond is only 5-10% as strong as a typical covalent bond but nevertheless very widespread and important. It is an important factor, for example, in determining the structure of liquid and solid water and of proteins. Hydrogen can also form *hydridic bridges*, in which the hydrogen atom is bonded to two other atoms simultaneously through what is sometimes called a *three-center bond*, corresponding to half a bond to each other atom. In a protonic bridge, a positive hydrogen bridges two negatively charged atoms each having a pair of electrons. In a hydridic bridge, a negative hydrogen with a pair of electrons bridges two positively charged atoms each having a vacant orbital. Intermediate examples of bridging by hydrogen are also observed.

Understanding chemical bonding remains the most important and fundamental problem in theoretical chemistry. Continuing evolution of these concepts is to be expected into the indefinite future.

BOSE-EINSTEIN STATISTICS AND BOSONS

Bose-Einstein statistics is a type of quantum statistics concerned with the distribution of particles of a particular kind among various allowed energy values taking into account the quantization of the energy values. Quantum statistics is a branch of STATISTICAL MECHANICS which treats the average or statistical properties of a system composed of a large number of particles using standard mathematical techniques and the properties of the constituent particles. It is different from classical statistical mechanics only in that the particles of the system are described quantum mechanically.

Let us consider a system of N non-interacting particles. Three different distributions of the particles among the various energy levels are possible depending upon the assumptions that are made about the particles. If it is assumed that each arrangement or distribution which conserves energy is equally probable and also that the particles are distinguishable, and if each permutation of particles among the possible levels is counted as a different distribution, one obtains an average for the relative number of particles in the various levels known as the Maxwell-Boltzmann distribution. If the particles are treated as indistinguishable and only the number of different combinations of particles is counted, the Bose-Einstein distribution is obtained. A third distribution, known as the Fermi-Dirac distribution, results if, in addition to indistinguishability, it is required that the particles obey the Pauli exclusion principle which permits no more than one electron in each quantum state.

These three distributions may be expressed mathematically as follows where $n(\epsilon)$ gives the number of particles per energy level at energy ϵ when the particles are in thermal equilibrium at temperature T:

$$(1)\quad n(\epsilon) = \frac{1}{e^{(\epsilon-\epsilon_0)/kT}} \qquad \text{Maxwell-Boltzmann}$$

$$(2)\quad n(\epsilon) = \frac{1}{e^{(\epsilon-\epsilon_0)/kT} - 1} \qquad \text{Bose-Einstein}$$

$$(3)\quad n(\epsilon) = \frac{1}{e^{(\epsilon-\epsilon_0)/kT} + 1} \qquad \text{Fermi-Dirac}$$

where k is the Boltzmann constant and ϵ_0 is related to the number of particles present and depends on the temperature in such a way that for energies large compared to kT (so that the probability of occupation for a level becomes considerably less than unity), all three distributions reduce to the Maxwell-Boltzmann distribution.

The appropriate form of statistics to apply to an assembly of particles can also be discussed in terms of the symmetry properties of the wave functions describing the particles. Two classes of wave function ψ (a solution of the SCHRÖDINGER EQUATION for two or more identical particles) result from interchanging all the coordinates, both spatial and spin, in the wave function. It should be noted that this symmetry class does not change as a function of time. The wave functions for particles obeying Fermi-Dirac statistics (fermions) are antisymmetric, while those for bosons (Bose-Einstein statistics) are symmetric. Therefore, for a system of bosons, if all the coordinates of any pair of identical particles are interchanged in the wave function, the new wave function will be identical with the original.

Photons, all mesons (except the mu meson which is really a lepton) and all nuclei of even mass number are bosons, while nucleons (i.e., neutrons and protons), quarks, all nuclei of odd mass number and all leptons, such as electrons, neutrinos and the muon are fermions. All known bosons have angular momentum $nh/2\pi$, where n is an integer or zero and h is Planck's constant. The statistics of some nuclei have been determined experimentally by the observation of the relative intensities of successive lines in the band spectra of homonuclear, diatomic molecules.

One application of Bose-Einstein statistics to a physical situation is the treatment of a "photon gas." It is possible to obtain the Planck distribution law for blackbody radiation by treating the electromagnetic radiation inside an enclosure at constant temperature as a gas of particles of zero rest mass which obey the Bose-Einstein distribution law. This treatment provides an interesting example of the wave-particle duality found in nature, since it is in marked contrast to the original derivation which was based on the wave nature of electromagnetic radiation.

Another interesting application is the qualitative explanation of the superfluid properties of liquid helium which occur below the so called lambda point of 2.186 K. At atmospheric pressure ^{4}He condenses into a liquid at 4.3 K. If the pressure is then reduced the liquid boils until the temperature reaches the lambda point, where the boiling immediately stops. The lack of boiling is caused by a very large increase in the thermal conductivity, which becomes essentially infinite, so that all parts of the liquid are at the same temperature. Below the lambda point, liquid ^{4}He seems to behave as if it had nearly zero viscosity when the viscosity is measured by passing the liquid through a fine capillary, but when the viscosity is measured by observing the drag on parallel plates moved through the fluid it is not zero. To explain these peculiar properties, F. London[4] suggested that liquid ^{4}He, below the lambda point (often called He II) is composed of two interpenetrating fluids, a normal and a "superfluid." The superfluid is composed of those molecules in the ground state or lowest energy state whereas the normal fluid would consist of the remaining molecules. The finite viscosity is due to the normal component. As the temperature is reduced toward absolute zero the number of molecules in the superfluid component increases until at absolute zero one would expect to have only a superfluid. Since ^{4}He is a boson and the Pauli exclusion principle does not apply, there is no limit to the number of molecules which can exist in the lowest energy state. Thus this completely different type of "condensation" caused by the quantum mechanical properties of the molecules not only provides a qualitative explanation of the strange superfluid nature of He II but also provides one of the few examples of a macroscopic system for which the mechanical behavior cannot be explained by classical mechanics. It is significant to note that no superfluid behavior has been observed for ^{3}He which has spin $\frac{1}{2}$ and obeys Fermi-Dirac statistics and thus is unable to condense into the lowest energy state even at temperatures as low as a few thousandths of a degree Kelvin.

BREMSSTRAHLUNG AND PHOTON BEAMS*

An electron can suffer a very large acceleration in passing through the Coulomb field of a nucleus, and in this interaction the radiant energy (photons) lost by the electron is called bremsstrahlung,[1] (bremsstrahlung† sometimes designates the interaction itself). If an electron

*This work was supported by the U.S. Atomic Energy Commission.

†"Bremsstrahlung"–German; bremsen, to brake and Strahlung, radiation.

whose total energy $E_0 \gtrsim 800/Z$ MeV traverses matter of atomic number Z, the electron loses energy chiefly by bremsstrahlung. This case is considered here.

Bremsstrahlung in the coulomb fields of the *atomic electrons* is adequately included by replacing Z^2 in the formulas by $Z(Z + 1)$. For $Z \lesssim 5$, more complicated correction is required.[1]

Protons and heavier particles radiate relatively little because of their large masses (radiation rate is proportional to the square of the acceleration, inversely proportional to the square of the mass). If a very energetic electron traverses one radiation length (X_0) of any matter, bremsstrahlung reduces the electron's energy to $1/e$ of its incident value on the average. Some examples are:

Element	Air	C	Al	Fe	Cu	W	Pb
Radiation length X_0 cm	29800	20	9.1	1.7	1.42	0.32	0.51

The energy dependence of radiation loss per centimeter by an electron of energy E_0, traversing matter of density n atoms/cm^3 is given by $dE/dx = -nE_0\phi_{\text{rad}}$ where ϕ_{rad} is given by the curves in Fig. 1.

A beam of energetic electrons incident upon a radiator produces a bremsstrahlung beam that is directed sharply forward. Photon angular distributions for typical "thick" tungsten targets are shown in Fig. 2. Curves for other heavy elements are similar if all radiator thicknesses are measured in units of the radiation length. In such thick radiators, the incident electrons scatter appreciably, as well as radiate, making any observed photon distribution actually an average over electron scattering angles of the basic bremsstrahlung distribution. The basic bremsstrahlung angular distribution has a zero at $\alpha = 0$, which is quite different from the curves of Fig. 2. The basic spectral shape is a weak function of photon angle and, in thick radiators, electron scattering modifies this shape slightly (Fig. 3). Examples of thick radiator spectra are shown in Fig. 4 for various incident electron energies. The bremsstrahlung spectra depend upon screening of the nuclear coulomb field by atomic electrons through the parameter $\gamma = 51k/[E_0(E_0 - k)Z^{1/3}]$, where k is the photon energy in million electron volts. For complete screening ($\gamma \approx 0$), the thick radiator spectrum is given by

$$\frac{d\sigma_b}{dk} = \frac{4Z^2 r_0^2}{137k}\left\{\left[1 + \left(\frac{E}{E_0}\right)^2 - \frac{2}{3}\frac{E}{E_0}\right] \cdot \ln\left(183Z^{-1/3}\right) + \frac{1}{9}\frac{E}{E_0}\right\} \text{cm}^2/\text{MeV}$$

where E is the final electron total energy in million electron volts and r_0 is 2.82×10^{-13} cm. For no screening ($\gamma \gg 1$),

$$\frac{d\sigma_b}{dk} = \frac{4Z^2 r_0^2}{137k}\left[1 + \left(\frac{E}{E_0}\right)^2 - \frac{2}{3}\frac{E}{E_0}\right] \cdot \left[\ln\frac{2E_0E}{0.51k} - \frac{1}{2}\right] \text{cm}^2/\text{MeV}$$

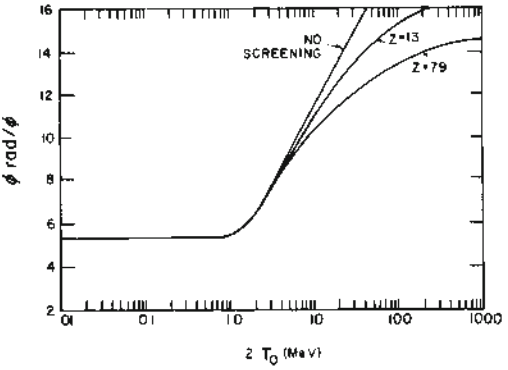

FIG. 1. Dependence of the total radiation cross section $\phi_{\text{rad}} = (1/E_0)\int_0^{E_0} k\, d\sigma$ on the initial electron kinetic energy, E_0. The parameter $\bar{\phi} = Z^2 r_0^2/137$.[1]

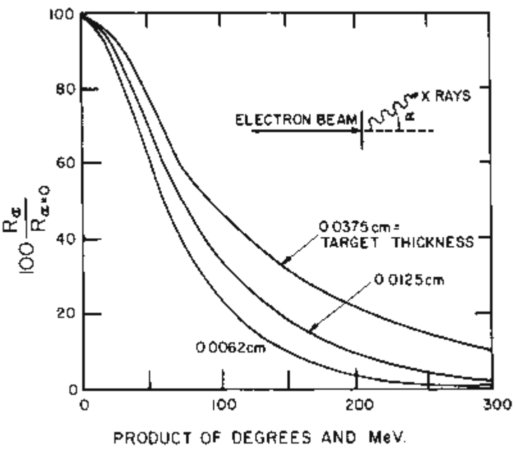

FIG. 2. Theoretical bremsstrahlung angular distributions from thick tungsten targets for relativistic energies. These data are obtained from the Natl. Bur. Std. Handbook, 55. R_α is defined as the fraction of the total incident electron kinetic energy that is radiated per steradian at the angle α.[1]

The angle α is measured with respect to the incident electron's direction. Since the electron may scatter before it radiates, $\alpha \neq \theta$ where α is shown in Fig. 3.

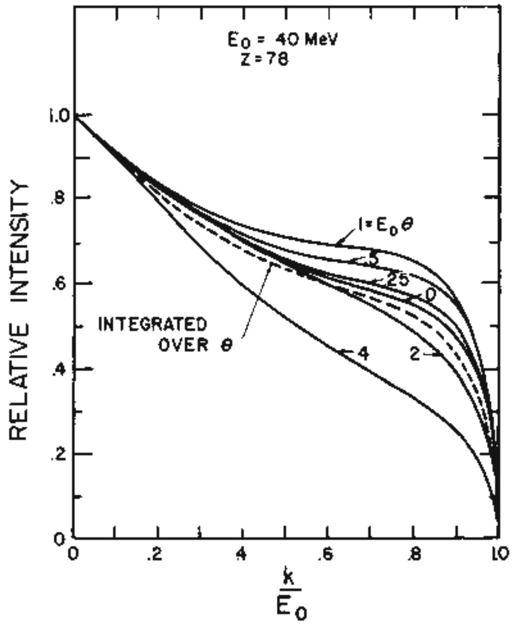

FIG. 3. Dependence of the spectral shape (Schiff's calculation) on the photon emission angle, θ. k is the photon energy in MeV. These curves are from reference 1. E_0 is the incident electron energy in MeV.

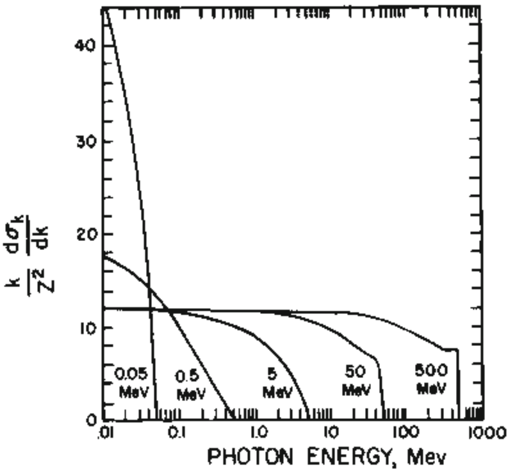

FIG. 4. Dependence of the Born-approximation absolute cross section (integrated over photon directions) on the photon and electron energy. These curves are from reference 1.

Intermediate screening ($2 < \gamma < 15$) leads to much more complicated formulas.[1]

A remark concerning formulas is in order. Generally, expressions for a given cross section are very different depending upon whether the electron energy is small or very large, upon whether the screening is zero, intermediate, or complete, and upon whether one is dealing with the most usual electron-nucleus collisions or with purely electron-electron collisions. Most calculations have been done in Born approximation. The reader is referred to Koch and Motz[1] for an excellent review article on the subject.

The absolute number of bremsstrahlung photons in the photon energy interval dk radiated by a single electron of energy E_0 traversing a radiator of thickness dt and n atoms/cm^3 is given by $(d\sigma_b/dk)n\ dt\ dk$, where $d\sigma/dk$ can be found from Fig. 4.

It must be noted that photon-electron showers begin developing in approximately one radiation length, and these formulas and curves apply only to the basic bremsstrahlung interaction itself or to radiators somewhat thinner than one radiation length.

Conventional bremsstrahlung beams are partially polarized only from extremely thin radiators ($< 10^{-3}$ radiation lengths) because the angular region of polarization is sharply peaked about the angle $\theta = m_0c^2/E_0$. Electron scattering in the radiator broadens the peak and shifts the maximum to larger angles. Polarization is

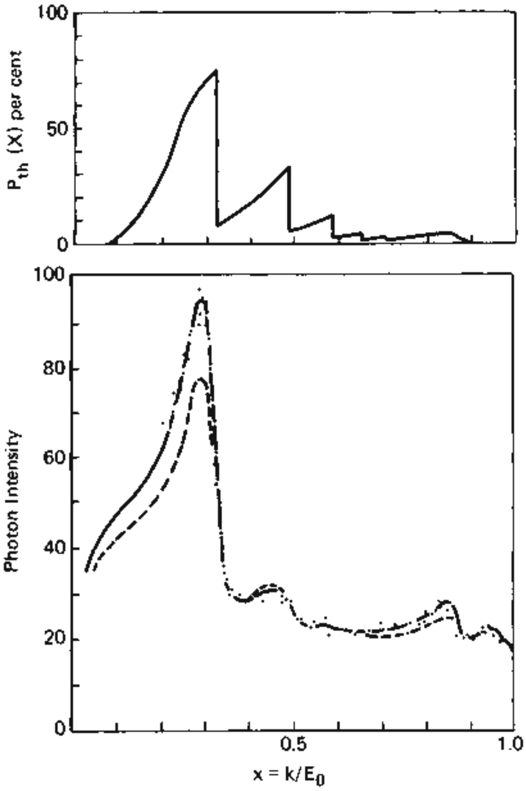

FIG. 5. Photon intensity and photon polarization from a diamond target; experimental spectra compared with the averaged intensity and theoretical polarization for photon angle equal to 50 mrad and electron energy E_0 = 4.8 GeV. The solid line represents Hartree potential, the dashed line shows exponential potential.

defined by

$$P(\theta, E_0, k) = \frac{d\sigma_\perp(\theta, E_0, k) - d\sigma_\parallel(\theta, E_0, k)}{d\sigma_\perp(\theta, E_0, k) + d\sigma_\parallel(\theta, E_0, k)}$$

where an electron of energy E_0 radiates a photon of energy k at angle θ. $\perp$ and $\parallel$ directions are with respect to the plane defined by the incident electron and the radiated photon. When the electron is relativistic before and after the radiation, the electric vector is most probably in the $\perp$ direction. Polarization in conventional beams is difficult to observe because thin, low-yield radiators are required. Practical thick-target bremsstrahlung shows no polarization effects whatever. One usually deals with this unpolarized bremsstrahlung and therefore averages over all possible states of polarization of the incident photons.

It is clear that if one makes use of polarized photons when investigating electromagnetic interactions, additional information on spin and angular momentum states can be obtained. The need for this additional information is so compelling that special techniques are frequently employed at the highest-energy electron accelerators (e.g., SLAC, DESY*) to generate polarized photons. Unfortunately, yields are low by normal intensity standards, but not unusably so.

Coherent bremsstrahlung from an electron incident upon a properly oriented single crystal (e.g., diamond) is discussed in a definitive review article by Palazzi.[2] This effect depends upon the interactions being coherent from the scattering centers in a given crystal plane. A typical spectral shape (Fig. 5) and polarization (Fig. 5a) prove to be extremely useful even though the spectrum is not monochromatic and free from background. Techniques for orienting the crystal radiator are given by Luckey and Schwitters.[3] Typical examples of high-energy polarized photon beams and their applications to physics are found in Ballam et al.,[4] Bingham et al.,[5] and in Bologna et al.[6]

Polarized photon beams from high-energy accelerators are frequently generated through the inverse Compton effect. Nearly 100 per cent polarization can be achieved with reasonable spectral shapes, but photon yields are somewhat lower than from the coherent bremsstrahlung process discussed above. Linearly polarized photons from a high-power pulsed laser are directed into a nearly head-on collision with a high-energy electron beam. Those photons that are back-scattered through approximately 180 degrees carry a large fraction of the electron's

*SLAC–Stanford Linear Accelerator Center, Stanford, California; DESY–Deutsches Elektronen-Synchrotron, Hamburg, Germany.

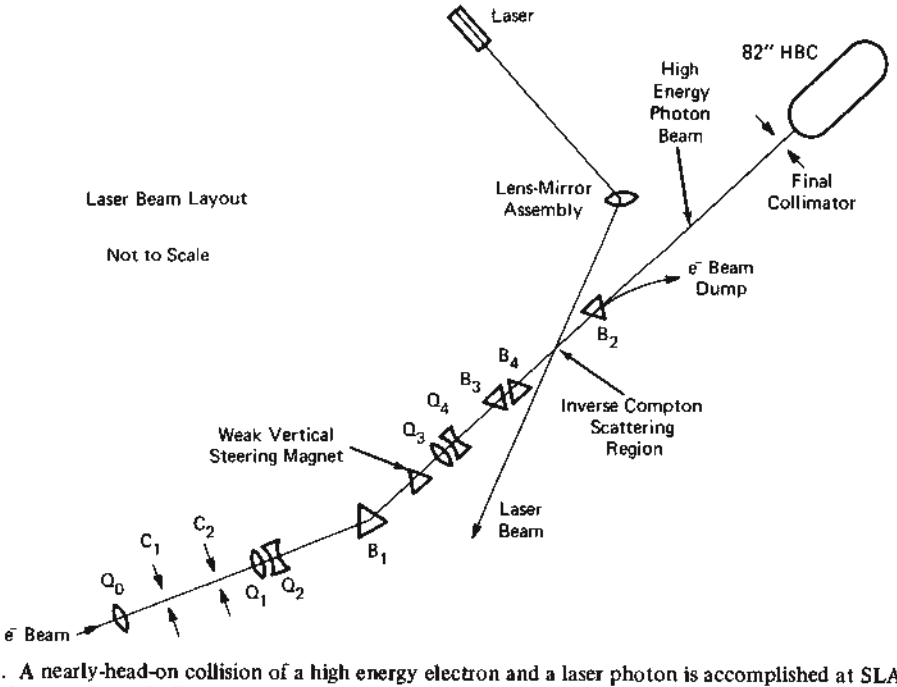

FIG. 6. A nearly-head-on collision of a high energy electron and a laser photon is accomplished at SLAC in the manner shown schematically here. The electron beam employed is part of the central beam facility at SLAC. Angles are exaggerated and there is no scale. Practical considerations eliminated the possibility of crossing the two beams at angles much less than 3 mrad. The high energy photon beam finally enters the 82" hydrogen bubble chamber where its interactions with hydrogen are studied.

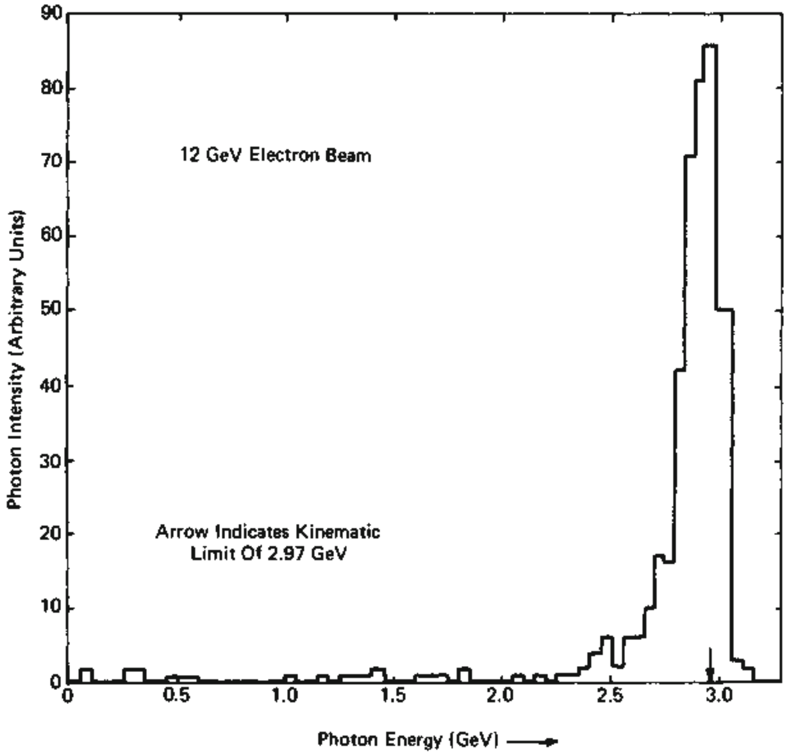

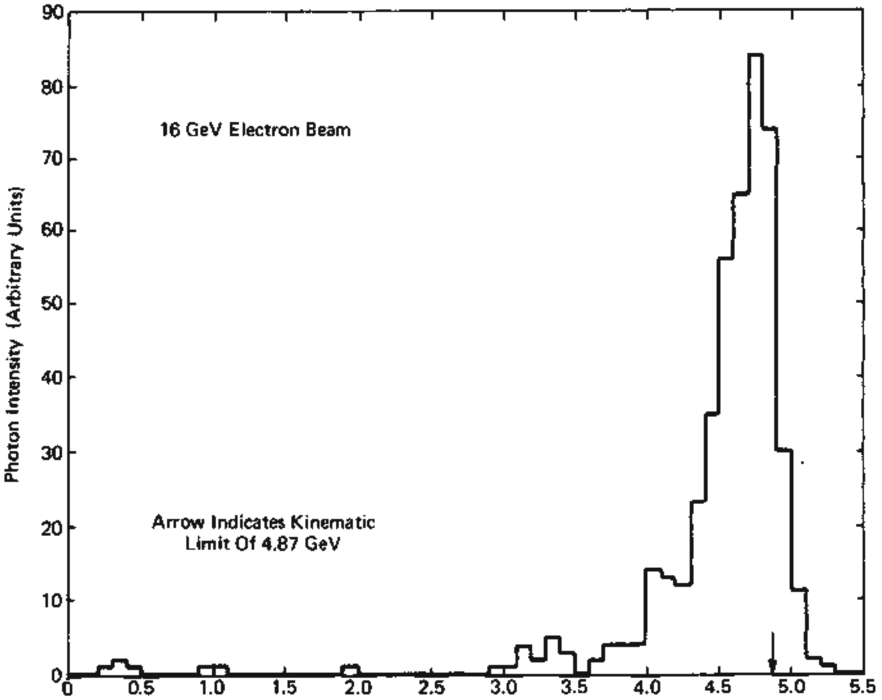

FIGS. 7 and 8. Energy spectra obtained from operation with 12 and 16 GeV electron beams, giving 2.97 and 4.87 GeV scattered photons respectively. These spectra were obtained by measuring e^+e^- pairs produced in the bubble chamber along the known beam line.

BROWNIAN MOTION

Brownian motion is the randomly agitated behavior of colloidal particles suspended in a fluid. The phenomenon is named for its discoverer, Robert Brown, an English botanist. In 1828 he observed the "perpetual dance" of microscopic pollen grains suspended in water. Initially, this effect was interpreted as being due to the motions of living matter, but it was later found that any tiny particles in suspension exhibit Brownian motion.

In 1888, M. Gouy attributed the motion to the bombardment of the visible particles by invisible thermally excited molecules of the suspension. In 1900, F. M. Exner expressed the view that the kinetic energy of the visible particles must equal that of the surrounding suspension particles, and he attempted to estimate molecular velocities on this basis.

In a series of papers published from 1905 to 1908, Einstein[1] successfully incorporated the suspended particles into the molecular-kinetic theory of heat. He treated the suspended particles as being in every way identical to the suspending molecules except for the vast difference of their size. He set forth several relationships which were capable of experimental verification and he invited experimentalists to "solve" the problem.

Several workers undertook this task. The most notable of these was Perrin.[2] Perrin's special success was due to his technique of preparing particles to suspend which were of uniform and known size. The uniformity was achieved by fractional centrifuging, and the size was established by noting that they could be coagulated into "chains" whose length could be measured and whose "links" could be counted. The microscopic observation of these uniform particles enabled Perrin and his students to verify the Einstein results and to make four independent measurements of Avogadro's number. These results not only established our understanding of Brownian motion, but they also silenced the last critics of the atomic view of matter.

Probably the simplest example of Perrin's experiments was his test of the Law of Atmospheres. If we assume that the air is at rest and has the same temperature from ground level upward, it can be shown that the pressure (and concentration) of the air falls off exponentially with increasing altitude. For particles of mass m and density ρ suspended in a medium of density ρ' at absolute temperature T, the ratio of the particle concentrations n_1 to n_2 at heights h_1 and h_2 is given by

$$\frac{n_1}{n_2} = exp \left[- \frac{mg(\rho - \rho')N_0(h_1 - h_2)}{\rho RT} \right]$$

where N_0 is Avogadro's number, g is the acceleration of gravity, and R is the universal gas constant. Although the concentration of air varies slowly with height, the concentration of the relatively heavy particles varied significantly over a height change of a few millimeters. By observing the concentration variation as a function of height, all quantities in the given equation were known except Avogadro's number which could therefore be determined.

kinetic energy and retain the full polarization of the original laser photons. Several hundred photons of ≈ 95 per cent polarization and 5 GeV energy are routinely obtained from each pulse of a two-joule ruby laser in conjunction with the linear accelerator electron beam at SLAC.[7] (See Fig. 6.)

Kinematics of these "laser beams" are given by

$$k = \frac{E_0(1 - a)}{1 + a(\Gamma\theta)^2} \qquad \theta << 1$$

where k = scattered photon energy in the lab, E_0 = electron energy in the lab, $a = [1 + (4\Gamma k_i/m)]^{-1}$, m = electron mass (0.5 MeV), and $\Gamma = E/m$. k_i = laser photon energy (ruby laser light has $k_i = 1.786 \times 10^{-6}$ MeV) and θ = lab angle (in radians) of scattered photon. (Electron beam has $\theta = 0$ rad.) For example, if E_0 = 20.000 MeV, k_i = ruby laser energy, then k = 7070 MeV. At photon energies in the several thousand MeV range (several GeV range), θ must be restricted to $\approx 10^{-5}$ radians to restrict the lower spectral limit of the photons to approximately 90 per cent of the maximum photon energy. Typical spectra are shown in Figs. 7 and 8.

Measurement of the photon flux in an accelerator bremsstrahlung beam is required in order to make quantitative determinations of cross sections and to normalize observations. An instrument called a "quantameter"[8] is used quite successfully for this purpose and is accurate to the order of 1 per cent. It basically provides sufficient matter (copper plates) to contain the entire electron photon shower volume generated by the incident bremsstrahlung beam as well as to sample and integrate the intensity of the showers over their entire extent.

"Inner bremsstrahlung" is an interesting example of true bremsstrahlung. In beta decay interactions and in orbital electron capture, one sees, on the average, a low-intensity photon continuum, the quantum limit of which is equal to the transition energy of the interaction. These photons are bremsstrahlen emitted by the electron in its transition to the final state.

The Feynman approach to theoretical treatment of the bremsstrahlung process is detailed by Williams.[9] A definitive review article on bremsstrahlung, especially from gaseous targets, has been written by Blumenthal and Gould.[10] They include the closely allied topic of synchrotron radiation and Compton scattering as well as some other interesting radiative effects. They provide an excellent and quite current bibliography.

A recent paper by Chahine[11] has shown the importance of the long radiative tail to wide angle hard bremsstrahlung in very inelastic scattering of mu mesons. Its bibliography is useful in further study of this aspect of bremsstrahlung.

A process called hard gluon bremsstrahlung has been newly observed (1979) in the head-on collisions of beams of high energy electrons and positrons.[12] At energies near 15 GeV for each colliding particle, jets of hadrons (collimated groups of strongly interacting particles, e.g., pions, protons, etc.) are sometimes produced. The usual two-jet structure has been seen to be accompanied occasionally by a third less energetic jet of hadrons. A model and theory for interactions of high energy particles, quantum chromodynamics (QCD), furnishes a quantitative explanation of the observed three-jet structures in terms of a fundamental (?) particle (quark) emitting a field particle (gluon) in the scattering process. Gluons in the interaction, as well as quarks, have the property of materializing in the laboratory as jets. The least energetic jet is usually interpreted as the materialization of a gluon emitted with relatively lower energy than the parent quark. In analogy with a charged particle (usually an electron) emitting a corresponding field particle (a photon), this latter process, properly termed bremsstrahlung, has given its name to the process of gluon emission by a quark. An excellent review article by Duinker[12] includes this subject as well as references to the current literature.

Hadronic jets have also been observed in the basic process of scattering of neutrinos by nucleons.[13] The hadronic jet structure occasionally arising from these interactions is, again, quantitatively explained in QCD only by invoking the idea of hard gluon bremsstrahlung.

These latter two processes are found in collisions of particles at the highest accelerator energies currently available. As energies increase with the advent of newer and larger accelerators, gluon bremsstrahlung will likely remain an important part of the scattering process.

C

CALCULUS OF PHYSICS

To label a topic as the "calculus of physics" is not intended to imply the establishment of some new type of mathematics, but rather that a point of view different from that comfortable to the professional mathematician is to be employed in its discussion. Concepts are introduced for the immediacy of their application to the description of physical phenomena, and a heuristic approach is used to introduce them. We shall not hesitate to ignore interesting but uncommon exceptions to our statements and shall make use of pictorial representations and special cases to illustrate our points.

Functions Since many of the processes of physics are continuing, with the state of things at a given instant developing smoothly out of the state of things in the previous instant, the means of describing these processes compactly is with the help of continuous functions. In some sense, any way of naming the members of a set of objects when given a member of another set comprises a functional relationship. Thus if one is given the set of numbers

$$x = 1, 2, 3, 4 \cdots$$

and the relation

$$y = x^3, \tag{1}$$

then one immediately knows that

$$y = 1, 8, 27, 64, \cdots.$$

Eq. (1) is one way of representing the function. Another would be to tabulate x and y side by side:

x	1	2	3	4
y	1	8	27	64

and another is to draw a graph of y against x, as in Fig. 1. The points contain exactly the same information as the table; the curve contains much more information, but not as much as Eq. (1). Thus it would be a hypothesis to say from the table alone that to $x = \frac{1}{2}$ there corresponded $y = \frac{1}{8}$. The curve (if it could be read accurately enough) would allow one to make that assignment, but would not allow one to conclude that $x = 5$ corresponds to $y = 125$. Equation (1) contains all of this information, and more. We understand from it that to *any* value of x one may obtain y by multiplying x by itself and the result by x again. In this case, x is the independent variable, y the dependent variable. The concept of continuity is contained in the idea that between any two values of x another can be found; and the concept of continuous function, that to all such values of x a value of y can be assigned according to the prescription in Eq. (1).

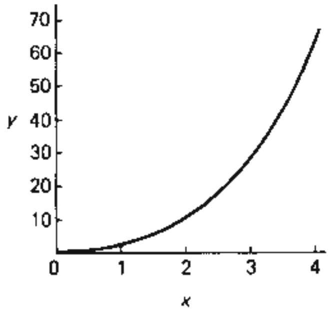

FIG. 1

Our example is one of the simplest types of function: an algebraic function. Functions of several variables may be considered: functions of complex variables, trigonometric functions, exponential functions, etc. Because of their importance in representing physical processes, let us consider the trigonometric functions a little more closely.

The trigonometric functions are functions of the variable θ (or x or y, or any other symbol you choose), which need not be an angle in the narrow sense, although in physics applications we shall insist that the variable be dimensionless as an angle is. (The distinction between *units* in which the size of a quantity is expressed relative to some standard and dimensions, which are fundamental attributes of a quantity in terms of mass, length, and time, will not hold us here. Suffice to say that, e.g., a *second* is a unit for the dimension time, and the ratio of an arc length to a radius of the arc, which may be expressed in the unit *radian*, is dimensionless.) The tables of trigonometric functions provide a discrete representation, and the familiar graphs are even more useful in visualizing their properties. Figure 2 is a graph of the function $y = \sin \theta$ and Fig. 3 of $y = \cos \theta$. The horizontal scale of each of Figs. 2, 3 should be thought of

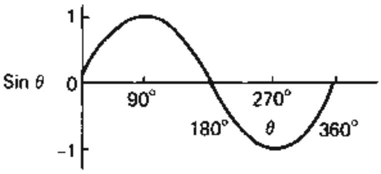

FIG. 2

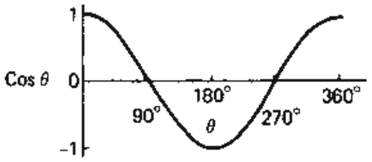

FIG. 3

as extending to the left and right indefinitely with the curves repeating the behavior as shown every 360°. The vertical scales for the sine and cosine functions need be no larger than shown, since their curves oscillate between plus and minus one.

These are examples of continuous functions of a single variable (θ in these illustrations). They are *periodic* functions, i.e., they repeat their values periodically as the independent variable continuously changes. It is the property of periodicity which makes these functions suitable for representing certain physical phenomena.

In Fig. 4 we represent two more useful functions for physics applications: the exponential curve, $y = e^x$ and its inverse, $y = e^{-x} = 1/e^x$.

As a matter of notational convenience, one frequently replaces y by $f(x)$, to be read as "function of x." As a rule, continuous functions can be represented by sums of *algebraic* functions of the independent variable. For example:

$$\sin\theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \frac{\theta^7}{7!} + \cdots + \cdots$$

$$\cos\theta = 1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \frac{\theta^6}{6!} + \cdots + \cdots$$

where θ must be expressed as a dimensionless ratio; i.e., in radians rather than degrees, and

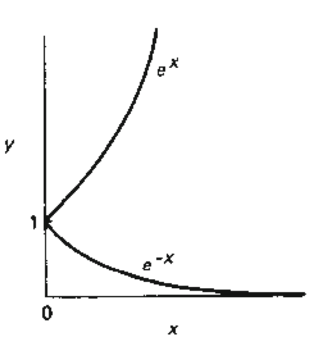

FIG. 4

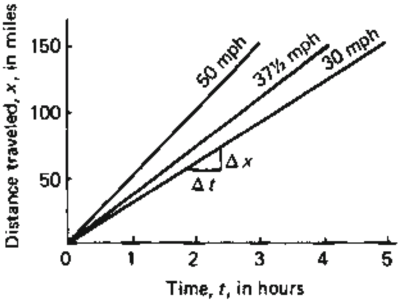

FIG. 5

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots + \cdots$$

$$e^{-x} = 1 - x + \frac{x^2}{2!} - \frac{x^3}{3!} + \cdots + \cdots.$$

Derivative We can now introduce a few of the concepts of the branch of mathematics which deals with functions and their properties, the calculus. To be specific, we should like to mention the *derivative* and the *integral* of a function. The reader will know something of these already: e.g., the speed of an automobile is the time derivative of its position. This is shown in Fig. 5. The slope of each line represents the speed with which the automobile traveled from New Haven to Boston: 50 mph, $37\frac{1}{2}$ mph, 30 mph. The speed, v, is given by $\Delta x/\Delta t$, where Δt is the time required to traverse the distance Δx. From the graph, one sees that the slope is also the tangent of the angle made by the line with the horizontal axis. These are general properties of the derivative.

The question arises as to what happens if the line is not straight. Then one defines the derivative in the same way, but expects its value to change from point to point along the curve. At each point, one draws the tangent line and calculates its slope. This is the derivative. The abstract definition of derivative is based on the notion of *limit*. In mathematical language, if a function approaches a fixed value as close as one pleases while the independent variable approaches a given value arbitrarily, the function is said to approach a limit as the parameter approaches its value. The notation is $\lim_{x\to a} f(x) = f(a)$, to be read as "the limit of $f(x)$ as x approaches a is $f(a)$." For simple algebraic functions the concept is rather obvious: If $f(x) = ax + bx^2$, then $\lim_{x\to 2} f(x) = 2a + 4b$. The reader should be warned, however, that the situation is not always so obvious. For example, let $f(x) = (ax + bx^2)/cx$. As $x \to 0$, both numerator and denominator approach 0, so $\lim_{x\to 0} f(x)$ seems to be 0/0, which is indeterminate. However, the limit is actually finite; namely, it is a/c. The derivative has been heuristically defined as $\Delta f(x)/\Delta x$, but this has signifi-

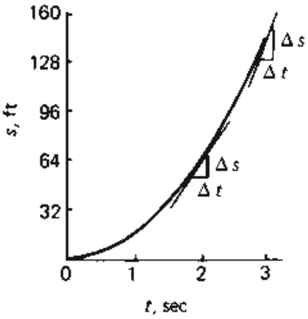

FIG. 6

cance only so long as the ratio remains determinate as $\Delta x \rightarrow 0$. Formally, one says

$$\frac{df(x)}{dx} = \lim_{x_2 \to x_1} \frac{f(x_2) - f(x_1)}{x_2 - x_1}, \text{ or}$$

$$\frac{df(x)}{dx} = \lim_{\Delta x \to 0} \frac{\Delta f(x)}{\Delta x}$$

For all the cases we shall be interested in discussing, the limit exists, is equal to the derivative, and is equivalent to the tangent to a curve of $f(x)$ vs x at the point in question. This is illustrated in Fig. 6, which is a graph of $s = 16t^2$. At 2 sec, the tangent has a slope of 64 ft/sec, and at 3 sec it is 96 ft/sec. Since the speed is changing with time, we can graph it and find its rate of change or derivative, as shown in Fig. 7. The slope is seen to be a constant: 32 ft/sec^2. What is its meaning? This is the *acceleration* of the object which is moving according to the graph in Fig. 6. Thus the acceleration is defined as the time derivative of the speed. For an object moving with constant speed, the acceleration is zero—as it should be to conform with common sense.

While speed and acceleration are among the most familiar examples of derivatives, we should note that the derivative of a function need not be taken with respect to time. If f is a function of an arbitrary variable, x, then the derivative is equal to $\Delta f(x)/\Delta x$, where Δf and Δx are measured on the tangent drawn at point x. The notation, which we shall have occasion to employ, is df/dx for the derivative, and d^2f/dx^2 for the derivative of the derivative (this would be the acceleration if $f(x)$ were distance and x were time). The reader will imagine that more derivatives may be taken, and wonder if the process is limitless. For some functions, e.g., e^x, there is no highest derivative to be taken. For others, e.g., x^3, all derivatives above a given one are zero—the zero values begin with the fourth derivative in this case.

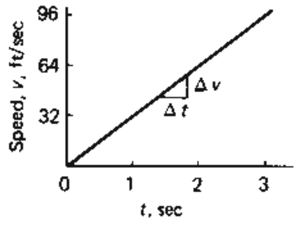

FIG. 7

Examples of derivatives which can be used in calculations are $da/dx = 0$, where a is a constant, $dx/dx = 1$, $dx^2/dx = 2x$, $dx^n/dx = nx^{n-1}$ where n is any number, and $d(ax^n)/dx = nax^{n-1}$, where a is a constant.

$$\frac{de^x}{dx} = e^x, \frac{de^{-x}}{dx} = -e^{-x},$$

$$\frac{d \sin \theta}{d\theta} = \cos \theta, \frac{d \cos \theta}{d\theta} = -\sin \theta.$$

Integral The other important operation of the calculus is *integration*. It may be simply defined as the inverse of taking the derivative, although such a definition has only limited usefulness—mainly it lulls the unwary into thinking he may know something of the process. An operational definition, lacking elegance, may be more nearly indicative of the true nature of the integral: It is a function so constructed that its derivative yields the function whose integral was to be found. From our examples of derivatives, the curve of Fig. 7 may be written as

$$dx/dt = 32t, \tag{2}$$

and of Fig. 6 as

$$x = 16t^2. \tag{3}$$

We have been at some pains to show that $dx/dt = 32t$, so by our definition of integral, x is the integral of dx/dt. The notation for integral is shown in Eq. (4):

$$x = \int (dx/dt)\, dt. \tag{4}$$

Although this is rather a special case, it contains a number of interesting features. If it were a legitimate operation to "multiply" dx/dt by dt, the expected product would be dx, and Eq. (4) would become

$$x = \int dx, \tag{5}$$

which somehow looks like an identity. In fact, if we think of dx replaced by Δx and $\int$ by "sum of," then

$$x = (\text{"sum of"})\, \Delta x$$

is pretty obvious. Pictorially, we may think of

TABLE 1

t Interval	0 to 1 sec	0 to 2 sec	0 to 3 sec
Area	16	64	144

the integral of a function as the area under a curve giving the graphical representation of the function. In the general case, the notation reads

$$\int f(x)\,dx,$$

where the dx performs some of the functions in the derivative notation: It identifies the independent variable and implies how the operation is to be carried out.

To give an example, let us return to Fig. 7 and calculate the area under the curve. Table 1 contains the results for the area up to 1 sec, up to 2 sec, etc. It is clear that the numbers in the "area" row can be obtained from Eq. (3) by evaluating it for $t = 1, 2, 3$ sec, respectively.

What of the integral as area when the curve is not as simple as our example? Even the case graphed in Fig. (6) appears to be beyond the definition. We are rescued from this dilemma by recalling that we deal with continuous functions, so we may employ as small a Δx as we please. Thus the integration becomes the summation of many areas whose bases are Δx and heights the values of $f(x)$ at the point in question. Some error will remain: The lined areas shown in Fig. 8 will not always cancel as they must for exact total area calculation. That is, our calculation of the area of the strip as $f(x) \cdot \Delta x$ omits the piece with vertical shading lines and incorrectly includes the piece with horizontal shading. However, as Δx becomes smaller, these two pieces will come nearer and nearer to canceling for each strip. The penalty for increased accuracy is increasing the number of strip areas to obtain and sum.

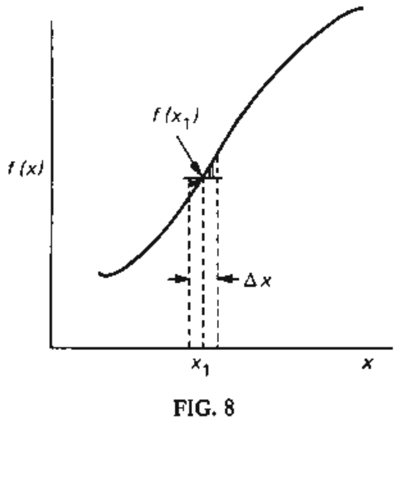

FIG. 8

In fact, for the simpler functions it is possible to obtain the integral without adding areas: The means we have already used of looking for a function whose *derivative* is the function in hand is one method of doing so. Of course, with the advent of high-speed digital computers, the task of adding up many little strips to calculate the integral numerically is reduced to preparing a program to control the computer–and the program will work for any function which can be tabulated.

Sample integral formulas which can be used are

$$\int dx = x + c,\ \int x\,dx = \frac{1}{2}x^2 + c,$$

$$\int ax\,dx = \frac{ax^2}{2},\ \int x^n\,dx = \frac{1}{n+1}x^{n+1} + c,$$

$$(n \neq -1)$$

$$\int \cos\theta\,d\theta = -\sin\theta + c,\ \int \sin\theta\,d\theta = \cos\theta + c,$$

$$\int e^x\,dx = e^x + c,\ \int e^{-x}\,dx = -e^{-x} + c\ ,$$

where c is a constant which cannot be determined in the integration.

CALORIMETRY

Calorimetry is the science of measuring the quantity of heat absorbed or evolved by matter when it undergoes a change in its chemical or physical state. The apparatus in which the measurement is performed is a *calorimeter*, and the experimenter is frequently referred to as a *calorimetrist*.

When matter is involved in a chemical or physical process, its total energy content is usually altered. The difference in energy between its initial and final states, ΔE, must be transferred to, or from, the environment of the system. This energy exchange between the system and its environment is in the form of heat or work or both. In calorimetry, the energy exchanged as heat is quantitatively evaluated. The heat absorbed by the system, q, is related to the work done by the system on its environment, ω, and the increase in internal (total) energy of the system, ΔE, by the thermodynamic relationship

$$q = \Delta E + \omega. \tag{1}$$

When calorimetric measurements are performed at constant pressure and only pressure-volume work is involved, q is equal to the increase in heat content or enthalpy ΔH. Most calorimetric measurements are performed under these conditions, but when other conditions are imposed, appropriate consideration must be made in the thermodynamic treatment of the data.

The process selected for calorimetric study may be a simple change in the physical state of matter, such as a change in temperature of the material, or it may consist of a series of complex chemical reactions such as are encountered in the combustion of many fuels. In fact, nearly any process involving a chemical or physical change in matter might well become a necessary subject for calorimetric investigation.

Calorimetric determinations of energy changes are essential in many theoretical and practical problems. Heat capacity or specific heat data are vital to the design of heat exchange equipment. The thermal properties of steam and certain metals are major considerations in the design of modern boilers and turbines. The heats of combustion of fuels are essential in rocket, engine, and gas turbine design. The heat liberated by chemical reactions must be considered in the development of chemical process equipment. Often the equilibrium constant required to determine directions and extent of chemical reactions is most conveniently obtained by a simple calculation from the free energy change ΔF. For a great many processes, numerical values of ΔF can be obtained from the change in heat content ΔH, and the entropies of the participating substances S, using the thermodynamic relationship

$$\Delta F = \Delta H - T\Delta S, \tag{2}$$

where T is the absolute temperature. The entropies of the individual substances can generally be evaluated from heat capacity measurements that extend to very low temperatures. In addition to these primarily practical design considerations, calorimetric measurements can provide information about the microscopic parameters of a material, such as its structure or the energy levels of its electrons and atoms. This information in turn can provide insight into the fundamental interactions in the material.

The design and constructional details of calorimeters vary widely because of the diversified nature of the processes suitable for calorimetric study. However, the basic principles are general, and their consideration constitutes a common requirement in practically all designs. Suitable devices and procedures for three essential measurements are usually required, but one or two can sometimes be omitted by operating under certain restrictions. The measurements are: (1) the temperature of the calorimeter and its contents, (2) the quantity of energy that is added to the calorimeter from an external source, and (3) the quantity of heat that is exchanged between the calorimeter and its environment.

Most calorimetric operations involve a temperature change, since the heat liberated (or absorbed) during the process is stored in the calorimeter and its contents by virtue of their combined heat capacity. Thermocouples, thermopiles, and resistance thermometers are commonly used for temperature measurements. The quantity of energy liberated or absorbed in a calorimetric process is most commonly evaluated in terms of electrical energy. This is done by three similar methods. (1) In an exothermic process where heat is liberated, the calorimeter is cooled to the original temperature; the temperature rise is then duplicated using an electrical resistance heater. (2) The heat absorbed in an endothermic process is supplied by an electrical heater at such a rate as to keep the temperature constant. (3) In heat capacity measurements an electrical heater supplies known amounts of energy to the sample. The resultant temperature change is then monitored. Electrical energy and temperature can be measured very accurately by modern methods.

The quantity of heat exchanged between the calorimeter and the environment is a more difficult problem. When two adjacent bodies (such as a calorimeter and its environment) are not at exactly the same temperature, heat is transferred from the warmer to the cooler body. This transfer is made by three major processes: (1) gaseous convection, (2) radiation, and (3) conduction. Gaseous convection can be completely avoided by evacuating the space between the calorimeter vessel and its environment. When evacuation is impractical, convection can be minimized by suitable geometrical considerations in the design of the calorimeter. It is very important to avoid or at least minimize convection, since the heat transported is a complex function of the temperature difference and an accurate evaluation is impossible. For small temperature differences, radiation is usually not a serious problem at low temperatures but is a major contributor to heat exchange at elevated temperatures. Heat exchange by radiation can be limited to a few percent of the blackbody (maximum) values by the use of suitable reflecting surfaces on the outside of the calorimeter and on the adjacent environment. Conduction by air or other gases is also usually minimized by evacuating as much as possible of the space between the calorimeter proper and its environment. Conduction in solid materials, used for supporting the calorimeter and for electrical leads is optimized by proper choice of materials and geometrical design.

In the absence of convection and for small temperature differences, the heat transferred, Q, is predominantly via conduction and is essentially proportional to the temperature difference ΔT and time t, in accordance with Newton's law of cooling,

$$Q = k\Delta Tt. \tag{3}$$

There are two approaches chosen currently. For large samples, this heat exchange is minimized by reducing the quantities on the right-hand side of Eq. (3). The constant k is a measure of the thermal link to the environment and is minimized by design considerations. Adiabatic calorimeters maintain the calorimeter and the environment at the same temperature so that the temperature difference ΔT equals zero. In this approach, corrections are made when the heat transferred is not exactly zero. For smaller samples, the connections necessary for measuring temperature and supplying electrical energy are a source of significant heat exchange and the corrections become rather large. The second approach therefore, instead of minimizing the heat transferred, actually uses the heat exchange to measure the heat capacity. The rate of change of the temperature of the sample $d\Delta T/dt$ times the heat capacity of the sample, C, is equal to the rate of heat exchange:

$$\frac{dQ}{dt} = -\frac{Cd\Delta T}{dt}. \tag{4}$$

By accurately measuring the quantities on the right hand side of Eq. (3), Eq. (4) may be used to obtain C.

In calorimeters containing liquids, there is a possibility of a fourth mechanism for transporting heat. This method involves the transport of matter from the calorimeter and its subsequent condensation on the surrounding surfaces. The effect can be avoided by keeping the environment warmer than the liquid or by completely enclosing the liquid. However, even in a completely enclosed system the possibility of vaporization into the space above the liquid with increasing temperature must be considered for volatile liquids.

There are many different varieties of calorimeters, each being particularly suited for a specific type of measurement. Some general features of several representative types are discussed below.

Low temperature calorimetry, used down to the temperatures available with liquid and solid hydrogen, ~10 K, has become an important source of heat capacity data for the evaluation of entropies of substances from measurements extending from near the absolute zero to room temperature or slightly above. This information may, in particular, be used by chemists to predict chemical reactions. The calorimetric vessel consists of a vacuum-tight metal container in good thermal contact with an electrical resistance heater and a thermocouple or resistance thermometer. The sample under study is sealed in the container along with a small amount of gaseous helium. The helium aids in attaining thermal equilibrium at low temperatures because of its high thermal conductivity. The calorimetric vessel is suspended in an evacuated chamber by some material, such as a strong thread, having low thermal conductivity. This chamber is often within a massive copper block which provides a uniform and stable thermal environment. The temperature of the protective block is kept at a temperature near that of the calorimetric vessel. The heat exchanged is evaluated by observing the temperature difference ΔT as a function of time and applying Eq. (3) in an integrated form. The constant k is evaluated by observing the change in temperature of the calorimeter vessel and its contents under equilibrium conditions. During this rating period the temperature change is due entirely to heat exchanged with the environment. Some calorimetrists use the adiabatic principle and maintain the temperature of a protective shield as near as possible to that of the calorimeter. This procedure results in the elimination of heat exchange corrections but is not entirely free from objections. Although low-temperature calorimeters are used chiefly for heat capacity determinations, heats of transition, heats of fusion, and heats of vaporization are also measured.

At very low temperatures, calorimetry is used to measure energies associated with the ordering of the magnetic moments of nuclei, transitions into the superconducting state of metallic elements and compounds, and other phenomena which require only small amounts, or quanta, of energy to be activated. A decade decrease in temperature means a decade decrease in the size of the energy quanta which can be studied, and in this sense the range from 0.1 to 0.01 K covers a range equivalent to that between 1000 K and 100 K (i.e., from far above, to far below room temperature at 300 K). Temperatures down to 0.3 K are achieved by reducing the pressure over a bath of the helium isotope of mass 3, a relatively simple process. Using a more complex process, a helium dilution refrigerator produces millikelvin temperatures and thus heat capacities can be measured in the decade around 0.01 K. One method which has been used to measure the heat capacity of small samples such as thin films weighing less than 1 mg (10^{-4}–10^{-6} moles) at low temperatures is the so-called *relaxation method*. The sample is heated by an electrical heater to a small ΔT above its environment. The electrical leads provide a previously measured heat link to the environment, so that when the heater is turned off the temperature of the sample will relax back to that of the environment with a time constant proportional to the heat capacity of the sample. Here, as in all heat capacity measurements, the heat capacity of thermometers, heaters, and electrical leads is lumped together with that of the sample. To isolate the heat capacity of the sample, therefore, all of these addenda must be accurately known and subtracted from the total.

An interesting type of measurement is time-dependent heat capacity. In some materials, it is possible to put energy into only the electrons or only the ion lattice because the time needed for the electrons and the lattice to exchange energy and reach equilibrium is very long (up to seconds). Measuring the heat capacity as a function of the time probes both the equilibration processes and the electron and/or lattice heat capacities.

The *dropping method* is the most common of the accurate high-temperature procedures for measuring heat contents. This apparatus consists of a carefully regulated furnace and a suitable calorimeter, such as a Bunsen ice calorimeter, operating near room temperature. The sample under investigation is sealed inside a container that will not undergo chemical reaction at the highest temperature of the measurements. The sample and container are thermally equilibrated with the furnace and then dropped into the calorimeter. The empty container is afterwards studied in an identical manner and the difference in the two measurements gives the heat content of the sample relative to the room temperature reference. Heat capacities are derived from a series of such measurements as a function of temperature and the thermodynamic relationship

$$C_p = \frac{\partial(H)}{(\partial T)_p} = \left[\frac{(\partial H - H_0)}{\partial T}\right]_p, \qquad (5)$$

where C_p is the heat capacity at constant pressure, H the heat content, H_0 the heat content at the reference temperature, and T the absolute temperature.

The *Bunsen ice calorimeter* is an example of an isothermal calorimeter that is operated at a fixed temperature. The calorimeter is usually surrounded by ice, making it also adiabatic and thus free from heat exchange. Bunsen's design makes use of the very large difference between the specific volume of ice and water. The calorimeter contains a closed chamber which is full of ice and water. A pool of mercury is maintained in the bottom of the chamber, and as the ice melts, additional mercury enters and keeps the chamber full. The calorimeter has a universal calibration in the form of energy per unit mass of mercury. In early versions, the quantity of ice melted was used as a measure of the heat liberated in the calorimeter. By replacing the ice with other suitable substances, the restriction of operating at one fixed temperature can be removed.

Quantitative measurements of the heat liberated (or absorbed) during the solution of a solid or of another liquid by a solvent are performed in *solution calorimeters*. Heats of solution, dilution, and mixing are common determinations of this type. In addition to participating in the process under investigation, the solvent is used as a means of attaining uniform temperature and composition throughout the calorimeter. This feature necessitates stirring, which is usually accomplished with mechanically or magnetically driven stirrers. Sometimes the calorimeter itself is rotated. Regardless of the method used, the quantity of heat introduced by the stirring must be determined either directly or indirectly and a suitable correction must be applied. Another feature characteristic of solution calorimeters is the method of adding the sample. Either it must be equilibrated with the solvent in the calorimeter, or its heat content relative to the calorimeter temperature must be determined. A common method for solids is immersing a capsule containing the sample in the solvent and breaking it at the desired time.

The heat of combustion of fuels and similar materials is usually measured by *bomb calorimetry*. The solid or liquid sample is contained in a bomb (pressure vessel) containing excess oxygen or other suitable gas under pressure. The bomb is immersed in a calorimeter containing a liquid, usually water. The reaction is initiated by igniting the sample with a measured amount of electrical energy, and the heat evolved is measured in terms of the temperature rise of the calorimeter. Electrical energy is usually used to duplicate the temperature rise and thus evaluate the heat liberated. However, sometimes a standard sample of a substance having a known heat of combustion, such as benzoic acid, is used to calibrate the apparatus. In bomb calorimetry, corrections to standard conditions must be applied (Washburn corrections) since the system is under pressure and because solutions are usually formed.

There are many other important types of calorimeters, such as flow calorimeters, microcalorimeters, flame calorimeters, etc. Nearly any process can be studied by the investigator who is ingenious enough to devise the appropriate apparatus and who has the resources and patience to undertake an extensive project. Although calorimetric measurements are in general time-consuming and tedious, they are essential for a fundamental and practical understanding of many important chemical and physical processes.

CAPACITANCE

Definition and Fundamental (Quasi) Static Properties If a constant voltage V[V = volts] is applied between two conductors insulated from each other, electrical charges Q [As = coulomb] are so distributed that the conductors form equipotentials. The measure for the charges stored is the capacitance C [F = farad = 10^6 μF = 10^9 mμF = 10^{12} pF] of the capacitor so formed.

$$Q = C \cdot V \tag{1}$$

(Q in coulombs, C in farads, V in volts.) It is often more convenient to express this storing capacity in terms of energy

$$E = (\tfrac{1}{2})\, V^2 C \tag{2}$$

(E in watts.) C is defined by

$$C = \frac{1}{V}\int i\, dt \quad \text{or} \quad C = I \bigg/ \frac{dv}{dt} \tag{3}$$

For capacitor discharge (E_0 = starting voltage),

$$e_c/E_0 = \epsilon^{-t/\tau} \tag{4a}$$

and for capacitor charge (E_b = battery voltage)

$$e_c/E_b = 1 - \epsilon^{-t/\tau} \tag{4b}$$

with the time constant τ

$$\tau = C\mathrm{R} \tag{5}$$

where R is the resistor through which the capacitor is being (dis)charged.

For sinusoidal excitation of angular frequency ω, the reactance of the lossless capacitor is

$$V[\mathrm{V}]/I[\mathrm{A}] = (-)jX[\Omega] = 1/j\omega C[\Omega] \tag{6}$$

If, in electrical circuits, capacitors are connected in parallel, their capacitances add

$$C = \sum_{k=1}^{n} C_k \tag{7a}$$

If capacitors are connected in series, their elastances (the reciprocal of capacitance, S) add

$$S = \sum_{k=1}^{n} S_k \tag{7b}$$

Losses in the dielectric may be expressed by a complex relative dielectric constant

$$\varepsilon = \varepsilon' - j\varepsilon'' \tag{8}$$

where $\varepsilon'/\varepsilon'' = Q_e$ determines the dielectric quality factor. For $Q_e > 10$, the loss resistance of the capacitor is given by

$$(1/\omega C)/r_s = Q_e = R_p/(1/\omega C) \tag{9}$$

where r_s is the equivalent series and R_p is the corresponding parallel loss resistance. $Q_e = 1/DF$ (DF = dissipation factor). The power factor is related to DF by

$$PF = DF\sqrt{1/(1 + DF^2)} \tag{10}$$

The loss factor = $(DF) \cdot \varepsilon$ is proportional to the energy loss/cycle/voltage^2/volume.

Capacitors are used for: (1) frequency determining or selective networks [LC circuits and filters; cf. Eq. (6)]; (2) energy storage [Eq. (2)], for instance, the capacitor being slowly charged and quickly discharged [Eqs. (9) and (10)] in a short burst of energy; and (3) integrators and differentiators [in conjunction with R; cf. Eq. (3)].

Geometry *Uniform Fields.* For a uniform field as, for instance, given between two closely spaced parallel metallic plates (area A in square meters, distance l in meters) and disregarding edge effects

$$C[\mathrm{F}] = \varepsilon_0 \varepsilon A/l \tag{11}$$

with $\varepsilon_0\varepsilon$ = dielectric constant of free space = $(36\pi \times 10^9)^{-1}$ [F/m] and ε = the relative dielectric constant (dimensionless) of the material between the plates.

Discontinuity in Uniform Fields. If, in the above case, the dielectric consists of two sheets of different materials with ε_1 (having thickness l_1) and ε_2 (having thickness l_2)

$$\frac{E_1}{E_2} = \frac{\varepsilon_2}{\varepsilon_1} \tag{12}$$

where E_n is electric field strength = V_n/l_n. (13)

Equation (12) is of great practical significance if one of the ε's is very high, since then the sheet with the low ε carries nearly all voltage (for this reason, for example, higher-ε ceramic capacitors have to have fired-on electrodes).

Nonuniform Fields. The most common capacitance with nonuniform fields is the coaxial capacitor (inside diameter d, outside diameter D). Its capacitance is

$$C'[\mathrm{pF/m}] = 55.6\,\varepsilon/\ln(D/d) \tag{14}$$

Extreme cases of nonuniformity, often causing corona, exist on the sharp edges of plate capacitors. Remedy: For field equalization, deform plates to follow equipotential lines of half potential in a capacitive field with twice the spacing of the original, flat plates (Rogowski profile).

Dielectrics The dielectric "constant" is often not constant but a function of crystal orientation (anisotropy), temperature, voltage, and frequency (dispersion).

The objective of developing a good fixed capacitor is to have the largest capacity in the smallest possible volume for a given operating voltage. Ideally, the capacitance is not to change with voltage, temperature, time, mechanical stress, humidity, and frequency, and (in most cases) is to have a minimum of losses. The greatest capacitance can be achieved by maximizing ε (Case a) and A (Case b), and minimizing l (Case c) [cf. Eq. (11)].

Typical for *Case (a)* are *ceramic* capacitors made in discoidal or tubular form (and now recently also as coaxially laminated capacitors). There are four classes of ceramic dielectrics:

(1) Semiconducting, so-called layerized, ceramics with dielectric constants above 10^5. These can be used only for very low voltages (transistor circuits), are quite lossy, and have a strong dispersion of ε in the megacycle range.

(2) High-ε′ dielectrics (mostly barium titanates) with ε′ in the order of 6000. These are quite temperature- and voltage-sensitive (nonlinearity and hysteresis) and are used as guaranteed-minimum-value capacitors (GMV).

(3) So-called stable dielectric capacitors with an ε′ of 2000 or, if doped with rare-earth materials, with an ε′ of 3000 to 4000. These are much less dependent on temperature and applied dc voltage.

(4) Linear, high-Q (in the order of several thousand) temperature-compensating capacitors made with a prescribed (P positive, N negative, or NPO) temperature coefficient of the capacity for incorporation in temperature-stable tuned circuits (compensation of the temperature coefficient of the inductance). The ε of such materials lies between 10 and 100.

Case (b) (large A) is exemplified best by stacked plates [silvered mica (for military use; excellent Q, temperature coefficient about −100 ppm) or ceramic (monolithic)] or rolled dielectric strips [polystyrene (excellent Q; commercial use; also about −100 ppm T.C.); "Mylar"; oil-impregnated paper; "Teflon" etc.].

Case (c) (small l) is represented by polarized capacitors (to make them unpolarized, two capacitors are connected in series in polarity opposition, usually in the same housing), and it includes the older, larger, and cheaper types like the aluminum foil electrolytics. The newer, more costly, but much smaller, types (having much less leakage current) are tantalum oxide capacitors. Ta_2O_5 stands continuously the extraordinary field strength of 3×10^6 V/cm with an ε′ of 25, l being measured in angstroms. The Q is about 100. For microminiaturization, silicon monoxide or dioxide or tantalum oxide films of very small l are utilized.

Rating The reliability of a capacitor is predominantly determined by the dielectric and the seal of the housing. One has to distinguish between failure value and withstand value. The failure value of dielectric strength is the voltage at which the material fails and is conventionally given as the average failure voltage. In contrast, the withstand value is a voltage below which no failure can be expected.

Deterioration of capacitors with time (aging) can be greatly reduced by systematic "physics of failure" investigations. Typical failure mechanisms are, for instance, precorona discharge in adsorbed air layers, or silver migration.

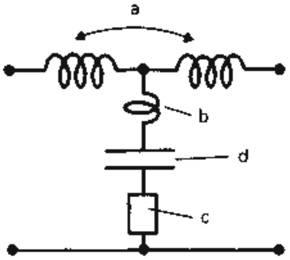

FIG. 1. High-frequency behavior of capacitors.

Non-ideal Behavior at Higher Frequencies Equation (6) presumes ideal conditions. An actual capacitor, particularly if considered over many decades of frequency, and more so, if used as a shunting element across lines, is much more aptly describable as a three-terminal network. Figure 1 marshals the four key deviations from the ideal behavior:

a. At very high frequencies, inductive input-output coupling may override the shunting effect of the capacitor. Remedy: use feed-through capacitors where input and output leads are separated by a shield.

b. Again, at high frequencies, unless as a remedy a feed-through configuration is selected, a series L in the shunt branch results in the capacitor behaving as an inductor above the resonance frequency thus determined ($\omega = (LC)^{-1/2}$).

c. If the capacitive reactance at high frequencies becomes very small, the resulting transfer impedance may be determined by the series loss resistance. A typical case is a tantalytic capacitor behaving this way. Remedy: It must be paralleled by a smaller capacitor of less high frequency losses.

d. At very high frequencies, let us say 100 MHz and above, even ceramic feed-through capacitors start to resonate internally (transmission line effect) rendering them useless above certain frequencies. Remedy: See, for instance, bibliography 1.

Nonlinear Capacitance The dielectric of highly nonlinear capacitors is the depletion layer formed at the p-n junction by application of proper bias. These back-biased diodes have a reasonable Q and are widely used as nonlinear reactances in parametric amplifiers for VHF and higher frequencies and for varactor tuning in TV receivers. Nonlinear ceramics are less suitable for this purpose because of their high losses and great temperature dependency.

"Parasitic" Capacitances Capacitances play a significant role in voltage limiters used extensively for interference control. If one employs sparkgap limiters, one has the advantage of a small shunt capacity. Thus, with $R = Z_0$ (characteristic impedance of line), the time constant is small and the bandwidth of the line is large—as it often needs to be. But sparkgaps have disadvantages like slow response time, possibility of sustaining arcs, etc. Solid state voltage limiters (single-crystalline Si Zeners or polycrystalline metal-oxide varistors) do not have such drawbacks, but have large C's which may be reduced (a) or exploited (b). To maintain large bandwidth, a small series capacitance is to be added (a). On the other hand (b), metal-oxide varistors have variable resistance, very high below the knee voltage and very high above it, and in parallel a considerable capacitance. Their dielectric constant is on the order of 3000 and is not bias sensitive and much less temperature dependent than corresponding ceramics. Feedthrough capacitors made of such material are not yet commercially available, but they are very small integrated interference suppression devices that filter at low voltages and limit at high voltages.

CARNOT CYCLES AND CARNOT ENGINES

Background Steam engines were first built to do heavy, tedious jobs such as pumping water out of deep mines. Not only could they pull harder than a team of horses, but they did not get tired. These engines were built by rule of thumb by practical men, for at that time there was no thermodynamics to guide the design. Still engines could be rated by how much water was pumped for a bushel of coal burned. For a century the quality of these engines improved, and the obvious question was whether there was any limit to this improvement. Carnot's work addressed that question. He set out to devise a heat engine against which all imaginable heat engines could be compared.

Description The engine Carnot devised is often represented, as shown in Fig. 1, by a device which uses an ideal gas as its working substance. A quantity of gas is confined in a cylinder with a wall so well insulated that no heat can flow through it. The cylinder's heat-conducting base rests on the first reservoir, whose constant temperature is T_h, and the gas assumes this temperature. A weighted insulating piston holds the pressure of the gas at P_1 at which pressure its volume is V_1. The gas is then said to be in thermodynamic state 1 characterized by P_1, V_1, and T_h. Little by little the weight on the piston is now set aside until the pressure is reduced to P_2 and the volume is expanded to V_2. The gas is now in state 2 characterized by P_2, V_2, and T_h. The transition from one thermodynamic state to another is called a thermodynamic process. A process is called reversible if done so slowly that no temperature differences arise within the gas and if the piston moves without friction. The cylinder base is kept at temperature T_h, so during this process the temperature of the gas remains at T_h; that is, it is an isothermal process. When this is shown on a pressure-volume diagram, the process appears as a portion of the T_h isotherm. To hold the temperature constant, some heat energy Q_h must flow from the reservoir into the gas. In expanding against the weight on the piston, the gas does work W_{12} which is represented on the P-V diagram by the crosshatched area. The cylinder is next moved to an insulated pad where the pressure is further decreased by setting aside more weights, and the gas again expands. No heat energy flows into the gas from the outside during this expansion, and this is called an adiabatic process. The temperature decreases and when it reaches T_c, the temperature of the second reservoir, the process is stopped. The gas is now in state 3 characterized by P_3, V_3, and T_c. During this process the gas does work W_{23} against the load. The cylinder is then moved to the second reservoir where enough weights are slowly replaced to bring the gas to state 4, the point on the T_c isotherm from which state 1 can be reached by an adiabatic process. During this isothermal compression, heat energy Q_c flows from the gas into the reservoir, and the piston does work W_{34} on the gas. To show that this work is done on the gas while previously the work was done on the piston, the appropriate portion of the crosshatched area has been removed. The cylinder is finally placed on an insulated pad, the remaining weights are slowly added, and the gas returns adiabatically to state 1. Again the fact that the piston does work W_{41} on the gas, is shown by the removal of the cross-hatched area. One Carnot cycle is now completed.

Definition and Characteristics A Carnot cycle is any reversible cyclic thermodynamic operation composed of four processes which are alternately isothermal and adiabatic. (The working substance need not be an ideal gas, but traditionally this is used in discussions.) Since no natural process is strictly reversible, the Carnot cycle is an idealization.

Although heat energy has entered and left it and work has been done on it, the gas undergoes no detectable physical changes for having passed through the Carnot cycle. Heat energy Q_h was removed from the hotter reservoir, and a smaller amount Q_c flowed into the cooler reservoir so that the heat energy budget of the gas increased by $Q = Q_h - Q_c$. The net work done by the gas on the piston is $W = W_{12} +$

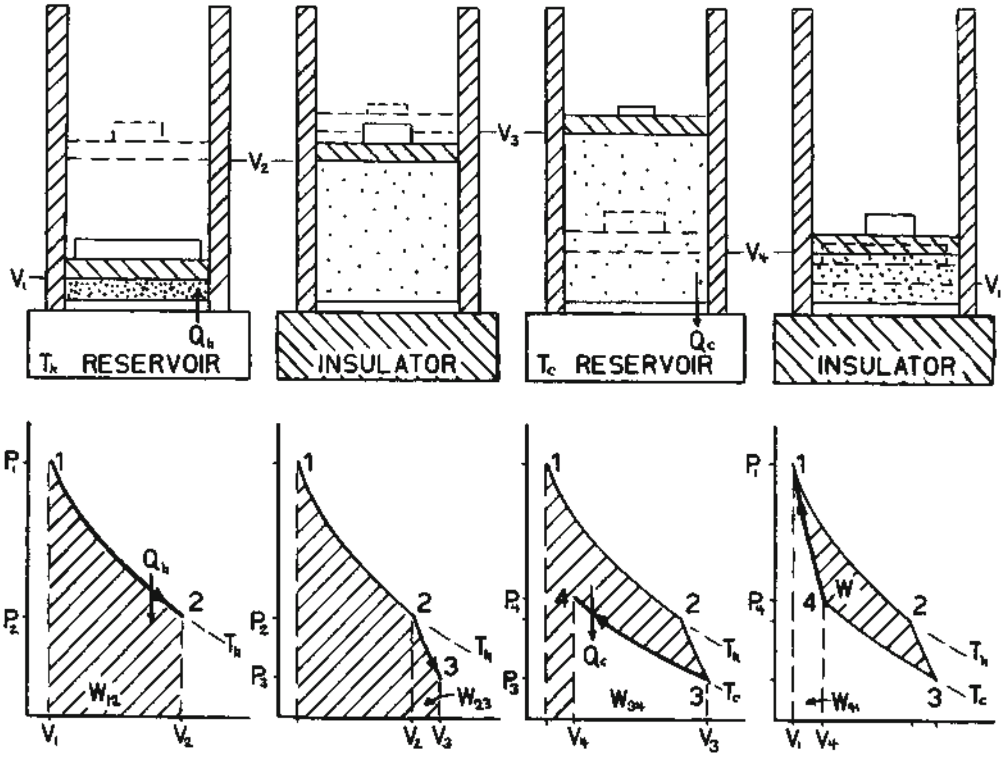

FIG. 1. The steps of a Carnot cycle and the corresponding pressure-volume diagrams. The piston location at the start of each process is shown in solid lines; at the end, in dashed lines. The pressure on the gas can be estimated by the area of the weight shown on top of the piston. The dots indicate that the molecules of the ideal gas are close together when the volume is small and are farther apart when the volume is large.

$W_{23} + W_{34} + W_{41}$, and the mechanical energy budget of the gas decreased by W which is represented on the P-V diagram by the area enclosed by the phase lines. The first law of thermodynamics requires that $W - Q = 0$ so no energy residue is left in the gas. If the cycle is traversed as described, heat energy Q_h is removed from the higher-temperature reservoir. Part of this remains in the form of heat energy Q_c as it flows into the cooler reservoir, and part of it is converted to mechanical energy as the work W done on the piston. A Carnot cycle operated in this direction is called a Carnot engine. If the direction of operation were reversed, the cycle would be called a Carnot refrigerator. In such a device mechanical energy, the work W done by the piston, is converted into heat energy which combines with the heat energy Q_c which flows from the cooler reservoir into the gas. All this heat energy Q_h flows out of the gas into the hotter reservoir.

The efficiency η of any engine is the fraction of the heat energy input Q_h which is converted into mechanical energy W; that is, $\eta = W/Q_h$. The following properties of Carnot engines are derived in many textbooks of thermodynamics.

(1) The efficiency of a Carnot cycle depends only on the temperatures of the two reservoirs. When these temperatures are measured on the absolute scale in Kelvin, then $\eta = 1 - (T_c/T_h)$.

(2) No heat engine operating in cycles between two reservoirs can have a greater efficiency than a Carnot engine operating between those reservoirs.

The Carnot engine is thus a standard against which other heat engines can be compared. Historically it was the source of a number of ideas that are now basic to the study of thermodynamics.

Although the Carnot cycle is the most efficient heat engine, it does not produce any power P. The requirement of reversibility means that a very long time t is required to complete even one cycle. Thus the power (defined as $P = W/t$) is zero. To speed up the cycle a temperature difference between the working substance and reservoirs can be introduced. Under this condition the power efficiency η' is found[1] to be $\eta' = 1 - (T_c/T_h)^{1/2}$. The efficiency of real heat engines is described rather well by this equation.

History of the Carnot Cycle In 1824 Sadi Carnot[1a] (1796–1832) analyzed a heat engine assuming that heat can perform mechanical work in falling from a higher temperature to a lower just as water can do work falling from a higher level to a lower, and assuming that no heat would be lost just as no water was lost. (His work preceded by more than 20 years the theory of Joule and Helmholtz on the mechanical equivalence of heat.) In his study he proposed an ideal heat engine that operated in a continuous cycle and was reversible. He then showed that it is impossible in a cyclic operation to obtain work from a single constant-temperature heat source and that no more work can be obtained from any process than is required to reverse it.

His ideas escaped notice until 1834 when Clapeyron[2] recognized their merit, suggested some of the details of the device described above, and plotted its behavior on a *P-V* diagram. Again the ideas were neglected until William Thomson (later Lord Kelvin) learned of Carnot's work through Clapeyron's memoir. In 1848, Thomson described[3] how a Carnot engine could be used to define a temperature scale that was absolute in the sense that it did not depend on what thermometric substance was used. It was based on a series of Carnot engines, each of which did the same amount of work. This was the first important idea drawn from a study of the Carnot cycle. In 1850 Clausius[4], who learned of Carnot's ideas through Thomson and Clapeyron, showed how Carnot's assumption (no loss of heat) could be reconciled with the newer views of Joule and Helmholtz (which now form the basis of tne first law of thermodynamics). It was only required that the engine exhaust less heat energy, by the amount of the work done, than it accepted. Thomson independently reached the same conclusion[5] in 1851.

In 1854 Clausius[6] in his study of the Carnot cycle identified the physical property he later named "entropy." This was the second important idea drawn from study of the Carnot cycle. In 1877 Boltzmann[7] took the principle of Clausius that real processes evolve naturally toward states of higher entropy (which is the second law of thermodynamics) as a basic point in his theory and thus had no need to consider the Carnot cycle from which that principle was derived. It is now common practice to discuss thermodynamics axiomatically rather than historically so that the Carnot cycle no longer plays the important role it once did. The most complete discussions are found in the older volumes,[8] but some recent books do describe the cycle in detail.[9] An historical account[10] with an elementary presentation of the theory and a review[11] of Carnot's work with excerpts from his original paper have been published.

CAVITATION

Cavitation is defined as the formation of one or more pockets of gas (or *cavities*) in a liquid.* Here the word *formation* can refer, in a general sense, both to the expansion of a newly created cavity or of a preexisting one to a size where macroscopic effects can be observed. The cavity's gas content refers to the liquid's vapor, some other gas, or combinations thereof. Sometimes these cavities are referred to as *bubbles* or *voids*, depending on the relative amount and type of gas.

Cavitation usually occurs in response to a reduction of the pressure sufficiently below the vapor pressure or the gas saturation pressure of the liquid or to the elevation of the temperature above the boiling point, although chemical, electrical, and radiation-induced phenomena can be important.

Although liquids, by definition, cannot sustain shearing forces without flow, they can sustain uniform tension. The tensile strength of a liquid refers to the limiting tension, or negative pressure, that a liquid can sustain before cavitation occurs. Ultimate cavitation *thresholds* can be reached only in the absence of weak spots or cavitation *nuclei* (usually gas or vapor pockets) which exist on solid surfaces of container walls and suspended impurities, or which

*The first two paragraphs are from Ref. 3 and are reprinted with the permission of Academic Press.

are generated by the interaction of ionizing radiation with the tensed liquid (see also BUBBLE CHAMBERS).

Because of the prevalence of these weak spots (typical tap water has in excess of 10,000 particles per cubic centimeter), the ultimate tensile strength of a liquid, theorized to range from 150 to 1500 atmospheres for most materials that are liquid at room temperature, has rarely been measured. Commonly measured tensile strengths measured by static or dynamic means are typically two to three orders of magnitude lower (approaching the vapor pressure of the liquid). Static tensile stresses can occur in the laboratory, in a liquid filled capillary that is spun at sufficient speed, and also in nature, it is presumed, in the xylem paths of tall trees, as water transpiring from the leaves is drawn up from the tree's roots.

Dynamic tensile stresses are produced hydrodynamically and acoustically. Hydrodynamic cavitation results from the local reduction of pressure produced by the motion of a body in a liquid (Bernoulli effect), as would be found in the vicinity of a rotating propeller of a ship or near the surface of a fast submarine traveling at an insufficient depth for the hydrostatic pressure to suppress the flow-induced tension. Acoustically generated cavitation occurs when a sufficiently energetic acoustic wave produces periods of high negative pressure exceeding the ambient hydrostatic pressure, as can happen near the surface of a high-power acoustic transmitter used for long range communication in the ocean (see SONAR).

In both hydrodynamic and acoustic cavitation, the size of cavitation nuclei and the degree they are wetted by the liquid will dictate the cavitation threshold (which is usually very low in the hydrodynamic case); the number of cavitation nuclei will dictate the amount of cavitational activity. And in both hydrodynamic and acoustic cavitation, the duration of the period of tension will determine how big the bubbles grow before the bubble will collapse under the positive ambient hydrostatic pressure. Inside a collapsing bubble the pressure and temperature will rise, with the severity of the collapse increasing with maximum bubble size and with the scarcity of trapped permanent gas, which tends to cushion the collapse. Collapsing bubbles can generate in the surrounding liquid shock waves and hydrodynamic jetting. Such effects in the vicinity of a solid surface can lead to severe erosion, as is commonly found on screw propellers of ships.

In addition to these effects, a number of interesting phenomena can occur in acoustic cavitation. Temperatures inside a collapsing bubble in fairly outgassed liquid can reach thousands of degrees Celsius and pressures can reach thousands of atmospheres. Light can be produced (called *sonoluminescence*) and sonochemical effects may occur due to free radical formation inside the bubble. These transient phenomena can be attributed to the concentration of energy which occurs when bubbles grow to at least twice their original size in one or no more than a few acoustic cycles. For this to occur, peak acoustic pressures must be at least an atmosphere greater in magnitude than the hydrostatic pressure, and the acoustic frequency must be sufficiently low (as must be the liquid's viscosity) so as to allow for adequate bubble growth during the tension part of the cycle.

There is also a relatively more stable and periodic type of acoustic cavitation that occurs when a bubble filled with relatively inert gas (often air, in practical circumstances) oscillates with an amplitude that is small compared to the bubble size. It may slowly grow by a process called *rectified gas diffusion* when the acoustic pressure is only a fraction of an atmosphere. If the bubble reaches a resonant size (for example 6500 Hz for a 1-millimeter-diameter air bubble in water at an ambient pressure of one atmosphere), it will go through much larger oscillations, producing acoustic emission in the liquid not only at the driving frequency but also at its harmonics ($2f$, $3f$, . . .), subharmonics ($f/2$, $f/3$, . . .), and ultraharmonics ($2f/3$, $3f/4$, . . .). The bubble may then become unstable and transient, eventually breaking up into smaller bubbles. The flow-induced effects induced in the liquid by this cavitational activity are used in a variety of practical applications, from removing embedded dirt (as with ultrasonic cleaners) to improving the efficiency of chemical reactions.

CENTRIFUGE

The centrifuge is a device consisting of a rotating container in which substances of different size, shape, or density are separated by the centrifugal field developed along the radial direction. In most cases the centrifuge is used with fluids for producing sedimentation of macromolecules of molecular weight $M > 10^4$ grams/mole or daltons.[1,2] It has been used extensively also in the separation of gaseous components and for determining the strength of materials as well as a number of other applications.[3,4] Centrifugal fields as large as 10^9 times gravity have been achieved; however, for most purposes the fields are of the order of 10^4–10^5 times gravity. The effective centrifugal force F on a particle of mass m and density ρ in a fluid of density ρ', is expressed by $F = m(\rho - \rho')\omega^2 r/\rho$, where ω is the angular velocity and r is the radial distance of the particle from the axis of rotation. For a spherical particle, F is opposed by the frictional force of the fluid on the particle according to Stokes' law, $6\pi\eta a v$, where η is the coefficient of viscosity, a the radius and v the speed of the particle (provided that the Reynolds number, $2av\rho/\eta$, is less than unity and wall effects are neglected). Thus, the average rate of sedimentation v of spherical particles is described by

$$\tfrac{4}{3}\pi a^3(\rho - \rho')\omega^2 r = 6\pi\eta a v = f v \qquad (1)$$

where f is the frictional coefficient. Nonspherical particles can be handled by the introduction of appropriate shape factors. Since the measured quantity in sedimentation is $v = dr/dt$ and the quantities ω, r, ρ, ρ', and η are also measurable, a and hence m can be determined. When m is expressed in terms of the molecular weight M, the buoyancy of the particles as a function of concentration C (mass/volume) is given by $(\partial\rho/\partial C)_\mu$, where ρ is now the density of the solution; this derivative is virtually constant for dilute macromolecules in a given solvent of much smaller molecular species. (In the general case for multicomponent solvents, such as when salts are added to reduce the effect of charge on the particles, the chemical potential μ of the solvent mixture is held constant rather than its composition as C changes.[5]) In dilute solutions the molar frictional coefficient is RT/D where D is the diffusion coefficient, which is measured independently. Thus, the equation for calculating M from the rate of sedimentation, in the absence of substantial charge effects, is

$$M = \frac{RT(dr/dt)}{D(\partial\rho/\partial C)_\mu \omega^2 r}. \qquad (2)$$

The rate of sedimentation in a unit field $(dr/dt)/\omega^2 r$ is called the ***sedimentation coefficient s***, which has the dimension of time. The coefficient s is often expressed in Svedbergs (10^{-13} sec), a unit named in honor of T. Svedberg, the pioneer in analytical centrifugation. The value of s or the Svedberg is very important in characterizing a substance in solution.

As noted, the net transport of particles through a solvent medium in a centrifugal or gravitational field is opposed by the tendency to restore the previously distributed condition through the process of diffusion. Thus BROWNIAN MOTION from thermal agitation prevents sedimentable particles from settling out if v, although finite, is sufficiently small. The average displacement X of a particle in time τ owing to Brownian motion is $\overline{X^2} = 2D\tau$, and for a sphere of radius a the average velocity v_τ over a period τ is expressed by

$$v_\tau = \frac{\sqrt{\overline{X^2}}}{\tau} = \left(\frac{RT}{N}\,\frac{1}{3\pi\eta a\tau}\right)^{1/2}$$

where N is the Avogadro number. As v_τ becomes larger than v, particles will no longer settle out; i.e., net transport becomes zero at a sufficiently small centrifugal field so that an equilibrium distribution of the particles along the column of solution in the radial direction will be reached. When this equilibrium state is achieved between the tendency to sediment and to back diffuse, the concentrations at any two levels in the column can be related to M by

$$\ln\frac{C_2\gamma_2}{C_1\gamma_1} = \frac{M(\partial\rho/\partial C)_\mu \omega^2(r_2^2 - r_1^2)}{2RT} \qquad (3)$$

where the numerical subscripts refer to two arbitrary positions in the radial direction and γ is the activity coefficient. In dilute solutions, as is usually the case in analytical work, $\gamma \to 1$ and the practical equation for determining the weight-average molecular weight M_w in sector-shaped cells (to avoid wall effects) is given by

$$M_w \approx \frac{2RT}{(\partial\rho/\partial C)_\mu \omega^2(r_2^2 - r_1^2)}\,\frac{C_2 - C_1}{C_0} \qquad (4)$$

where C_0 is the initial concentration of the solution before sedimentation is initiated. The concentrations at radial distances r_1, r_2 are normally determined (by various optical means) at the meniscus and at the bottom of the solution column, respectively. Since charge effects may be large with sedimenting macromolecules, suppression of this effect is usually carried out by raising the ionic strength (via a neutral salt) if the system cannot be studied at the isoelectric point. In Eqs. (2)–(4) accurate densities as a function of C must be available from which to calculate $(\partial\rho/\partial C)_\mu$;[6] the chemical potential μ of the solvent is maintained constant for this purpose by first dialyzing to equilibrium the sedimentable species against the chosen solvent via a semipermeable membrane.[5]

Preparative Centrifuges For the purification and concentration of substances in solution or suspension in a fluid, the centrifugal field is made high enough so that appreciable separation of each material in a mixture is realized. Often one substance is sedimented to the bottom of the centrifuge cell (i.e., toward the periphery of the rotor), thereby concentrated as a pellet or simply enriched relative to the slower sedimenting substances which are present. Repeated centrifugation of the redissolved pellet material then further purifies it from the slower moving impurities. Conversely, the pelleted material may be the contaminant which is freed from the medium containing the desired substance. Centrifuges for these purposes are called *preparative centrifuges*; the variety, convenience, and sophistication of preparative instruments for a wide range of purposes in both industry and research is great indeed. Equations (1) and (2) are used for estimating the required rotor speed, size and style of rotor, and the time needed for achieving the desired degree of differential sedimentation of mixtures. These equations hold strictly only when the sedimentation is radial and so that no turbulence or remixing occurs. Moreover, the temperature must be uniform throughout the sedimentable column so that convection does not occur. The force generating thermal convection is roughly proportional to the density gradient along the column times the centrifugal field. Since the latter is often large, the temperature gradient must be small. In high-speed centrifugation the rotor is usually spinning in a good vacuum ($<10^{-5}$ torr) in a temperature-controlled instrument, so that heating and thermal gradients are avoided. In general, biomacromolecules, including enzymes, are not inactivated by the increase in pressure along the radial path in the fluid at high rotor speeds. Ordinarily, these pressures amount at most to a few hundred atmospheres, which are insufficient to irreversibly alter the structure of these macromolecules.

A major development in preparative centrifugation is toward the separation of substances along a density gradient. When a column of fluid is prepared such that the density increases smoothly along the sedimenting path and then a thin layer of solutes or suspended particles to be separated is applied to the top of the column, the solutes tend to segregate into distinct bands during the centrifugation. For the preparation of the density gradient, nearly inert, denser materials, such as sucrose, cesium chloride, or osmotically inert silica sols are often used and methods exist for constructing these gradients in the fluid column. This technique has become a great boon in several kinds of research. In some methods the mixture of test materials moves down the column until each material has reached a level where it becomes isodense with the layer of fluid of a particular density (*isopycnic centrifugation*). In this way each test material exhibiting a different density in solution concentrates as a thin band at different levels along the column because the density gradient, made up of much smaller molecules or stable sols, is approximately invariant relative to the transport of the macromolecules or larger entities in the centrifugal field. The isolation attempts with live cells, viruses, nucleic acids and proteins have met with remarkable success by the use of the isopycnic method.[7] For example, the clear separation of complementary strands of nucleic acid and the parent double-stranded molecule have been achieved owing to the fact that each complementary strand, while of the same size, has a slightly different density in solution or partial volume, $(\partial V/\partial m)_\mu$.[8] This quantity is contained in the buoyancy term of Eqs. (2), (3), and (4), wherein

$$\left(\frac{\partial\rho}{\partial C}\right)_\mu = \left[1 - \rho'\left(\frac{\partial V}{\partial m}\right)_\mu\right]$$

Analytical Centrifuges When a centrifuge is designed for analytical work it is called an *ultracentrifuge*.[1] The ultracentrifuge is employed in one of two general methods. The first method makes use of Eqs. (1) and (2), whereas the second is based on Eqs. (3) and (4); both methods are applied extensively. In the first method, called *velocity sedimentation*, comparatively large centrifugal fields (e.g., 2×10^5 times gravity) are generated in order to produce an easily measured rate of sedimentation v of a molecular species. The value of v is usually determined by optical means and s is computed. The latter is normalized to the rate (per unit field) under standard conditions, such as at 20° in a medium corrected to the density and viscosity of water ($s_{20,\mathrm{w}}$). Because s depends on the concentration of the sedimenting molecules its value is further reduced to that at vanishing concentration ($s^0{}_{20,\mathrm{w}}$) by extrapolating s at finite concentrations to that at $C = 0$. In this way different macromolecules can be compared on the basis of their rates of sedimentation. The slopes of the regression lines, s versus C, reflect on the shape and other properties of the sedimenting molecules and in their interactions with other chemical species present.[2] The high centrifugal field quickly produces a small density gradient along the radial path which stabilizes the liquid column. As a result, highly precise control of the temperature and speed of the rotor is not mandatory, although it is desirable. The time requirements of velocity sedimentation is comparatively small (1-2 hours). Also, if the solution contains more than one sedimenting species, the characteristic value of s for each can be measured by observing certain precautions.[2] Thus, the method is useful for comparing the effects of treatments on the product output and for following the degree of purification during isolation procedures. Historically, velocity sedimentation serves as a criterion for the degree of homogeneity of a purified macromolecular species. Furthermore, the self association and interaction of species in a mixture often can be determined. These and other aspects yielding important information have been studied both theoretically and experimentally on a broad front.[2,9,10] The velocity method, however, requires knowledge of D or another measurement reflecting f, which are determined less accurately than is s. Hence, the value of M is more uncertain than by the second method (below).

The second method, known as *equilibrium sedimentation*, is on more firm theoretical grounds, being based upon equilibrium thermodynamics. Also, the value of M, not being dependent upon a separately determined function of f, is more reliable. The equilibrium method permits an analysis of the various factors contributing to non-ideal behavior of solutions from which much valuable information can be gained about the total system. Further, the equilibrium method has been employed successfully in resolving equilibrium constants for self-associating and other interacting macromolecules in mixed systems.[9,10,11] In general, high purity of the sedimenting species is required. Also, this method usually entails relatively small rotor speeds in order that the test molecules do not sediment to the bottom but rather distribute at equilibrium along the column of solution as a function of the radial distance. Thus, much more time is needed to achieve the relevant data than by the velocity method. However, various procedures have been devised to shorten the time requirement. Molecules as small as $M \sim 10^3$ daltons as well as particles of $M > 10^7$ daltons have been studied successfully, the latter using fields of only a few gravities by use of a magnetically suspended rotor in order to reduce rotor precession effects to a safe level.[12] For larger species, the gravitational field of the earth can be used.[13]

Gas Centrifuge The gas centrifuge has been used for removing fine particles suspended in gases, for the separation of gaseous mixtures, and for the separation of isotopes, with the last of these being one of the most important large scale applications. The first suggestion of using a centrifugal field to separate isotopes was in 1919,[14] and the first successful demonstration was made in 1934 by J. W. Beams at the University of Virginia with the isotopes of chlorine.[15] In recent times, large scale gas centrifuge plants have been built for separating the isotopes of uranium to produce uranium enriched in the fissionable isotope U^{235} for fuel in light water power reactors. These plants employ tens or hundreds of thousands of centrifuges depending on the size and peripheral speed of the rotor.

When a centrifugal field is applied to an ideal gas, it sets up a pressure gradient

$$\frac{dp}{dr} = \frac{Mp}{RT}\,\omega^2 r \qquad (5)$$

where p is the pressure, M the molecular weight of the gas, R the gas constant and T the absolute temperature. For the case of an isothermal centrifuge, Eq. (5) is readily integrated to yield

$$p(r) = p(0)\exp\left(M\omega^2 r^2/2RT\right) \qquad (6)$$

which gives the pressure $p(r)$ at any radial position r in terms of the pressure at the axis $p(0)$. For a mixture of two ideal gases of molecular weights M_1 and M_2, each gas would have a pressure governed by Eq. (6) and the ratio of the two equations gives the radial separation under equilibrium conditions (i.e., no gas circulation). An equilibrium separation factor between the two gases is therefore given by

$$\alpha_0 = \frac{x_1(0)}{x_2(0)}\Big/\frac{x_1(a)}{x_2(a)} = \exp\left[(M_2 - M_1)\,\omega^2 r^2/2RT\right] \qquad (7)$$

where x_1 and x_2 are the concentrations of species 1 and 2, respectively. The details of the theory of isotope separation by the gas centrifuge have been considered by numerous authors,[16-19] and the separative performance depends upon the internal circulation of the process gas which has been analyzed in detail.[20]

The operation of a gas centrifuge is illustrated in Fig. 1. The rotor is suspended at the bottom by a low friction bearing and at the top by a frictionless magnetic bearing. In the case of the separation of uranium isotopes, uranium hexafluoride (UF_6) is introduced into the spinning rotor from the stationary central post and removed from stationary pipes called scoops located at either end of the rotor. In practice gas centrifuges are spun in a vacuum at very high peripheral speeds, 400 m/s or greater, so that the process gas is compressed into a thin stratified layer adjacent to the cylindrical wall of the rotor. If we consider the process gas to be a binary mixture of the two isotopic species $U^{235}F_6$ and $U^{238}F_6$, then the heavier molecules containing U^{238} will tend to be concentrated near the cylinder wall and the lighter molecules containing U^{235} will tend to be concentrated near the axis.

In addition to removing mass, the stationary scoop at the bottom of the rotor induces a countercurrent flow by removing angular momentum and pumping the gas radially inward, forcing it to travel up near the axis and down along the cylinder wall. In order to prevent an opposing circulation, the scoop at the top is shielded by a baffle which rotates with the rotor and has holes which allow the gas to enter the scoop chamber and be removed through the scoop. A similar countercurrent flow can be induced by heating the bottom of the rotor and cooling the top of the rotor, which is analogous to the high altitude winds driven by thermal gradients in the earth's stratified atmosphere. This countercurrent flow produces a net transport of heavy isotopes to the bottom of the rotor and a net transport of light isotopes to the top of the rotor, which establishes a concentration gradient in the axial direction. Therefore, the gas removed by the top scoop is enriched in U^{235} (product) and the gas removed by the bottom scoop is depleted in U^{235} (tails). Cascades are formed by centrifuges connected in series to obtain the desired enrichment and in parallel to obtain the desired throughput.

The maximum theoretical separative capacity of a gas centrifuge has been shown to be[16,18]

$$\delta U(\max) = \frac{\pi Z \rho D}{2}\left(\frac{\Delta M\omega^2 a^2}{2RT}\right)^2 \qquad (8)$$

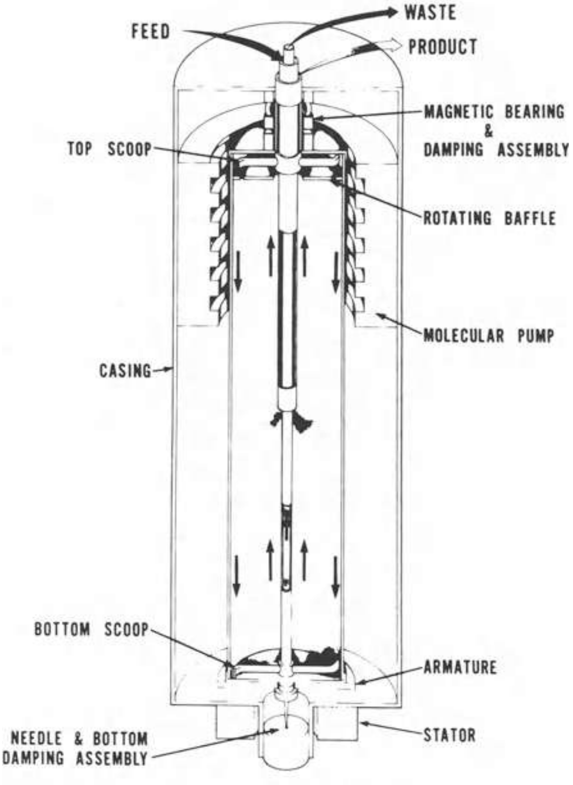

FIG. 1. Gas centrifuge.

where Z is the length of the rotor, ΔM is the difference in molecular weights, and δU is the separative capacity in moles per unit time. Therefore, long, high speed rotors are desirable features of the gas centrifuge process. The peripheral speed is limited by the strength of the rotor material. As in the case of a rod that is rotated, the rotor will have certain natural frequencies which will be determined by the materials of construction, the rotor length to diameter ratio, and the damping of the suspension systems. Centrifuges which operate at rotational frequencies which are below the lowest natural flexural frequency of the rotor are called *subcritical centrifuges*, and those which operate at rotational frequencies above the first flexural natural frequency are called *supercritical centrifuges*.

ČERENKOV RADIATION

This is a feeble radiation in the visible spectrum, which occurs when a fast charged particle traverses a dielectric medium at a velocity exceeding the velocity of light in the medium. It is thus a shock-wave phenomenon, the optical analog of the "supersonic bang." The radiation arises from the local and transient polarization of the medium close to the track of the particle. Consider, Fig. 1(a), an arbitrary element S of the medium to one side of the track AB of a fast electron, the track defining the z-axis. At a particular instant of time, when the electron is at say e_1, the local polarization vector P_1 will be directed along S $e_1{}'$, to a point $e_1{}'$ slightly behind e_1, owing to the retarded fields. As the particle goes by, the vector P_2 will turn over and, when the electron reaches e_2, will be directed to a point e_2'. The variation of P with time, may be resolved into radial and axial components P_ρ and P_z, as shown in Fig. 1(b). Owing to cylindrical symmetry, this polarization, viewed at a point distant from the particle, appears as an elementary dipole lying along the axis z, Fig. 1(c). As the particle plunges through the medium, radiation arises from the coherent growth and decay of this sequence of elementary dipoles. Two essential features of the radiation become at once apparent. First, since it is only the P_z component which is important, the field variation, Fig. 1(b), is that of a double δ-function. Thus, from Fourier analysis, if the circular frequency is ω, we will expect a spectrum of the form $\omega \cdot d\omega$, i.e., radiation which is bluer than that from an equi-energy spectrum. Secondly, since the radiating element is an axial dipole, the angular distribution, for this element alone, will be of the form $\sin^2\theta$, Fig. 1(c). It is important to realize that the radiation arises from the medium itself, not directly from the particle. Since the medium is stationary, the intensity and angular distributions do not contain the relativistic factor (mc^2/E); in this respect, it is essentially different from Bremsstrahlung or synchrotron radiation.

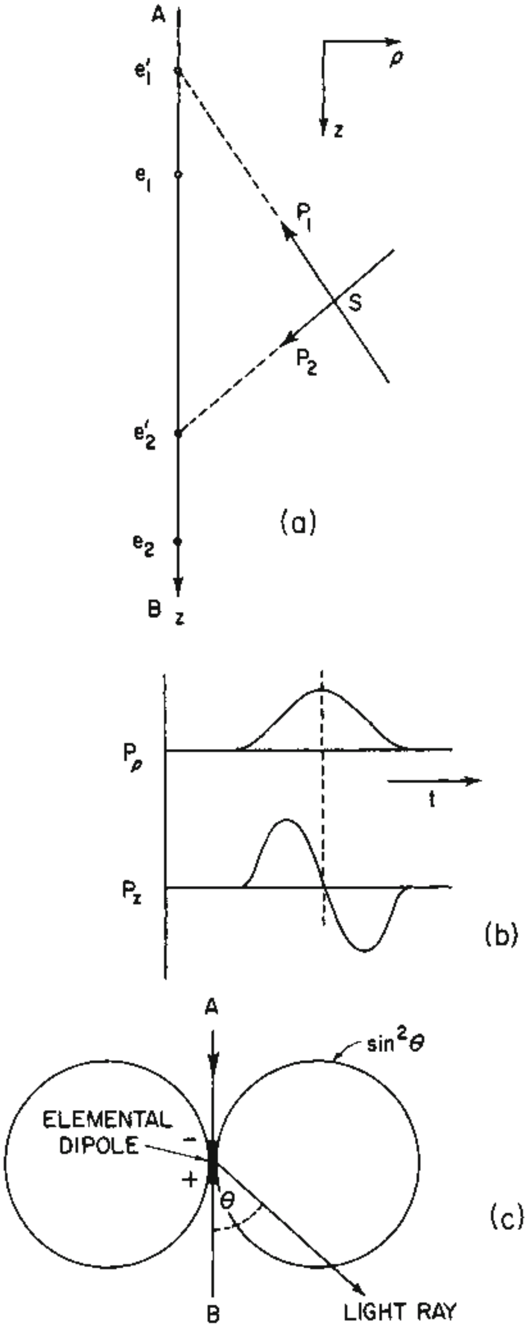

FIG. 1

The description above applies only to one element along the track. The most characteristic feature of Čerenkov radiation, its coherence, is at once apparent when we now consider an extended region of track. In Fig. 2(a) it is easily seen that there is only one angle θ at which it is possible to obtain a coherent wave front. If the velocity of the particle is v ($=\beta c$, where c is the velocity of light in vacuo), and n is the refractive index of the medium, the particle travels a distance AB in a time Δt, given by $AB = \beta c \cdot \Delta t$; in the same time the radiation, emitted at A, travels a distance $AC = (c/n)\Delta t$, from which we obtain the Čerenkov relation:

$$\cos\theta = (1/\beta n) \qquad (1)$$

From Eq. (1) it is at once evident that there is a threshold velocity given by $\beta = (1/n)$, below which no radiation takes place. At ultrarelativistic velocities, as $\beta \to 1$, the Čerenkov angle θ tends to a maximum value $\theta(\max) = \cos^{-1}(1/n)$. The polarization vectors E and H of the radiation which, owing to symmetry, takes place over the surface of a cone, are shown in Fig. 2(b).

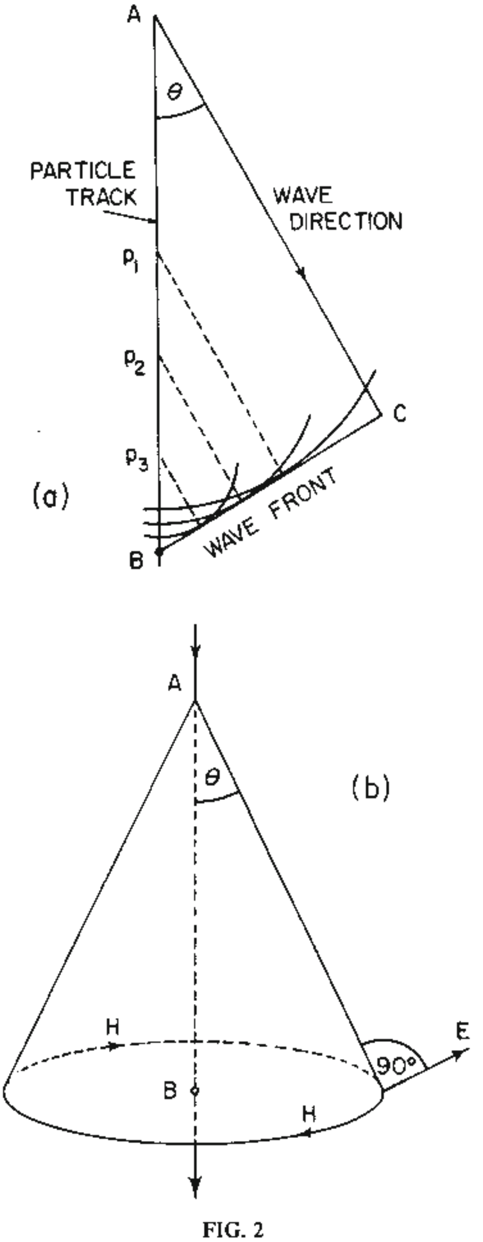

FIG. 2

The radiation yield, from the theory of Frank and Tamm, is

$$\frac{dW}{dz} = \frac{e^2}{c^2}\int_{\beta n > 1}\left[1 - \frac{1}{\beta^2 n^2}\right]\omega \cdot d\omega, \text{ ergs/cm path} \qquad (2a)$$

or

$$\frac{dN}{dz} = 2\pi\left(\frac{e^2}{hc}\right)\cdot\left[\frac{1}{\lambda_2} - \frac{1}{\lambda_1}\right]\cdot \sin^2\theta \quad \text{photons/cm path} \qquad (2b)$$

between wavelength limits λ_1 and λ_2 (in cm). The spectral distribution is $(dW/d\omega) \propto \omega$ or $(dW/d\lambda) \propto \lambda^{-3}$, expressed as energy per unit circular frequency or per unit wavelength, respectively. The radiation has, therefore, a continuous spectrum toward the blue and ultraviolet. There is no radiation in the x-ray region, for which $n < 1$. For example, in the case of a fast electron in water, $n = 1.33$, we find from Eq. (2b), that when $\beta \to 1$ and $\theta(\max) = 41°$, the yield (dN/dz) is ~ 200 photons/cm, between λ_1 and λ_2 of 3500 and 5500Å, respectively.

Before elaborating on the many applications of the effect, we will first trace a few of the theoretical developments following the original classical theory of Frank and Tamm,[2] which applied to isotropic transparent media, and which neglected quantum effects. A quantum treatment of the effect, which shortly followed,[3] revealed results which deviated slightly from those obtained by the classical treatment. These deviations in the threshold condition and in the angular and intensity distributions of the emitted light were, however, extremely small, as one might have expected, since $\hbar\omega \ll E$, where E is the kinetic energy of the particle; e.g., $\hbar\omega$ would be $\sim$3 eV for blue light, while E would be typically $\sim$MeV.

There followed, in the forties and fifties, a spate of theoretical papers, mostly in Russian journals, extending the general theory to many specialized cases. These are too numerous to discuss in detail, but some of them will be mentioned in passing. If the medium is anisotropic (e.g., a crystal), or optically active, the threshold condition, angular distribution, intensity distribution, and especially the polarization characteristics of the radiation, depend in a complex way on the relationship of the direction of the path of the particle relative to the orientation of the crystal axes (anisotropic media), or the axis of gyration (optically active media).

Much work was also devoted to cases in which the fast-moving single-point charge is replaced by one which also carries a magnetic moment, and to cases in which the moving particle is either an electric or magnetic dipole; continuing further, work was also carried out on the radiation caused by the motion of multipoles and oscillators through the medium. In the latter case, below the normal Čerenkov threshold, a straightforward Doppler effect is observed, while above the threshold, a "complex" Doppler effect occurs, but not truly related to Čerenkov radiation.

Another case of some interest, one which occurs mainly in the UV part of the spectrum, is the region of anomalous dispersion, where one meets a "complex" index of refraction; in this case the Čerenkov spectrum deviates from the smooth λ^{-3} law, above, and is broken up into bands which occur in those regions where the real part of the dielectric constant $\epsilon > \beta^{-2}$.

Most of these theoretical problems mentioned so far, apply to transparent media and to the optical region of the spectrum.

It was early realized, however, that Čerenkov radiation could also be expected to occur in ferrites (both isotropic and anisotropic), having a permeability μ, under the same conditions of threshold, i.e., $n = \beta^{-1}$, where n in this case is $(\epsilon\mu)^{1/2}$. This can occur in the microwave and radio-frequency regions of the spectrum. In these cases, referring back to Fig. 1, it is only necessary that the distance between a point S and the track of the particle shall be $<\lambda$, so that, in the microwave region of the spectrum, the particle need not pass through the "body" of the medium, but can travel down a tunnel, eliminating the otherwise accompanying ionization losses. Some enhancement of the radiation, poor in this case, because of the λ^{-3} relation, can however be achieved, if it is possible to "bunch" the electrons. Loaded waveguides are also potential media for Čerenkov radiation.

We mention briefly three other associated effects, that radiation, in limited bands, can occur in a plasma, that there are various diffraction and scattering effects,[4] and that the phenomenon of Čerenkov radiation has a certain relationship with that of transition radiation.[5]

Much of what we have discussed above is of mostly academic interest as far as applications are concerned, though these topics lay the foundations for the many applications.

While a summary of the results of these theoretical studies will be found in Ref. 6, the most comprehensive review of these aspects of the phenomenon will be found in the work of Bolotovskii.[7]

At this stage let us discuss the situation in which the medium is a gas rather than a liquid or solid. Take air for instance. In this case, we have $n = 1.000293$, $\theta_{\max} = 1.3°$, $E_{\min}$(electrons) = 21 MeV, and $dN/dl = 0.3$ photons cm^{-1} path.

These energy yields, both in gases and even in solids and liquids, are extremely small, relative to the ionization energy losses, which amount to ~2 MeV gm^{-1} cm^{-2} for relativistic particles. However, while the energy yields in Čerenkov radiation are small compared with the ionization losses, the emitted photons, having energies ~2–3 eV, are so numerous, and light detectors such as photomultipliers so efficient, that it is possible to utilize the effect in many branches of high-energy nuclear and cosmic-ray physics.

Let us now turn to the experimental and application aspects of the phenomenon of Čerenkov radiation. While the early experiments carried out by Čerenkov himself were based on relatively strong radioactive sources and used the photographic technique, the first detection of *single* charged particles in a liquid is attributed to the writer,[8] as is the first detection of the Čerenkov light from single cosmic-ray particles in air,[9] in conjunction with a colleague.

While most of the theoretical work on the topic has been carried out in the USSR, it would appear that the West has contributed by far the larger fraction of the work on the experimental side.

The phenomenon has found considerable application in the fields of high-energy and nuclear physics, and in cosmic-ray research. The unique directional and threshold properties of the radiation may be used in a number of different ways. For example, by velocity selection, it is possible to distinguish between particles of different mass having the same energy, and it is also possible to measure particle velocities directly, by measuring θ. Other examples may be cited: The e^2 dependence, Eq. (2) above, has been used to determine the charge spectrum of the primary cosmic rays, and transparent lead-loaded glasses have been developed as total absorption spectrometers for high-energy γ-rays.

Reference 6 contains a review of some of the early types of Čerenkov detector, while Refs. 10 and 11 cover somewhat later developments.

More recently, developments have taken place in very sophisticated detectors, especially ring-imaging systems based on gaseous media which have proved to be especially valuable in high-energy particle physics.[12,13]

Čerenkov radiation in the atmosphere produced by cosmic-ray showers from ultra-high-energy primary particles[14] has become a most valuable tool in high-energy γ-ray astronomy. This in fact provides the only tool, and it is ground-based, for searching for point sources of γ-rays in the energy region 10^{11}–10^{13} eV.[15,16]

A further application of Čerenkov radiation is the search for neutrinos of cosmic origin in seawater, in a deep ocean trench off the island of Hawaii, a project known as DUMAND (*D*eep *U*nderwater *M*uon and *N*eutrino *D*etector),[17] the volume of water involved in this detector being ~1 km^3. A somewhat similar type of experiment is likewise under investiagation in attempt to observe the decay of the proton.[18]

Three further aspects of the phenomenon will also be made in passing: (1) the application of the effect to produce extremely weak standard light sources for testing astronomical equipment;[19] (2) the interpretation of a particular type of radio emission from sunspots;[20] and (3) the inverse Čerenkov effect,[21] proposed as a way of accelerating charged particles.

By contrast, there have been two applications in biological areas. One of these is that flashes of light observed by astronauts involved in the NASA Apollo program during periods of translunar flight have been attributed, partially or possibly totally, to Čerenkov radiation produced by primary cosmic rays of relatively high nuclear charge traversing the retinas of the eyes of the astronauts on these missions.[22]

And finally we mention that there is evidence[23] that Čerenkov radiation may be a contributing or even dominant effect in the repair mechanism by photoreactivation of the DNA in the bacterium *Esherichia coli* subsequent to damage by ionizing radiation.

CHEMICAL KINETICS

Besides offering useful rate equations to describe the speeds of chemical reactions, chemical kinetics attempts to describe exactly how each reaction occurs. It does so in terms of one or more elementary steps, which are reactions having no observable intermediate chemical species. The ultimate goal is a theory interrelating energy, structure, and time for these single chemical events. Many of the ideas, developed since 1850 when the first quantitative rate study was made, have been extended by analogy to explain electron-hole processes in semiconductors, various solid-state processes, and thermonuclear reactions.

Reaction rates depend on the nature of the reactants, temperature, pressure, kind and intensity of radiation, nature of catalyst or solvent, and many other factors. The extent of a reaction can be followed by withdrawal of samples for early chemical analysis. It is more common, however, to analyze the main reaction mixture continuously and nondestructively by spectroscopic means or by observing physical properties like density, electrical conductivity, optical activity, dielectric constant, and so on.

The rate v of a reaction $a\mathrm{A} + b\mathrm{B} \rightarrow e\mathrm{E} + f\mathrm{F}$ is best related to the rate of change of the concentrations [A] and [B] of reactants by rewriting the equation as $0 = e\mathrm{E} + f\mathrm{F} - a\mathrm{A} - b\mathrm{B}$. If the change is an elementary step, its rate is

$$v = -\frac{1}{a}\frac{d[\mathrm{A}]}{dt} = -\frac{1}{b}\frac{d[\mathrm{B}]}{dt} = +\frac{1}{e}\frac{d[\mathrm{E}]}{dt} = +\frac{1}{f}\frac{d[\mathrm{F}]}{dt} = k[\mathrm{A}]^a[\mathrm{B}]^b$$

Here k is a rate constant independent of concentration. If the step is not elementary, its rate is often presumed to be expressible as proportional to certain empirically observed powers $m, n, \cdots$ of the concentrations of species present in the reaction vessel. The values of m, $n, \cdots$ need not be integers and cannot be predicted from the balanced chemical equation if the step is not elementary. The over-all order of a reaction is the sum of these exponents, and the order with respect to a particular species is its own exponent. The order of a reaction can be determined in several ways. In the method of initial rates, concentrations of all but one reactant are held constant, if possible at great values, and v is observed at the start of reaction for several values of [A]. The order with respect to A is the slope of a graph of log v vs. log [A].

The first major reaction rate theory was founded on the kinetic theory and classical mechanics. It still is very useful when reactants approach each other in an attractive potential field (e.g., ions), when the distribution of energies is nonequilibrium (e.g., electrical discharge in gases), or when the molecules involved are tremendous in size. In general, however, the collision theory suffers from its inability to satisfactorily predict effective cross sections (molecular sizes for reaction) or the effect of isotopic substitution.

Most modern theories suppose the existence of an undetectable transition state of high energy and fleeting existence. The configuration of this activated complex lies, as it were, atop the mountain pass of lowest height between energy-valleys of reactants and products. It is mechanically stable to all vibrations except the one that describes the progress of reaction over the saddle-point at the pass. This one motion is assigned a very low (sometimes imaginary) frequency, but otherwise the activated complex is just another molecule. It is supposed to be in dynamic equilibrium with reactants and its free energy can be calculated from its partition function by the usual methods of STATISTICAL MECHANICS. The rate constant k_n then takes the form $(kT/h)\exp(-\Delta A/kT)$ where k is the gas constant per molecule, T is the absolute temperature, h is Planck's constant, and ΔA is the increase in free energy on going from reactants to activated state. This resembles the well-known relation $k_n = s\exp(-E/kT)$ discovered empirically in 1889 by Arrhenius. In it, s and E are approximately independent of T, and E is called the activation energy.

A recent theory of promise treats reactants as a wave packet that gradually spreads in time. The rate of reaction is taken to be the probability that the packet will be found in a configuration that is indentified with products.

Thermal decomposition of an initially pure gas is seemingly a simple change, yet its order often changes gradually from first to second as the pressure falls. Moreover, there is always the question why like molecules do not all decay at once. The answers lie in understanding the mechanism, which is presently taken to be collision with any other molecule M ($0 = A^* + M - M - A$ with rate constant k_2') to yield an energized molecule A* that may suffer a stabilizing collision ($0 = A + M - M - A^*$, with k_2) or internal change ($0 = A^\ddagger - A^*$, with k_1) that leads to the activated state A‡. The reaction is called unimolecular because the activated complex A‡ contains only one reactant molecule. The rate of decomposition of A at any instant is $v = k_2'[M][A] - k_2[M][A^*]$, and the rate of decomposition of A* is $v^* = k_1\,[A^*] - k_2'[M][A] + k_2[M][A^*]$. Since the v's are time derivatives, these are simultaneous differential equations.

It is generally impossible to solve the simultaneous differential equations that describe a mechanism. The least restrictive and most useful simplification is generally the steady-state approximation, wherein the concentration of a species of low concentration is assumed to reach an effectively constant value after a certain reasonable time (induction period) has passed. If [A*] reaches a steady-state concentration, $v^* \simeq 0$ and the v^* differential equation becomes an algebraic one for [A*]. Moreover, the rate of decomposition of A then is $v = k_1[A^*] = k_1k_2'[M][A](k_1 + k_2[M])^{-1}$. This rate equation becomes second order if $k_2[M] \ll k_1$; this occurs at low pressure or when A* changes rapidly into A‡. If A is a simple molecule of few atoms, the activation energy easily becomes effective in one bond to cause decay. On the other hand, the order becomes first if $k_2[M] \gg k_1$; this corresponds to high pressure or an A with many degrees of freedom to accommodate the activation energy.

A generally more restrictive way to simplify the mathematics of a sequence of reactions is to assume that one step is so much slower than the others that it alone limits the rate. All steps besides the rate-limiting one are assumed to be at equilibrium in this approximation. If, in unimolecular decomposition, the rate-limiting step is $A^* \rightarrow A^\ddagger$, then the rate is $k_1[A^*]$. The reaction is then first order in A because $v = 0$ for the equilibrium $A + M = M + A^*$. If, however, the rate-limiting step is $A + M \rightarrow A^* + M$, then the rate is $k_2'[M][A]$.

Bimolecular reactions, wherein the activated state consists of two reactant species, are very common. The rates of the fastest of these are limited by the rates of diffusion of reactants and have rate constants of the order of 10^{10} liter mole^{-1} sec^{-1} in aqueous solution. Typical examples are the aqueous neutralizations $NH_4^+ + H_2O \rightarrow NH_3 + H_3O^+$ and $H_3O^+ + F^- \rightarrow HF + H_2O$. Typical bimolecular gaseous reactions are the linear chain reactions $X + H_2 \rightarrow HX + H$ and $H + X_2 \rightarrow HX + X$ where X is H, D, Cl, Br, or I. A nice way to initiate these reactions of H_2 and X_2 is by a photon: X_2 + photon $\rightarrow X + X$. Thermal dissociation of X_2 is also sufficient to start reaction.

Carbon compounds undergo many reactions, but most of them can be classified into a few types. Nucleophilic substitution, wherein a basic reactant replaces another initially on C by a net reaction $X + RY \rightarrow XR + Y$, may be first order in RY alone or in both X and RY. If first order in just RY, the mechanism is labeled S_N1 and the rate-limiting step is conceived as production of the active carbonium ion R^+ by the process $RY \rightarrow R^+ + Y^-$. If second order (S_N2), the rate-limiting step is considered to be production of the bimolecular activated complex $X \cdots R \cdots Y$. Elimination reactions typically yield a double bond with loss of part of the organic reactant RCH_2CH_2Y. If first order in organic reactant (type E_1), the rate-limiting step is said to be production of the carbonium ion $RCH_2CH_2^+$, which then swiftly eliminates H^+ to become $RCH=CH_2$. If first order in both base and organic reactant (type E_2), the rate-limiting step is thought of as production of a bimolecular complex which eliminates H^+ and Y^- almost simultaneously. A fifth class of organic reaction (S_Ni) describes how an electrophilic reagent (e.g., NO_2^+ in mixed HNO_3 and H_2SO_4 or Br^+ in Br_2 with $FeBr_3$) may attack an aromatic ring like that in benzene to form a positively charged intermediate that soon loses H^+ to a base in the solution.

A catalyst is a species that changes the rate of a reaction and yet is regenerated by that reaction so that it seems to be unchanged in the net reaction. Catalysts do not affect the equilibrium state but they do lower the activation energy and sometimes may provide a needed steric arrangement. The most general mechanism of catalysis is $A + C_1 \rightarrow D + C_2$ followed by $B + C_2 \rightarrow E + C_1$ to give the net change $A + B \rightarrow D + E$. Many so-called catalysts of industry need regeneration ($C_2 \rightarrow C_1$) by a reaction other than that catalyzed. For example, silica-alumina cracking catalysts used in making gasoline must be cyclically burned free of carbon deposited during cracking. A catalyzed reaction is almost always first order in catalyst concentration (or surface area) and usually has an order that is less than the true order by unity.

Enzymes are biological catalysts. Many act by the well-known Michaelis-Menten mechanism $E + S \rightleftarrows C \rightarrow P + E$, where enzyme E attacks substrate S with a rate $k_A[E][S]$ to form a complex C that may yield products P at a rate $k_P[C]$ or may revert to S with rate $k_R[C]$. The rate of disappearance of S is $v_S = k_A[E][S] - k_R[C]$ and the rate of appearance of C or disappearance of E is $v_E = k_A[E][S] - k_R[C] - k_P[C]$. The total concentration of enzyme in the system is $[E]_0 = [C] + [E]$. In the steady state, $v_E = 0 = k_A([E]_0 - [C])[S] - (k_R + k_P)[C]$ so that

$$v_S = k_P[C] = \frac{k_P k_A [S][E]_0}{(k_R + k_P) + k_A[S]}.$$

The rate of disappearance of S is always first order in total enzyme but may change from first to zero order in S as [S] increases. The maximum rate at which E can act occurs when [S] is great and $v_S = k_P[E]_0$.

Much industrial research is devoted to finding catalysts which speed (or slow) specific desired (or undesired) reactions. Academic research on rates tends, however, to search for mechanisms and to propose models useful for prediction. Very fast reactions are of particular interest and they offer several kinds of challenge to experimenters. If a decrease in temperature does not affect the mechanism, a very fast reaction can perhaps be slowed to fit the response time of the analytical devices in use. Typically for analysis in real time one uses visible and ultraviolet spectrometers or a mass spectrometer. If a reaction is fast, the reactants must be mixed in a time very short relative to the time of the reaction; for times less than a millisecond, reactants are generally mixed before reaction, which is later initiated by a pulse of pressure or radiation (e.g., flash photolysis) or introduction of a catalyst. Or, instead of working in real time, a reaction may be maintained in a steady state (e.g., a flame) with concentrations noted as a function of position, with of course some direct link between position and time. For reactions that occur in a time of the order of 10^{-3} sec, typical experimental methods are: nuclear magnetic resonance, sudden changes in pressure or temperature, flash photolysis, shock waves, and various methods of controlling flow. For reactions done in 10^{-6} sec, one has: electric field displacement, ultrasonic methods, electron paramagnetic resonance, dielectric relaxation, and pulsed radiolysis. A few special techniques (e.g., fluorescence quenching) are useful at 10^{-9} sec. In liquid solution, the rate of a fast reaction may be independent of the nature of the reactants and become, instead, a function of liquid viscosity, with a temperature coefficient appropriate to viscosity's change with temperature. Rate of reaction is thus controlled by diffusion; for this, the activation energy of the chemical change seldom exceeds about 20 kJ per mole.

Very fast gaseous reactions and their mechanisms are often studied by crossing molecular beams in a vacuum. A heated reservoir with small hole allows molecules to effuse (ca. 10^{-7} torr). A beam is defined by slits or orifices, and a selection of velocities is then made by rotating sectors in the beam, which at the start contains the usual Boltzmann distribution of velocities. For easier detection, a much more intense beam of high-energy molecules can be made by fluid flow through a supersonic nozzle, but extremely rapid pumping is needed to maintain the necessary vacuum. The simplest collision in crossed molecular beams is "elastic," with momentum and translation energy conserved by whole molecules. Inelastic collision modifies their internal energies. Reactive scattering of beam by beam involves a transfer of atoms during an encounter. To link the results of such scattering to a bulk reaction rate, one must average properly over angles, energies, and so on. While typical reactive collisons in gases occur at distances of the order of (or less than) 100 Å, certain other reactions involving a preliminary transfer of an electron may occur at distances of the order of 200 Å. These last are rather poetically called "harpooning."

CHEMICAL PHYSICS

Chemical Physics is a term used to describe a rather broad set of research activities that fall on the borderline between the traditional disciplines of chemistry and physics. As with all interdisciplinary endeavors, it is difficult to arrive at a precise definition of chemical physics that is generally acceptable to the practioners of the field and that remains meaningful over an extended period of time. In particular, the distinction between chemical physics and physical chemistry is rather arbitrary, depending more on the background and training of the individual conducting the work than on the nature of the work itself. Many universities have a curriculum option that requires formal training in both chemistry and physics departments. The graduates of such programs tend to think of themselves as chemical physicists; others, who have a primarily chemistry background, may identify themselves as physical chemists even though their research is very similar.

Chemical physics did not emerge as an identifiable research field until well into the twentieth century. The atomistic approach to chemistry was introduced by Dalton and others at the start of the nineteenth century, and important contributions were made by physicists such as Avogadro. However, the lack of a detailed model for the atom and molecule made it impossible to relate the microscopic structure of matter to macroscopic behavior. Thus, physics and chemistry pursued their own evolutionary development through most of the nineteenth century, with rather limited interaction.

These paths began to intersect at the turn of the century: J. Willard Gibbs, a professor of mathematical physics, developed a powerful tool for chemists in the form of statistical mechanics; Peter Debye created detailed physical models that explained the properties of electrolyte solutions in terms of forces between electrically charged particles; William and Lawrence Bragg developed x-ray techniques for determining the structure of crystals, which opened the chemistry of solids to detailed investigation for the first time; Niels Bohr recognized that the theory which explained atomic spectra should also permit a physical explanation of the periodic table of the elements. With the advent of quantum mechanics in the 1925–30 period, physics and chemistry were drawn so closely together that there was no longer a definable boundary. Quantum mechanics provided for the first time a quantitative theory capable of explaining the forces between atoms that lead to the formation of molecules. During a remarkably prolific period the foundations were laid for a detailed understanding of molecular structure, the kinetics of chemical reactions, the relation of thermodynamic properties to structure, the interaction of light with matter, and many other subjects of long-standing importance in chemistry.

Another important factor was the development by physicists of instruments that allowed chemical phenomena to be probed in new ways. Infrared and mass spectrometers were used successfully by chemists in the 1930s, and the postwar period saw the introduction of more and more sophisticated instrumentation—microwave, nuclear magnetic resonance, electron spin resonance, and Mössbauer spectrometers, to name only a few. More recently, the laser has opened many new avenues for chemical research. In a pattern which has been repeated many times, a new instrumental technique is developed by physicists, applied first to problems of current interest in physics (usually involving atoms or simple molecules), and then adapted by chemists to study larger molecules and more complex chemical phenomena.

The birth of chemical physics as an identifiable research field can perhaps be dated from the establishment of *The Journal of Chemical Physics* in 1933. The driving force for this event was the rapid increase in research papers, resulting from the new theoretical and experimental tools described above, which could not be accommodated by the traditional journals of either physics or chemistry. More than any other single measure, the contents of this journal have defined the scope of chemical physics. More recent journals and publication series using the term *chemical physics* in the title have tended to adopt the same scope and emphasis as *The Journal of Chemical Physics*.

It is therefore instructive to analyze the contents of *The Journal of Chemical Physics*. The articles appearing in the journal are currently sorted into five categories, which are listed below along with the approximate distribution of papers in early 1982:

Spectroscopy and light scattering	35%
Molecular interactions and reactions, scattering, photochemistry	22%
Statistical mechanics and thermodynamics	20%
Quantum chemistry, theoretical electronic and molecular structure	18%
Polymers, surfaces, and general chemical physics	5%

Titles of papers on spectroscopy show emphasis on topics such as laser-induced fluorescence, double resonance, and other techniques that permit measurement of the fine details of molecular structure. Studies of energy distribution in molecules, ionization processes, and reaction kinetics as determined by molecular beam experiments are prevalent in the second category. The application of statistical mechanics to the understanding of phase transitions and critical phenomena is now an active topic. Papers in quantum chemistry range from diatomic molecules to complex aromatics but stress the calculation of the full range of molecular properties, not only energy levels and stability. The relatively small number of papers classified as surface physics is somewhat misleading, in view of the growing interest of chemical physicists in this area of research. The explanation probably lies in the existence of a number of competing journals.

Another measure of the topics currently emphasized in chemical physics research is provided by a 1981 survey of members of the Division of Chemical Physics of the American Physical Society. This division has a membership of about 2,800, which gives a rough idea of the number of scientists in the United States who regard themselves as chemical physicists. The areas of special interest were ranked as follows in the survey:

Spectroscopy and light scattering
Molecular interactions and reactions
Photochemistry
Surfaces
Statistical mechanics and thermodynamics
Scattering processes
Polymers

Here the importance of surface science is more evident.

In recent years the overlap between chemical physics and solid state (condensed matter) physics has become stronger. A number of ideas derived from the chemist's traditional approach to bonding have been introduced into solid state physics. Likewise, the distinction between atomic physics, which in the past focused on interactions between electrons, photons, and atoms, and the part of chemical physics that deals with molecular interactions and reactions has become blurred. There is also a trend toward a closer relation between chemical physics and biophysics.

In summary, chemical physics is a research area of somewhat diffuse and fluid boundaries which is characterized by use of the theoretical and experimental tools from physics to further the understanding of phenomena of interest to chemistry. It bridges the gap between two historically different approaches to natural science, whose distinction is gradually disappearing.

CHEMISTRY

Chemistry is the branch of natural science that is concerned with the nature, composition, and structure of matter. The chemist attempts to provide a consistent model of the macroscopic behavior of materials in molecular terms. Because of the focus on the behavior of matter, chemistry is in a central position in the array of natural sciences and has strong interdisciplinary ties to both physics and biology. In fact the core of conceptual models of chemistry is familiar to the physicist and includes primarily quantum mechanics and thermodynamics.

The drive to understand matter at the molecular level has lead the chemist to follow the age old goal of transformation of matter both at the molecular and, more recently, the atomic level. In this field man is able to synthesize new combinations of elements, substances and materials. Actually, chemists have created in the laboratory several chemical elements (43, 61, 87, and 93 to 105 inclusive) that apparently are not normally present in or on our planet. Even a cursory examination of the concept of isomerism (the existence of two or more different compounds that have identical compositions) yields the conclusion that literally trillions and trillions of different compounds of carbon could be synthesized. In fact, there are possible at least 62×10^{12} different compounds (called isomers) all having an identical composition indicated by the formula $C_{40}H_{82}$. This specific combination of atoms is just one of millions of other possible combinations, and some of these would have thousands of isomers. The current chemical literature contains documented evidence for either the existence, or the synthesis by man, of well over a million different compounds of carbon. And carbon is only one of the 105 known chemical elements.

As with most areas of science, the explosive growth of chemical knowledge in the twentieth century, particularly since the Second World War, has lead to the development of several subdisciplines of chemistry. The four main areas which are generally recognized are analytical, inorganic, organic, and physical chemistry. Interfacial areas bridging the natural sciences range from medicinal and biochemistry to geochemistry, astrochemistry, theoretical chemistry, and chemical physics.

A unique and important factor associated with chemistry is the existence of a strong industrial connection. The chemical industry is one of the major components in the economy of any developed nation. The continually increasing need for commodities such as structural materials, fabrics, fertilizers, pesticides, and pharmaceuticals will enhance the chemical industry. The consumption of sulfuric acid, for instance, has for several decades been considered a significant indication of general industrial activity. This strong academic/industrial link is shown in the development of various subdisciplines such as polymer and industrial chemistry.

Historical Background The history of alchemy is a fascinating record of man's earliest investigations of matter. However, the mixture of rational and mystic approaches hampered significant progress. Consequently, it was not until the rationalist eighteenth century that the serious origins of chemistry developed. Robert Boyle and Antoine Lavoisier, two of the earliest proponents of exact quantitative experimentation, exerted profound influences on late eighteenth and early nineteenth century chemistry. Their techniques were mainly physical measurements.

Around the middle of the nineteenth century, Friedrich Kekulé and Archibald Couper independently proposed a system for writing graphic formulas for chemical compounds. Their concepts were based apparently on the notion that physical forces held together the atoms in compounds. About the same time, general acceptance was finally accorded Amedeo Avogadro's hypothesis (proposed about 50 years earlier) which stated that equal volumes of gases at the same temperature and pressure contain equal numbers of molecules. The importance of the establishment of a direct link between observable and molecular scale behavior contained in Avogadro's hypothesis cannot be overestimated.

In addition to this interest in conceptual models, considerable activity revolved about phenomenological models. These studies culminated in the development of the periodic table of the elements by Mendeleev. In this scheme regularities in the chemical and physical behavior are organized and provided a powerful predictive tool for the discovery of new elements, compounds, and physical properties.

During the period 1860–1920, the first great period of synthesis of new compounds occurred. Both organic and to a lesser degree inorganic chemistry flourished, and hundreds of compounds were prepared, correctly analyzed and identified, and logically classified as to structure and reactivity. And yet, throughout this period, chemists had no knowledge whatsoever about the structure and composition of atoms. Also they had a rather shallow conception of chemical bonding and molecular geometry. The growth of organic chemistry during the nineteenth century is an epic example of the productivity of sound inductive and deductive reasoning.

As was the case with physics, the quantum revolution in the early decades of the twentieth century had a profound effect on the direction and development of modern chemistry. Although the influence of quantum theory is pervasive throughout chemistry there are three particularity significant cases which bear mentioning. The organization of elements in the periodic table is directly correlated to electronic configurations hence establishing electronic structure as the basis of chemical behavior. Due to the pioneering efforts of Lewis, Pauling, and others, quantum theory provides a basis for both a qualitative and quantitative understanding of the chemical bond. The explosive growth of various forms of atomic and molecular spectroscopy which accompanied the development of quantum theory has added a significant battery of methodologies which are available for modern chemical research. These techniques have proven invaluable both in the measurement of amounts of materials present in a given sample and in the elucidation of molecular structure. Types of spectroscopic measurements include: atomic absorption/emission, ultraviolet, photoelectron, fluorescence, infrared, microwave, nuclear magnetic resonance, electron spin resonance, nuclear quadrupole resonance, and Mössbauer. The last mentioned technique is an interesting example of the rapidity of information transfer between physics and chemistry in that within a few years after Mössbauer's discovery of the effect, it had become a significant tool for investigation of the geometric and electronic structure of iron and tin compounds. Other, nonspectroscopic, physical methods are also of importance. In particular, one can cite mass spectrometry, which is of value in the determination of molecular structure and the study of isotope masses and diffraction methods (x-ray and electron) for the determination of geometrical structure.

During and following World War II there was considerable investigation of the transuranic elements and of technetium, francium, and promethium in relation to their production and use. All these radioactive elements were produced by extraordinary nuclear reactions, whereas all ordinary chemical reactions involve only the electrons outside the nucleus. Ordinary chemical reactions are, in a sense, extranuclear.

The utilization of chromatographic techniques such as column, paper, thin-layer, vapor phase (gas), and high performance liquid chromatography has allowed chemists to effect the separation of the components of complex mixtures. The use of ion exchange in the resolution of ionic mixtures and in the removal of ions from solutions has been extended during the past twenty years.

The applications of the molecular orbital and ligand-field concepts have been highly successful in the description of the bonding in and geometry of complex molecules. These concepts have firm physical bases.

Chemists, like most scientists, take a special delight in doing experiments that are considered to be theoretically impossible; consequently the discovery in 1962 by Bartlett of a stable compound of xenon, $Xe^+(PtF_6)^-$, was an epic event. Since the discovery of the noble gases during the period 1894–1900, most chemists had assumed or believed that these elements were chemically inert. Therefore, Bartlett's discovery prompted much activity to produce other noble gas compounds.

The importance of chemistry in modern biology, and especially in medicine, has been reemphasized by knowledge of the role of the nucleic acids, such as DNA and RNA, in the genetic scheme. The increased use of chemotherapy in medicine is common knowledge.

Analytical Chemistry The qualitative and quantiative determination of elemental composition of matter resides in the branch of chemistry called analytical chemistry. Any means of determining molecular structure is often called an analytical technique. Until relatively recently most analyses were performed by using specific chemical reactions and techniques in liquid solutions. Recent advances in spectroscopy and other physical techniques have yielded a variety of instruments that greatly facilitate chemical analyses. The ability of the analytical chemist to measure trace quantities of materials has played a central role in the development of awareness of the hazards of environment pollution.

Biochemistry Investigations of the chemical phenomena in, and the constituent compounds of, living organisms are performed mainly by biochemists. Because every chemical reaction in any living organism involves compounds of carbon, biochemistry is in part the application of organic chemistry to investigations of vital systems. However, physical and analytical and more recently inorganic chemistry are essential to biochemistry.

Inorganic Chemistry This branch of chemistry is mainly that of all forms of noncarbon compounds. Although its potential scope is huge, it has attracted, until recently, much less attention than have organic and physical chemistry. The availability of sophisticated physical methods have made detailed knowledge of inorganic materials possible. The very breath of this subdiscipline has lead to the existence of several interdisciplinary activities. The most important of these are organometallic chemistry, in which one studies carbon derivatives of the elements, and bioinorganic chemistry, which focuses on the role of inorganic species, especially metal ions, in biological systems.

Organic Chemistry This division of chemistry is essentially that of the compounds of carbon. Originally organic chemistry was confined to materials in or from living organisms, probably because nearly every compound either isolated from or produced by a living organism is a compound of carbon. Although there are more compounds of hydrogen than of any other element, the compounds of carbon are next in line. The property of catenation (ability of identical atoms to bond together) is exhibited most extensively by carbon. The hundreds of different carbon-atom skeletons of the thousands of known organic compounds attest this fact. All foods, nearly every fabric, every ordinary commercial fuel, and almost all pharmaceuticals are organic in the sense that they contain compounds of carbon. The great tradition of syntheses of new compounds has developed to an art form in modern organic chemistry. One now can prepare structures ranging from highly symmetrical geometric forms to huge, complex naturally occurring molecules such as vitamin B-12.

Physical Chemistry The quantitative measurements of the properties and behavior of the elements and their compounds are the major concern of the physical chemist. Nearly every technique and concept has been adopted from physics. The development of new chemical concepts follows logical consideration of quantitative data. The major branches of physical chemistry are spectroscopy, nuclear chemistry, kinetics, thermodynamics, quantum and statistical mechanics, and solution and surface chemistry. Physical organic and inorganic chemistry have gained prominence during the past 25 years. The availability of modern high speed computers has allowed for the application of the methods of quantum chemistry to molecules of increasing size and complexity. Calculations are usually divided into ab initio and semiempirical methods, the latter having a higher degree of presupposition and/or parameters derived from experimental data.

There are certain discernable trends in the current direction of chemical research which are worth noting. The first of these is the increasing tendency of interdisciplinary activities between subdisciplines. The most prominent of these include bioinorganic, bioorganic, physical inorganic, physical organic, and organometallic chemistry. On a larger scale, joint programs involving chemistry, physics, and engineering may be found in the rapidly increasing number of material sciences programs. One should also note the pervasive utilization of analytical instrumentation in virtually all areas ranging from synthetic organic to experimental physical chemistry. In similar fashion, methods traditionally associated with physical chemistry, such as X-ray diffraction and molecular orbital calculations, are now extensively used by inorganic and organic chemists. There has also been a strong interest in chemistry related to industrial processes giving rise to continued growth not only of polymer chemistry but also the study of catalysis and surface chemistry.

CIRCUITRY

Basic Concepts An electric circuit may be defined as a path or group of interconnected paths capable of carrying an electric current or an arrangement of one or more closed paths to accommodate an electron flow. Electrons bear ***electric charges***, and the unit of electric charge is the coulomb, defined as the quantity of charge possessed by 6.24×10^{18} electrons, and the electrical ***through variable*** is the ***current***. The unit of current is the ampere, defined as the flow of one coulomb (6.24×10^{18} electrons) per second (1 ampere = 1 coulomb/sec).

The passage of a current through a ***circuit element*** yields a change of potential designated as the ***voltage drop*** or ***voltage*** (in volts) and convention dictates that in passive elements such as resistance R, inductance L, capacitance C, short circuits and open circuits, the current flow ***through*** the element is the direction of voltage drop or voltage ***across*** the element. In source elements such as ideal voltage sources and ideal current sources, the current flow is in the direction of the voltage rise across the source. The use of the words ***through*** with regard to current and ***across*** with regard to voltage may be observed.

Three types of equations are used in the analysis and synthesis of electrical circuits. These are the continuity, compatability and elemental equations. A continuity equation is a relationship among through variables, and in the electrical case this is the *Kirchhoff Current Law:* The algebraic sum of the currents entering a point (node) in an electrical circuit (network) must be zero ($\sum i = 0$). A compatability equation is a relationship among across variables, and in the electrical case, this is the *Kirchhoff Voltage Law:* The algebraic sum of the voltage drops around a closed path (loop) in an electrical circuit (network) must be zero ($\sum \Delta v = 0$). It is to be noted that in applying the Kirchhoff Laws, currents flowing ***away*** from a point are treated as a negative current flowing ***toward*** the point and negative voltage ***drops*** within a path are treated as voltage ***rises***.

Elemental Equations The third type of equation is the elemental equation which is a relationship between the through and across variables for a particular element. For the cases of R, L and C, the elemental equations are

$$v = Ri; \quad i = v/R = Gv \tag{1}$$

which is known as *Ohm's Law* and where it is to be noted that $G = 1/R$,

$$v = L\frac{di}{dt}; \quad i = \frac{1}{L}\int i\,dt \tag{2}$$

and

$$i = C\,\frac{dv}{dt}; \qquad v = \frac{1}{C}\int v\,dt. \tag{3}$$

Equations (1), (2), and (3) demand that the elements be *linear*, that is, they possess an output (either i or v) that is in direct proportion to the input (either i, v, di/dt or dv/dt) which shows that R, L, and C may be viewed as simple proportionality constants. Equations (1), (2), and (3) may also be derived experimentally or by an interpretation of electromagnetic field phenomena.

For the case of the short circuit

$$i = i; \qquad \Delta v = 0 \tag{4}$$

which states that a short circuit passes all of the current with no voltage drop and for the open circuit

$$i = 0; \qquad \Delta v = v \tag{5}$$

which states that an open circuit possesses the impressed voltage but passes no current.

Circuit Connections Circuit elements may be connected in *series* in which they are connected in such a manner as to provide a single path for the flow of current or in *parallel* in which they are connected so as to provide a division of current among the elements. It is apparent that in series circuits, the Kirchhoff Voltage Law must prevail and in parallel circuits, the Kirchhoff Current Law must apply to the element connection points. Equivalent single values of R, L, and C may be determined (R_{eq}, L_{eq} and C_{eq}) where for the series circuit

$$R_{\text{eq}} = \sum_{i=1}^{m} R_i; \qquad L_{\text{eq}} = \sum_{j=1}^{n} L_j; \qquad C_{\text{eq}} = \frac{1}{\displaystyle\sum_{k=1}^{p} \frac{1}{C_k}} \tag{6}$$

and for the parallel circuit

$$R_{\text{eq}} = \frac{1}{\displaystyle\sum_{i=1}^{m} \frac{1}{R_i}}; \qquad L_{\text{eq}} = \frac{1}{\displaystyle\sum_{j=1}^{n} \frac{1}{L_j}}; \qquad C_{\text{eq}} = \sum_{k=1}^{p} C_k. \tag{7}$$

It is useful to define a quantity called the *impedance to exponentials* or merely the *impedance* as the ratio of an exponential voltage, $v = Ve^{st}$ to an exponential current $i = Ie^{st}$. With the *admittance to exponentials* taken as the reciprocal of impedance, Eqs. (1), (2), and (3) can be used to show that, for R, L, and C,

$$Z_R(s) = R; \qquad Y_R(s) = 1/R = G \tag{8}$$

$$Z_L(s) = Ls; \qquad Y_L(s) = 1/Ls \tag{9}$$

$$Z_C(s) = 1/Cs; \qquad Y_C(s) = Cs. \tag{10}$$

Then if a *direct current (d-c) voltage* $v = v(s = 0)$ is applied $Z_R(0) = R$, $Z_L(0) = 0$, $Z_C(0) = \infty$ and $Y_R(0) = 1/R = G$, $Y_L(0) = \infty$ and $Y_C(0) = 0$. If an *alternating current (a-c) voltage* is applied, Euler's equations can be used to show that $s = j\omega$ ($j = \sqrt{-1}$) and $Z_R(j\omega) = R$, $Z_L(j\omega) = j\omega L = jX_L$, $Z_C(j\omega) = -j(1/\omega C) = -jX_C$, $Y_R(j\omega) = 1/R = G$, $Y_L(j\omega) = -j(1/\omega L)$ and $Y_C(j\omega) = j\omega C$. In the foregoing X_L and X_C are respectively called the *inductive reactance* and the *capacitive reactance*.

The Kirchhoff Laws can be employed to yield the familiar voltage and current divider relationships. For n impedances in series with an applied voltage $V_{\text{in}}(s)$, the voltage drop *across* the ith impedance is given by the *voltage divider relationship*

$$\Delta V_i(s) = \frac{Z_i(s)}{\displaystyle\sum_{k=i}^{n} Z_k(s)}\, V_{\text{in}}(s), \qquad k = 1, 2, 3, \ldots, i, \ldots, n. \tag{11}$$

In similar fashion, for n admittances in parallel (recall that $Y(s) = 1/Z(s)$) with an applied current $I_{\text{in}}(s)$, the current *through* the ith admittance is given by the *current divider relationship*

$$I_i(s) = \frac{Y_i(s)}{\displaystyle\sum_{k=1}^{n} Y_k(s)}\, I_{\text{in}}(s), \qquad k = 1, 2, 3, \ldots, i, \ldots, n. \tag{12}$$

Circuit Analysis Electrical circuit or network analysis involves the determination of unknown currents or voltage drops when the circuit is specified and subjected to a forcing function. For a particular quantity of interest such as the current through a series connection of circuit elements when subjected to a voltage forcing function, the response is composed of a transient and a steady state response. For example, consider the connection of a resistor, capacitor, inductor and a switch all in series with a voltage source $v_{\text{in}}(t)$. Kirchhoff's Voltage Law can be employed to yield the integro-differential equation

$$L\,\frac{di}{dt} + Ri + \frac{1}{C}\int i\,dt = v_{\text{in}}(t) \tag{13}$$

where it is presumed that the switch closes at $t = 0$. The *total response* is given by

$$i(t) = i_c(t) + i_p(t)$$

where $i_c(t)$ is the *complementary function* (also termed the *natural* or *transient response*) and $i_p(t)$ is the *particular integral* (known also as the *forced* or *steady state response*).

The complementary function derives from the assumption of an exponential solution, $i(t) = Ie^{st}$ and its substitution into the *homogeneous* integro-differential equation yields

$$L \frac{di_c}{dt} + Ri_c + \frac{1}{C} \int i_c \, dt = 0$$

which leads to the factored and algebraically adjusted auxiliary equation

$$L \frac{s^2 + \frac{R}{L} s + \frac{1}{LC}}{s} Ie^{st} = 0.$$

Here it is observed that because $I = 0$ or $e^{st} = 0$ will yield trivial solutions

$$s^2 + \frac{R}{L} s + \frac{1}{LC} = 0.$$

With $\alpha = R/2L$ and $\omega_n{}^2 = 1/LC$, this equation becomes the simple quadratic

$$s^2 + 2\alpha s + \omega_n{}^2 = 0$$

with two solutions for the exponent s in the assumed $i_c(t) = Ie^{st}$,

$$s_1, s_2 = -\alpha \pm \sqrt{\alpha^2 - \omega_n{}^2}.$$

The form of the response is dictated by the discriminant $\alpha^2 - \omega_n{}^2 = \omega_d{}^2$. If $\alpha > \omega_n$, then ω_d is positive and s_1 and s_2 are both negative, real, and distinct. The complementary solution will be a pair of exponentials, each with an arbitrary constant of integration

$$i_c(t) = I_1 e^{(-\alpha + \omega_d)t} + I_2 e^{(-\alpha - \omega_d)t} \qquad (14)$$

which is the *overdamped* case.

If $\alpha = \omega_n$, then s_1 and s_2 are negative, real and equal. In this case $s_1 = s_2 = s = -\alpha$ and the solution will be given by

$$i_c(t) = I_1 e^{-\alpha t} + I_2 te^{-\alpha t}. \qquad (15)$$

This is the *critically damped* case.

If $\alpha < \omega_n$, then $\alpha^2 - \omega_n{}^2$ is negative and $s_1 = -\alpha + j\omega_d$ and $s_2 - \alpha - j\omega_d$, a pair of complex conjugate roots with negative real parts. A damped oscillation occurs

$$i_c(t) = e^{-\alpha t}(I_1 \cos \omega_d t + I_2 \sin \omega_d t) \text{ (16a)}$$

which may be written in terms of a sinusoidal function and a phase angle

$$i_c(t) = Ie^{-\alpha t} \cos (\omega_d t + \sigma) \qquad \text{(16b)}$$

or

$$i_c(t) = Ie^{-\alpha t} \sin (\omega_d t + \phi). \qquad \text{(16c)}$$

Any of the oscillating forms of (16) describe the *underdamped* case.

The particular integral of Eq. (13) may be found by standard methods such as undetermined coefficients or variation of parameters. The complete general response is then the sum of $i_c(t)$ and $i_p(t)$ and the arbitrary constants in $i_c(t)$ are evaluated after this sum is taken from two different initial conditions to form the particular response.

Other Methods Other methods for analysis of the complete response are in frequent use. One of these is the method of *Fourier analysis*, which is useful when the circuit is subjected to a periodic input. The input function is represented as a *Fourier series*. Because the circuit is linear, the principle of *superposition* (the total response to the total stimulus is equal to the sum of individual responses due to individual stimuli acting alone) permits the response to be evaluated from a term-by-term solution summation from the individual terms of the input Fourier series.

Fourier analysis may be extended beyond Fourier series to first the *Fourier integral*, then to the *Fourier transform*, and finally to the *Laplace transform*. This permits the entire analysis to be conducted algebraically in the complex frequency domain instead of on a differential equation basis in the time domain via the Laplace transform of $f(t)$:

$$\mathcal{L}[f(t)] = F(s) = \int_0^\infty f(t) e^{-st} \, dt \qquad (17)$$

where $s = \alpha + j\omega$, a complex frequency.

Finally, by making use of the idealization of the *unit impulse* defined as a pulse of unbounded magnitude acting over an infinitesimal time period so that its behavior is not defined by its magnitude but by its behavior under integration

$$\int_{0^-}^{0^+} \delta(t) \, dt = 1 \qquad (18)$$

one can employ the *Faltung* or *convolution integral* (or simply the convolution of two functions)

$$r(t) = \int_0^t f_1(t - \tau) r_2(\tau) \, d\tau \qquad (19)$$

where $f_1(t)$ is the actual input function, $r_2(t)$ is the circuit response to the unit impulse function, $r(t)$ is the actual circuit response, and τ is a dummy variable of integration. This procedure is known as *Borel's Theorem*.

Steady State a-c and d-c Analysis The concepts of circuit impedance and admittance permit a direct analysis of the steady state condition. The simplest possible case is that of the *ladder network* in which every element current or voltage can be determined from any or all of the following: the two Kirchhoff Laws, voltage or current dividers, and systematic combination of impedances (admittances) in series or parallel.

When the network possesses loops in the graph theoretical sense, the method of *loop* (*mesh*) *analysis* to yield loop currents or *node analysis* to yield node-to-datum voltages can be used. Both of these methods involve systematic application of one of the Kirchhoff Laws to each loop or node (loops and nodes are evident from the *topology* of the circuit)—the voltage law for loop analysis and the current law for node analysis. The inevitable result is a set of *n* simultaneous, linear (and linearly independent) algebraic loop or node equations which are easily solved by several methods.

For certain networks, the *superposition theorem* (discussed above) or the network theorems of *Thévenin* (also *Helmholtz*) and *Norton* may be employed to advantage. The Thévenin and Norton Theorems permit calculation of the performance of a portion of the circuit (possibly a single circuit element) from the terminal properties of the rest of the network.

Nonlinear Circuits and Circuits with Time-Varying Elements Analysis of circuits with nonlinear and time-varying elements poses a problem that is substantially more difficult than the analysis of their linear counterparts. For nonlinear elements such as the *pn* junction diode or tunnel diode (resistors), the varactor diode (capacitor), and the common inductor driven to flux saturation by large currents, analysis can be conducted using perturbation techniques or by successive small signal approximations.

Examples of time-varying elements are the potentiometer or rheostat (resistor) and the moving plate capacitor used in communications systems for tuning. Analysis of circuits with such elements requires a valid mathematical model of the element variation. For example, for a resistor which is time varying, Eq. (13) becomes

$$L\,\frac{di}{dt} + R(t)i + \frac{1}{C}\int i\,dt = v_{\text{in}}(t) \qquad (20)$$

and the degree of analysis difficulty will depend on the form of $R(t)$.

Microelectronics and Microelectronic Circuitry Microelectronics, as the prefix *micro* implies, pertains to the area of technology that is associated with the fabrication of and operation of circuits, devices and systems (and subsystems) utilizing extremely small components. Four technologies are in widespread use:

Thin-film hybrid circuits consist of conductor, dielectric, and resistor materials which are deposited on glass, ceramic, or crystalline substrates by evaporation, sputtering or electroplating. The form of the deposition is obtained by patterning through photoengraving, or by printing through a mask. In this technology, semiconductors, monolithic circuits, capacitors, and inductors can also be added consistent with the device function.

Thick-film hybrid circuits consist of conductor, dielectric, and resistor patterns which are screen printed on ceramic substrates. Miniature components such as monolithic integrated circuits, semiconductor devices, capacitors, inductors, and transformers are then added after the basic circuitry patterns are formed.

Monolithic bipolar circuits consist of bipolar junction and monopolar junction field-effect transistors, Schottky diodes, junction diodes, resistors and capacitors formed by oxidation, diffusion, ion-implantation, chemical vapor deposition and photoengraving on and perhaps within a single crystal semiconductor substrate. Interconnection is accomplished through the use of thin film circuitry.

Monolithic metal-oxide-semiconductors (MOS) consist of MOS field-effect transistors, capacitors, conductors and resistors which are formed by oxidation, diffusion, photoengraving, chemical vapor deposition, thin-film deposition, and ion-implantation on and within a single-crystal semiconductor or substrate.

COHERENCE

Basic Definitions The term coherence as it is used in electromagnetic radiation studies is best explained by a discussion of Young's interference experiment. Referring to Fig. 1, we consider a self-luminous radiating source S (like a mercury arc lamp) placed a distance l_1 from an opaque screen A. In the screen A two pinhole openings P_1 and P_2 are made a distance d apart. The radiation passing through the pinholes impinges upon and is recorded upon a photographic plate B a distance l_2 from screen A.

If l_1 is a very large distance from A (say $l_1 \gg bd/\lambda$, λ being the average radiation wavelength) and the spectral width of the radiation is made very narrow by filtering, then the fringes observed on B in the neighborhood of O will be very sharp, and we say that the radiation fields impinging *upon* P_1 and P_2 are very coherent. This is in accord with our usual notions about the radiation from a point source. If, on the other hand, we use the same source and l_1 is taken to be small (say of the order of b) and the dimension b is large compared to d then fringes will not be observed on B, and we say that the radiation fields impinging *upon* P_1 and P_2 are incoherent. Again this is to be expected

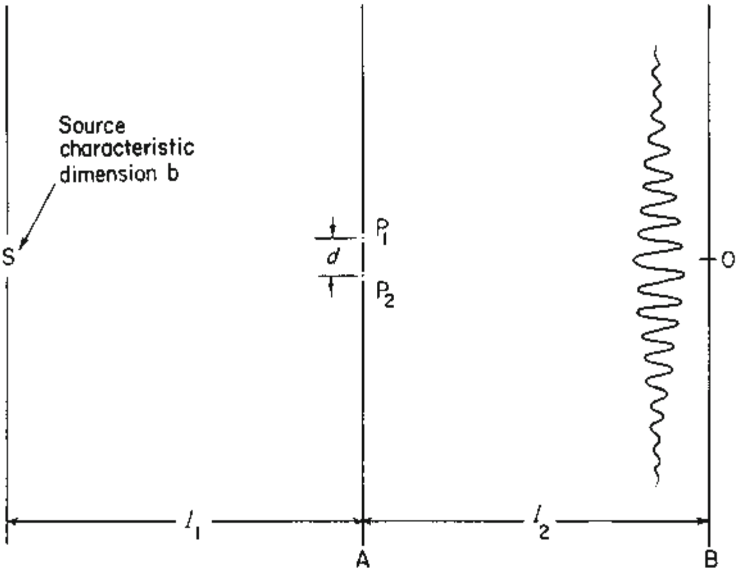

FIG. 1. Young's interference experiment.

since in this case we observe the radiation just as it emerges from the lamp. As the distance l_1 is increased from the order of b, faint fringes will begin to appear upon B. As l_1 increases, the fringes will become progressively stronger until they become very pronounced when $l_1 \gg bd/\bar{\lambda}$. The intermediate states, when the fringes are present but not necessarily very strong, are termed states of partial coherence. This experiment may be performed using a variety of sources. The experiment, as we have emphasized, measures the coherence of the radiation when it reaches P_1 and P_2; it does not measure the coherence of the source.

A quantitative measure of the fringe strength called the visibility $\mathcal{V}$, was given by Michelson.[7] It is defined as

$$\mathcal{V} = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \qquad (1)$$

where $I_{\max}$ is the maximum intensity recorded in the vicinity of O and $I_{\min}$ is the minimum intensity. $\mathcal{V}$ varies between 0 and 1 and, roughly, we term radiation fields at two points coherent when $\mathcal{V} = 1$ (strong fringes) and incoherent (no fringes) when $\mathcal{V} = 0$.

In the above introduction, d was held fixed but it is most important to realize that the fringe visibility at O is a function of the spacing d and that $\mathcal{V}$ may be close to 1 for one spacing of d and close to zero for another spacing of d. For example, if we fix l_1, we will generally decrease the visibility of fringes at O by making d larger (more precisely it will decrease and then increase in a succession of oscillations with the successive peaks being reduced in magnitude.) The visibility may thus be viewed as a measure of the correlation (coherence) between the radiation at P_1 and the radiation at P_2. To give a more precise definition of coherence, Wolf[9] considered the correlation function $\Gamma(P_1, P_2, \tau)$, commonly termed the mutual coherence function, defined as

$$\Gamma(P_1, P_2, \tau) = \langle V(P_1, t + \tau) V^*(P_2, t) \rangle \quad (2)$$

where $V(P_1, t)$ is the radiation field at P_1 and time $t + \tau$ (in a scalar approximation), V^* is the radiation field at P_2 at time t and the brackets $\langle\,\rangle$ denote a time average. For convenience Wolf used a complex notation (V^* is the complex conjugate of V), but this need not concern us here.

It can be shown that the magnitude of the normalized form of $\Gamma(P_1, P_2, \tau)$, $\gamma(P_1, P_2, \tau)$, where

$$\gamma(P_1, P_2, \tau) = \frac{\Gamma(P_1, P_2, \tau)}{\sqrt{\Gamma(P_1, P_1, 0)\Gamma(P_2, P_2, 0)}} \quad (3)$$

is equal to the visibility $\mathcal{V}$ when the radiation is quasi-monochromatic (narrow spectral width) and all path lengths in the problem are small compared to $c/\Delta\upsilon$ (where c is the velocity of light and $\Delta\upsilon$ is a characteristic spectral spread). In this case it is appropriate to fix τ at some value τ_0 usually taken to be zero.

The definition given by Eq. (2) was intended to consider polychromatic fields in addition to the quasi-monochromatic fields so often studied using the visibility $\mathcal{V}$. Beran and Parrent[1] have shown that the full function $\Gamma(P_1, P_2, \tau)$ is, in principle, measurable by an extension of the techniques used in a Young's interference experiment. Modern discussions of coherence now center on the calculation and measurement of the mutual coherence function $\Gamma(P_1, P_2, \tau)$. For calculation it is convenient to note that Wolf[9] has shown that $\Gamma(P_1, P_2, \tau)$ satisfies the pair of wave equations

$$\nabla_i^2 \Gamma(P_1, P_2, \tau) = \frac{1}{c^2} \frac{\partial^2 \Gamma(P_1, P_2, \tau)}{\partial \tau^2} \quad (i = 1, 2) \quad (4)$$

The vector properties of the electromagnetic field may easily be introduced into the mutual coherence function. In general one must consider the tensor

$$\mathcal{E}_{ij}(P_1, P_2, \tau) = \langle E_i(P_1, t + \tau) E_j^*(P_2, t) \rangle \quad (5)$$

where $E_k(P_s, t)$ is the kth component of the electric field at the space point P_s and time t. In general, this function has proved most useful in the study of polarization effects for fields in which the radiation has a principal direction of propagation. The form of $\mathcal{E}_{ij}(P_1, P_2, \tau)$ has, however, been derived for the radiation in a black body cavity.

The above considerations have been for radiation fields that are stationary in time. That is, the statistical parameters, as opposed to the detailed structure of the radiation field, are independent of the absolute scale of time. For fields in which this is not true we must introduce the concept of an ensemble average (similar to that used in statistical mechanics). The mutual coherence function $\mathcal{E}_{ij}(P_1, P_2, \tau)$ must be replaced by the function $\mathcal{E}_{ij}{}^E(P_1, t_1; P_2, t_2)$ defined as

$$\mathcal{E}_{ij}{}^E(P_1, t_1; P_2, t_2) = \overline{E_i(P_1, t_1) E_j(P_2, t_2)} \quad (6)$$

where the overbar denotes an average over an ensemble of systems.

Higher-order Coherence Functions and Quantum Aspects As the concept of coherence grew and the statistical formulation of the theory came more into the fore it was realized that a two-point moment like $\mathcal{E}_{ij}(P_1, P_2, \tau)$ or $\mathcal{E}_{ij}{}^E(P_1, t_1; P_2, t_2)$ was inadequate to completely describe the radiation field. Two fields could have the same mutual coherence function and yet differ in the statistical content of the field. To completely describe the field, it was necessary to consider higher-order moments like $L_{ijkl}(P_1, t_1; P_2, t_2; P_3, t_3; P_4, t_4)$ defined as

$$L_{ijkl}(P_1, t_1; P_2, t_2; P_3, t_3; P_4, t_4) =$$

$$E_i(P_1, t_1)\overline{E_j(P_2, t_2) E_k(P_3, t_3) E_l(P_4, t_4)} \quad (7)$$

and, in fact, for a complete description it was necessary to consider the probability density function $P[E_i(P_1, t_1)]$ defined roughly as the probability of the occurrence of a particular realization of the field.

There are a number of problems that require consideration of higher-order moments. These moments are necessary in intensity interferometry, the study of laser radiation and the study of the radiation from turbulent gases. The measurement of the contracted fourth-order moment

$$R_{ik}(P_1, P_2, 0) = \langle |E_i(P_1, t)|^2 |E_k(P_2, t)|^2 \rangle \quad (8)$$

(called intensity interferometry) has received considerable attention since it entailed consideration of the quantum aspects of the electromagnetic field. This moment may be thought of as the correlation of instantaneous intensities

$$I_i(P_1, t) \equiv |E_i(P_1, t)|^2$$

at two points and was originally studied as an alternate method to the measurement of $\Gamma(P_1, P_2, 0)$ for determining the angular diameter of visible and radio stars.[4,5] In measuring $\Gamma(P_1, P_2, 0)$, we may use the Young's interference experiment described above; the quantum nature of the field rarely explicitly enters since averaging times are usually long enough to permit a classical analysis. To measure R_{ik}, however, we need to correlate the two signals $I_i(P_1, t)$ and $I_k(P_2, t)$ which are recorded using photomultipliers or coincidence counters. Since the relationship between the impinging electric field and the ejected photoelectron is a statistical one, classical considerations did not suffice for a deep understanding of the problem or for consideration of the very important signal-to-noise problems resulting from inadequate averaging times.

A quantum field formalism for coherence theory has been studied by a number of authors. References 6 and 14 summarize and reference most of the basic work. Optical correlation phenomena have been studied extensively and particular consideration has been given to the fundamental differences between laser light and thermal light. Laser models have been developed using coherence concepts. In addition it is possible to study the basic interaction between light and matter from a coherence point of view. For example, the Kramers-Heisenberg dispersion formula may be generalized to include the effects of partially coherent incident electromagnetic fields, and spontaneous radiation may be studied when the initial atomic states are correlated.

Applications (Measurement of the Angular Diameter of Stars) Coherence theory is of great use in the treatment of imaging and mapping problems. It is especially convenient for treating problems involving the effects of the turbulent atmosphere on resolution and acoustic scattering in the ocean.[2,10,11] Radiometry has also been studied using coherence theory.[12,13] To present the reader with a definite example of the use of the coherence theory formalism, we will conclude this brief discussion with an outline of the measurement of the angular diameter of visible stars.

Let us suppose that the source in Fig. 1 is a visible star so that l_1 is many light-years. There is no telescope big enough to resolve any star, and to make direct measurements of the angular diameter of a star, Michelson introduced the use of interference experiments to essentially give one a bigger effective aperture.

For purposes of visible star measurement we can replace the star of diameter D by a circular disk of diameter D lying in a plane parallel to A. The radiation leaving the star is assumed to be incoherent so that for all points on the disk we may take $\Gamma(P_1, P_2, 0) = c\delta(P_1 - P_2)$. Using Eq. (4) this allows us to solve for $\Gamma(P_1, P_2, 0)$ on the earth (screen A) if we filter the starlight to insure the validity of the quasi-monochromatic approximation. We find

$$\Gamma(P_1, P_2, 0) = \text{const.}\ \frac{J_1\left[\dfrac{\bar{k}dD/2}{l_1}\right]}{\dfrac{\bar{k}dD/2}{l_1}} \tag{10}$$

where $\bar{k}$ is the average wave number of the light and J_1 is a first-order Bessel function.

If we define the angular diameter of the star as $\theta = D/l_1$, we see that J_1 equals zero when $\theta = 1.22\bar{\lambda}/d$, where $\bar{\lambda} = 2\pi/\bar{k}$. When J_1 equals zero, there are no fringes on the screen B. Hence to find the angular diameter of the star, we need only increase d from zero, when there will be high contrast fringes, to the separation d when there are no fringes. Putting this latter value into our expression for θ gives us the angular diameter of the star. The effects of turbulence may be taken into account in this problem if Eq. (4) is generalized to include a variable index of refraction.

COLLISIONS OF PARTICLES

Introduction Scattering experiments provide the principal technique by which physicists attempt to understand the structure and interactions of matter on a microscopic scale. Scattering theory provides the basis of analyzing and interpreting scattering experiments. Other applications are the scattering of acoustic waves by sonar systems and electromagnetic waves by radar systems. Detailed descriptions of scattering theory are available in several references.[1,2,3,4]

A description of the development of scattering theory may be divided into several topics. The oldest and simplest branch of scattering theory is that of potential scattering, or scattering of two particles which interact through a local potential.[1] Potential scattering was studied extensively in the first two decades following the development of quantum mechanics in the analysis of elastic scattering of particles by atoms and of nucleon-nucleon scattering. The latter topic, in particular, led to the introduction of an elaborate theory of scattering by noncentral interactions.[5] The development of nuclear physics, with the observation of resonance reactions, indicated the need for more general descriptions of scattering. The resulting theory of resonance reactions[6,7] has leaned only rather lightly on the details of the Schödinger equation. Quantum field theory was developed to describe electromagnetic phenomena.[8] Of major importance in the development of scattering theory was the introduction of renormalization techniques into FIELD THEORY.[9]

It might be claimed that modern scattering theory began with the integral equation formulation of Lippmann and Schwinger[10] and the introduction of S-matrix theory by Heisenberg[11] and others.[12] This work has stimulated much of the development of theoretical physics in the last two decades. Of particular significance are the clarification of the study of rearrangement collisions and the development of the so-called dispersion techniques and current S-matrix formalism.

The Scattering Cross Section The properties of scattering interactions are usually expressed most conveniently in terms of the *scattering cross section*. To define this term, we consider the following scattering experiment: A beam of particles (called *beam particles*) is directed on a scatterer consisting of *target particles*. As a result of collisions between beam and target particles, there are particles which emerge from the reactions (called *reaction products*) and these are detected in *particle detectors*. To describe this quantitatively, we suppose that the scatterer contains N_t target particles and that this is uniformly illuminated by a flux F_B (expressed as the number of beam particles per unit area per unit time arriving at the target) of beam particles. We suppose also that the scatterer is sufficiently small that the beam is negligibly attenuated in passing through it. Then, if there are δN_s scattering interactions per unit time which lead to detected particles, we define the scattering cross section $\delta\sigma$ as

$$\delta\sigma = \frac{\delta N_s}{N_t F_B} \tag{1}$$

In the limit that the detectors subtend very small solid angles, as seen from the target, we define the differential scattering cross section $d\sigma$. When a single detector subtending a solid angle $\delta\Omega$ is used to define $\delta\sigma$, we may define the cross section per unit solid angle as

$$\frac{d\sigma}{d\Omega} = \lim_{\delta\Omega\to 0} \frac{\delta\sigma}{\delta\Omega} \tag{2}$$

The total scattering cross section σ is obtained by summing $\delta\sigma$ over all scattering events:

$$\sigma = \sum \delta\sigma \tag{3}$$

(Eq. (3) does not exist for scattering by a coulomb force).

The scattering cross section may be expressed in terms of the square of the magnitude of a scattering amplitude (or S-matrix, or $\mathfrak{T}$ = matrix element) and is completely described as a function of the momenta and internal states of the particles in the initial and final states. Thus, for the two particles prior to collision[13] we may take the momenta $\mathbf{p}_1$ and $\mathbf{p}_2$ and the internal state quantum numbers s_1 and s_2 as variables. (For example, s_1 and s_2 may describe spin orientation, isotopic spin, etc. For colliding molecules these variables will describe vibrational, rotational and electronic states). We may suppose there to be μ particles in the final state following the collision and specify this state by the momenta and internal variables $\mathbf{k}_1 \ldots \mathbf{k}_\mu, s_1' \ldots s_\mu'$. The scattering cross section may be expressed in terms of these variables. Because of symmetries, the number of variables required to describe $\delta\sigma$ may ordinarily be reduced. The most commonly encountered of these symmetries are: (1) energy and momentum conservation; (2) rotational invariance; (3) the Lorentz invariance of the scattering cross section $\delta\sigma$.

Energy and momentum conservation imply that $\delta\sigma$ contains the Lorentz invariant factor

$$\delta(\mathbf{P}' - \mathbf{P})\delta(E' - E),$$

where $\mathbf{P}$ and E are the respective initial total momentum and energy and the primed variables refer to the final state. The quantities δN_s and N_t in Eq. (1) represent integer numbers of particles and are thus Lorentz invariants. The beam flux F_B is also invariant under Lorentz transformations along the beam axis parallel to $\mathbf{p}_1$. For such transformations $\delta\sigma$ is therefore invariant. It is, in fact, customary to define $\delta\sigma$ to be invariant under an arbitrary Lorentz transformation. This will be the case if F_B in (1) is replaced by F_I, the value of F_B in the *laboratory* frame of reference (for which $\mathbf{p}_2 = 0$).

The particle detectors for which Eq. (1) is defined will ordinarily record events for a restricted domain of the final spins and momenta $s' \ldots \mathbf{k}_\mu$. From this and its Lorentz invariance we infer that $\delta\sigma$ is of the form

$$\delta\sigma = \sum_{s_1' \ldots s'} \int \frac{d^3k_1}{\epsilon_{k1}} \cdots \frac{d^3k_\mu}{\epsilon_{k\mu}} (\mathbf{P}' - \mathbf{P})\delta(E' - E)I. \tag{4}$$

Here ϵ_{k_1} is the energy of a particle with momentum $\mathbf{k}_1$ and integration is over the domain of detection. Since d^3k_1/ϵ_1 etc. are Lorentz invariant, we see that I must be a Lorentz invariant function of the momenta and spin variables.

We have noted that in the *laboratory* frame of reference the target particles are initially at rest, so $\mathbf{p}_2 = 0$. In the center-of-mass, or *barycentric*, frame of reference the total momentum is zero, so $\mathbf{p}_2 = -\mathbf{p}_1$.

Potential Scattering We briefly illustrate the discussion of the preceding section with the example of nonrelativistic scattering by a local central potential $V(r)$. The SCHRÖDINGER EQUATION for scattering in the barycentric coordinate system is[14]

$$[\nabla_r^2 + \kappa^2 - v(r)]\psi_\kappa^+(\mathbf{r}) = 0 \tag{5}$$

Here $\hbar\mathbf{K}$ is the momentum of particle "1" in the barycentric system and $v(r) = (2M_r/\hbar^2)V(r)$, with M_r the reduced mass of the two particles. In the limit of large separation $\mathbf{r}$ between the particles the wavefunction $\psi_\kappa{}^+$ has the asymptotic form [our notation is such that we represent a unit vector in the direction of $\mathbf{K}$ by $\hat{\mathbf{K}}$]

$$\psi_{\kappa}^{+}(\mathbf{r}) \rightarrow (2\pi)^{-3/2}\left[e^{i\kappa\cdot\mathbf{r}} + \frac{e^{i\kappa r}}{r} f(\hat{\kappa}\cdot\hat{\mathbf{r}})\right] \quad (6)$$

Here $f(\hat{\mathbf{K}}\cdot\hat{\mathbf{r}})$ is the scattering amplitude for scattering particle "1" from the direction $\hat{\kappa}$ into the direction $\hat{\mathbf{r}}$. The corresponding cross section per unit solid angle is

$$\frac{d\sigma}{d\Omega} = |f(\hat{\kappa}\cdot\hat{\mathbf{r}})|^2 \quad (7)$$

The wave function ψ_{κ}^{+} may be expanded into partial waves as follows:

$$\psi_{\kappa}^{+}(\mathbf{r}) = \sum_{l=0}^{\infty} \frac{(2l+1)}{4\pi\kappa r} P_l(\hat{\kappa}\cdot\hat{\mathbf{r}}) i^l e^{i\delta_l} w_l(\kappa; r) \quad (8)$$

Here P_l is the Legendre polynomial of order l, δ_l is the scattering phase shift [see Eq. (10) below], and $w_l(\kappa; r)$ satisfies the differential equation

$$\left[\frac{d^2}{dr^2} + \kappa^2 - \frac{l(l+1)}{r^2} - v(r)\right] w_l = 0 \quad (9)$$

This is to be integrated subject to the condition that w_l is regular at $r = 0$. For large r, w_l has the asymptotic form

$$w_l(\kappa; r) \rightarrow \sqrt{\frac{2}{\pi}} \sin\left(\kappa r - \frac{\pi l}{2} + \delta_l\right) \quad (10)$$

It is Eq. (10) which permits the determination of the phase shift δ_l. The quantity

$$S_l(\kappa) = \exp\left[2i\delta_l(\kappa)\right] \quad (11)$$

is an eigenvalue of Heisenberg's S-matrix.[11]

For scattering by noncentral forces, the potential $V(\mathbf{r}, S_1, S_2)$ is a function of $\mathbf{r}$ (and sometimes the orbital angular momentum operator) and the spin operators S_1 and S_2 of the two colliding particles (if either has no spin, we consider its spin operator to be zero). Spin eigenfunctions $u(\nu_1, \nu_2)$ may be introduced as depending on the orientations ν_1 and ν_2). Then the wave function $\psi_{\kappa,\nu_1,\nu_2}{}^{+}$ is to be labeled with the initial spin orientations ν_1 and ν_2. The asymptotic form corresponding to Eq. (6) is

$$\psi_{\kappa,\nu_1,\nu_2}{}^{+} \rightarrow (2\pi)^{-3/2}\Bigg[e^{i\kappa\cdot\mathbf{r}} u(\nu_1, \nu_2) + \frac{e^{i\kappa r}}{r} \sum_{\nu_1',\nu_2'} \langle \nu_1', \nu_2' | f(\hat{\kappa}, \hat{\mathbf{r}}) | \nu_1, \nu_2 \rangle u(\nu_1', \nu_2')\Bigg] \quad (12)$$

Here $\langle \nu_1', \nu_2' | f(\hat{\kappa}, \hat{\mathbf{r}}) | \nu_1 \nu_2 \rangle$ is the scattering amplitude for scattering to a final spin orientation ν_1, ν_2'. The cross section per unit solid angle is in this case

$$\frac{d\sigma}{d\Omega} = |\langle \nu_1', \nu_2' | f(\hat{\kappa}, \hat{\mathbf{r}}) | \nu_1, \nu_2 \rangle|^2 \quad (13)$$

For an unpolarized initial state, corresponding to a uniform mixture of the $(2S_1 + 1)(2S_2 + 1)$ spin states, the cross section for scattering particle "1" into the direction $\hat{\mathbf{r}}$ with any spin orientation is

$$\frac{d\bar{\sigma}}{d\Omega} = \frac{1}{(2S_1 + 1)(2S_2 + 1)} \times \sum_{\nu_1',\nu_2'} \sum_{\nu_1,\nu_2} |\langle \nu_1', \nu_2' | f | \nu_1, \nu_2 \rangle|^2 \quad (14)$$

where the sums extend over all spin orientations.

Following scattering by noncentral forces, the particles will in general have preferred spin orientations, or be polarized. When, for example, particle "1" has spin one-half with a spin operator σ_1, we define its polarization vector $\mathbf{P}(\nu_1, \nu_2)$ by the equation

$$\mathbf{P}(\nu_1, \nu_2) = \Bigg\{\sum_{\nu_1'',\nu_1',\nu_2'} [\langle \nu_1'', \nu_2' | f | \nu_1, \nu_2 \rangle]^* \times \langle \nu_1'' | \sigma_1 | \nu_1' \rangle \langle \nu_1', \nu_2' | f | \nu_1, \nu_2 \rangle\Bigg\} \times \Bigg\{\sum_{\nu_1',\nu_2'} |\langle \nu_1', \nu_2' | f | \nu_1, \nu_2 \rangle|^2\Bigg\}^{-1} \quad (15)$$

For an unpolarized initial state, the polarization is

$$\bar{\mathbf{P}} = \frac{1}{(2S_1 + 1)(2S_2 + 1)} \sum_{\nu_1,\nu_2} \mathbf{P}(\nu_1, \nu_2) \quad (16)$$

The study of polarization following scattering has provided an important tool for analyzing nuclear and elementary particle reaction.[15,16] In particular, the role of noncentral interactions in nucleon-nucleon scattering has been studied in great detail.[17]

Formal Scattering Theory To describe a general scattering reaction Lippmann and Schwinger[10,18] introduced a scattering matrix $\mathfrak{T}_{\mathrm{ba}}$ to describe scattering from an initial state χ_{a} to a final state χ_{b}.[18]

$$\mathfrak{T}_{\mathrm{ba}} = (\chi_{\mathrm{b}}, V\psi_{\mathrm{a}}{}^{+}) \quad (17)$$

where κ_{a^+} is the steady-state wave function for the event and V is the scattering interaction. Since momentum is conserved for an isolated scattering, we may write

$$\mathfrak{T}_{\mathrm{ba}} = \delta(\mathbf{P}_{\mathrm{b}} - \mathbf{P}_{\mathrm{a}}) T_{\mathrm{ba}} \quad (18)$$

where $\mathbf{P}_{\mathrm{a}}$ and $\mathbf{P}_{\mathrm{b}}$ are the total momenta of the particles in the initial and final states, respectively, and T_{ba} is defined only for states b and a corresponding to $\mathbf{P}_{\mathrm{b}} = \mathbf{P}_{\mathrm{a}}$.

The scattering cross section $\delta\sigma$ [Eq. (1)] is expressed in terms of T_{ba} as

$$\delta\sigma = \frac{(2\pi)^4}{v_{\mathrm{rel}}} \sum_{\mathrm{b}} \delta(\mathbf{P}_{\mathrm{b}} - \mathbf{P}_{\mathrm{a}})\delta)(E_{\mathrm{b}} - E_{\mathrm{a}})|T_{\mathrm{ba}}|^2 \tag{19}$$

Here v_{rel} is the relative velocity of beam and target particles, E_{b} and E_{a} are the respective total energies of the particles in states b and a, and the sum on b extends over those states which lead to the reaction products striking the detectors and thus to register an event. We emphasize that Eq. (19) is Lorentz invariant and conforms to the general structure of Eq. (4).

The Heisenberg S-matrix[11] is given by the expression

$$S_{\mathrm{ba}} = \delta_{\mathrm{ba}} - 2\pi i\delta(E_{\mathrm{b}} - E_{\mathrm{a}})\,\mathcal{T}_{\mathrm{ba}} \tag{20}$$

where δ_{ba} is a Dirac δ-function. The S-matrix is unitary, so

$$\sum_{\mathrm{b}} S_{\mathrm{cb}}{}^{\dagger} S_{\mathrm{ba}} = \delta_{\mathrm{ca}} \tag{21}$$

On substituting Eq. (20) into this, we obtain the equivalent expression of unitarity

$$i[\mathcal{T}_{\mathrm{ca}} - \mathcal{T}_{\mathrm{ca}}{}^{\dagger}\} = 2\pi \sum_{\mathrm{b}} \mathcal{T}_{\mathrm{cb}}{}^{\dagger}\delta(E_{\mathrm{b}} - E_{\mathrm{a}})\,\mathcal{T}_{\mathrm{ba}} \tag{22}$$

which is defined only for states c and a on the same energy shell (corresponding to $E_{\mathrm{c}} = E_{\mathrm{a}}$).

The fundamental problem of scattering theory is to determine the $\mathcal{T}$-matrix on the energy shell (or, equivalently, the S-matrix). The first step in doing this is to make use of general symmetry principles (such as Lorentz invariance) to limit the functional forms allowed. Following this a dynamical principle is needed. Such dynamical principles (reviewed in Chapters 5 and 10 of Ref. 2) have been proposed in a great variety of forms including integral equations, variational principles and conditions of functional analyticity.

Scattering from Composite Systems Scattering from systems composed of two or more particles is generally very complex. This is in part due to the occurrence of sequential interactions, in part due to the dynamics of the scattering system, and in part due to the possibility of rearrangement phenomena.

Description of sequential interactions can be given in terms of the multiple scattering and optical model equations.[19]

Rearrangement collisions (i.e., collisions in which bound particles rearrange themselves) have been studied extensively following the development of formal scattering theory. Much of the early work[20] was stimulated by the observance of apparent paradoxes. Later work has tended to be directed toward specific applications. The formulation of Fesbach, for example, has led to a variety of applications in nuclear and atomic physics.[21] The eikonal approximation has been used in the description of rearrangement collisions of slow ions, atoms, and molecules.[22]

The careful description of three-body scattering given by Fadeev[23] has led to active study of this and related phenomena.[24]

Variational principles have also been developed for application to several body collisions.[25]

Field Theory Quantum field theory was originally developed to describe electromagnetic phenomena. It was applied in a promising context during the 1930s to β-decay and to the meson theory of nuclear forces. The great optimism following the development of renormalization theory[9] faded for want of adequate mathematical techniques for handling strong interactions. Semiphenomenological calculations of Chew and others[26] gave useful insight into the strong interaction phenomena. Heisenberg suggested in 1946[11] that a proper quantum theory of scattering would deal with only observable quantities such as the S-matrix and should not require off-the-energy-shell matrix elements of such quantities as $\mathcal{T}$ [Eq. (18)]. Considerable impetus for this point of view has been given by the development of dispersion theory, following early suggestions of Wigner and others.[27] The first attempt at a systematic formulation of a dispersion relation within the context of quantum field theory was made by Gell-Mann, Goldberger, and Thirring.[28] Further development followed applications of formal scattering theory to quantum field theory.[29] The development of the Mandelstam representation[30] provided an important step toward obtaining a "dynamical principle." A further important step was the proposal by Chew and Frautschi[31] and Blankenbecler and Goldberger,[32] who suggested that the only sinularities of the S-matrix are those required by the unitarity condition [Eq. (22)] and that families of particles should be associated with Regge Trajectories.[33]

Considerable impetus was given to the application of quantum field theories by the development of gauge theories of weak interactions, following a model of Yang and Mills.[34,35] Quantum chromodynamics, an $SU(3)$ gauge theory, has provided insight into the "strong" particle interaction scattering phenomena.[36]

COLLOIDS, THERMODYNAMICS OF

All colloids can be physically described by agglomerates of microparacrystals (mpc's). Their size depends on the paracrystalline lattice distortions (see MICROPARACRYSTALS and MICROPARACRYSTALS, EQUILIBRIUM STATE OF). Within each microparacrystal the distortion energy U at the boundaries reaches such high values that the netplanes are destroyed because the angles of the valence bonds are overstrained. Figure 1 shows schematically an atom and its valence bond in unstrained position; hence $r = 0$ has a minimum potential ΔU. ΔU increases with the square of the deviation r from the undistorted position. Averaging over all atoms one obtains for ΔU a value proportional to $\overline{r^2}$. In the case of microparacrystals this value is proportional to the number n of netplanes (see

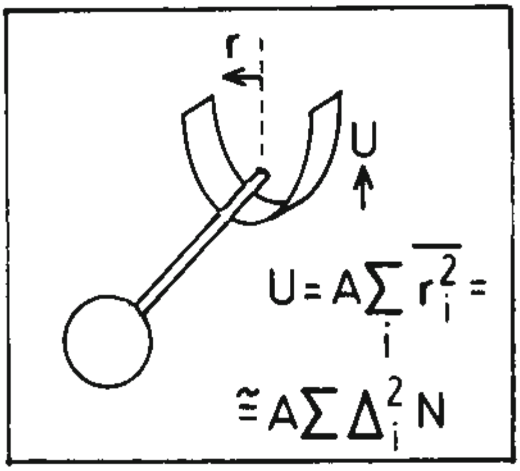

FIG. 1. Atom with one of its valence bonds to a neighboring atom and its potential U which depends on the value r by straining the valence angle.

MICROPARACRYSTALS, EQUILIBRIUM STATE OF), hence $\Delta U = \sum_i A r_i^2 = 2AN^2 \int_0^{N/2} n\Delta_1^2 = A_0 N^4 g^2/4$, where $\Delta_1^2 = g^2 \bar{d}^2$ is the distance variance between adjacent netplanes: $\Delta U \sim A_0 g^2 N$. The free energy ΔG of a cubic microparacrystal now contains, in addition to the well known terms of the surface free energy σ and the volume enthalpy ΔG_v (which are proportional to N^2 and N^3, respectively), a third term proportion to N^4:

$$\Delta G = \bar{d}^3\left(\frac{N^2\sigma}{\bar{d}} + \tfrac{1}{6}N^3\Delta G_v + \tfrac{1}{6}N^4 A_0 g^2\right).$$

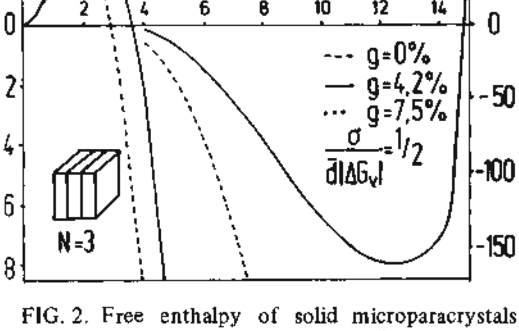

FIG. 2. Free enthalpy of solid microparacrystals ($0 < g < 7.5\%$), crystals ($g = 0\%$), and liquid microparacrystals ($g \sim 7.5\%$). For details see text.

Here $\bar{d}$ is the mean netplane distance. For $g = 0$ the well known dependence of ΔG on N is plotted as the dashed line in Fig. 2. When $g = 4.2\%$, the size of the critical nuclei increases by 10% and at $N = 13$ there is a stoppage of growth (solid line in Fig. 2). In the limiting case, $g = 7.5\%$ (dotted line in Fig. 2), the critical nuclei have the same sizes as the mean number $\bar{N}$ of the equilibrium state. Now one is concerned with microparacrystals in a melt. The thermodynamics of solid colloids can be understood as having g-values smaller than those of the limiting case.[1]

COLOR

Definitions

1. *Color (n)* The noun *color* is used in different ways by different people to convey something about what we see when we look at an object. It has been used to describe differences among spectral power distributions of objects, differences among chemical constitutions of colorants, and conditions for color measurement by colorimetry, in addition to the perceived appearances of objects or media. There is, then, no single, universal, definition of color. The Commission Internationale de l'Éclairage (CIE) recommends two definitions: *perceived color* and *psychophysical color*. CIE perceived color is "an aspect of visual perception by which an observer may distinguish differences between two fields of view of the same size, shape, and structure, such as may be caused by differences in the spectral composition of the radiation concerned in the observation." CIE psychophysical color is said to be "a characteristic of a visible radiation by which an observer may distinguish differences between two fields of view of the same size, shape, and structure, such as may be caused by differences in the spectral composition of the radiation concerned in the observation."

2. *Color Perception* An attribute of vision consisting of *chromatic* and *achromatic* components. Chromatic components of color perceptions allow organisms to distinguish among *hues*, such as those called red, green, yellow,

blue, etc., and to distinguish among their *saturations* or degrees of chromatic content. Achromatic components of color perceptions refer to intensive aspects of the perceptions such as those commonly designated by the words white, gray, black, bright, dim, light, or dark.

3. *Color Stimulus* The agent by which an organism is stimulated to see color; color stimuli commonly consist of radiant energy called *light*. In general, then, color stimuli consist of visible radiation entering the eye and producing the sensation of color, either chromatic or achromatic.

4. *Color Measurement* The practice or methodology of attempting to measure the relationships between color stimulation and color perception; one form of *psychophysics*, the science of determining correspondences between stimuli and responses. A special case of color measurement is called *colorimetry*, which deals mainly with the specification of stimuli that match in color appearance.

Perception of Color All color perceptions have at least three attributes: hue, saturation or chromatic content, and brightness. When a color stimulus is perceived as part of an array of other stimuli, it may also have other attributes derived from the perceived relationships of its basic attributes to those of the other stimuli in the field of view. These are called relative hue, relative chromatic content (or saturation), and relative brightness (or lightness). These and other derivative attributes of color perceptions are conscious awarenesses that arise in the brain as a result of stimulation of the organism and signal processing carried out within the organism's nervous system.

The mechanism of human color vision consists of an optical system for collecting and forming images of light, neural networks that detect and respond to light and that transmit encoded signals, and neural cells in the brain that elaborate and interpret the signals. The visual mechanism then includes the eye, the neural pathways, and the brain.

The lens of the eye forms an image of light on the *retina* at the rear of the eyeball. The retina contains six kinds of cells called *neurons*. One class of neurons consists of photodetectors, which are capable of responding to light or changes in light. They are called *receptors*. There are about 10^8 *rod* receptors and 8×10^6 *cone* receptors, so named because of their respective shapes. Each receptor contains one of four kinds of photolabile *pigments*, the stereochemical forms of which can be altered by absorption of *photons* (light quanta). The distribution of rods and cones varies over the retina; there are many more cones than rods near the visual axis. Rods are useful for night vision but do not contribute significantly to color vision or acuity. There are three classes of cones, distinguished by their different spectral sensitivities to light. One class of cones (ρ) is most sensitive to long wavelengths of light, with a maximum sensitivity in the region of 560 nm. A second class of cones (γ) is most sensitive to middle wavelengths of light and has a peak sensitivity around 530 nm. The third class of cones (β) is most sensitive to light of short wavelengths near 420 nm. Estimations of the distributions of spectral sensitivities of ρ, γ, and β cones are illustrated by dashed curves in Fig. 1.

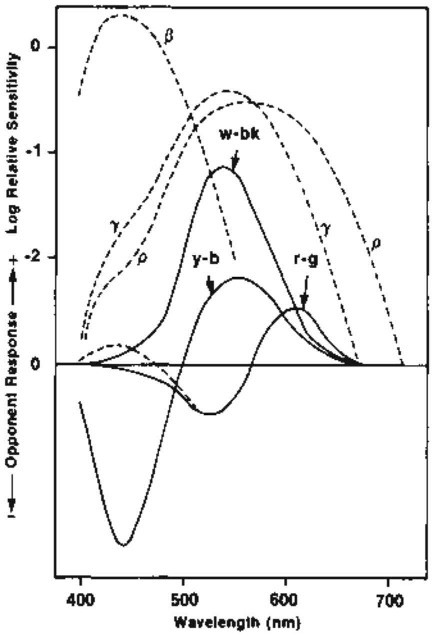

FIG. 1. Estimated ρ, γ, β cone receptor systems sensitivities (upper dashed curves) and sensitivities of achromatic (*w-bk*) and chromatic (*r-g* and *y-b*) neural processes (solid curves), both as functions of wavelength.

Discrimination among color stimuli of different spectral powers occurs as a result of the different spectral sensitivities of the cones. However, regardless of differences in spectral power, when two color stimuli excite the cones equally, the stimuli cannot be distinguished as different; that is, when the rate of photon absorption is the same for each stimulus, the stimuli appear identical. This *principle of univariance* is the basis for *metameric* color matching, where two spectrally different stimuli can be made to match in color by properly adjusting their relative radiances.

The remaining neurons of the retina combine, elaborate, and encode electrophysiological signals set up in response to absorption of photons by the receptors. Many receptors may be interconnected, and their signals converge on higher order (i.e., more proximal) neurons. The axons of the most proximal neurons of the retina (ganglion cells) form the *optic nerve*, a sheath of about 10^6 fibers that transmit signals to the *lateral geniculate nucleus* of the thalamus (the next highest level of the visual mechanism). The encoded signals that leave the eye through the optic nerve are of two kinds: spectrally *opponent* and spectrally *nonopponent* (most are also spatially opponent). Spectrally opponent cells signal to different extents and with different polarities as a function of wavelength of stimulation, whereas spectrally nonopponent cells signal to different extents with the same polarity as a function of wavelength. The spectrally nonopponent signals (A) are thought to be the result of additive combinations of signals from ρ and γ cone networks. The spectrally opponent signals (C_1 and C_2) are thought to consist of differences among classes of cone signals. The neural signals are conventionally represented mathematically as:

$$A = a_{11}\rho + a_{12}\gamma \tag{1}$$

$$C_1 = a_{21}\rho - a_{22}\gamma \tag{2}$$

$$C_2 = a_{31}\rho + a_{32}\gamma - a_{33}\beta \tag{3}$$

although there are a number of variations on these expressions.

A represents a neural signal analogous to achromatic perceptions: white to black or bright to dim (sometimes symbolized *w-bk*). C_1 represents a neural signal corresponding to redness (for positive values) or greenness (negative values); it is therefore sometimes symbolized *r-g*. C_2 represents a neural signal corresponding to yellowness (positive values) or blueness (negative values); it is therefore sometimes symbolized *y-b*. When $C_1 = C_2 = 0$, only A remains for any suprathreshold stimulus and so it is seen as achromatic (white, gray, black, etc.). The spectral distributions of sensitivities for the A, C_1, and C_2 neural mechanisms depend upon those of ρ, γ, and β and upon the interconnections in signal processing; there are also differences between threshold and suprathreshold processing conditions. Estimated spectral sensitivities of the neural functions are shown as the solid curves in Fig. 1. The viewing or adaptation condition represented by that figure is a physiological neutral state such as that associated with dark adaptation or, for the dashed extension of the *r-g* curve, suprathreshold daylight adaptation.

Figure 1 corresponds to observers with normal color vision. Deviations from normal color vision are thought to arise when one or more of the cone classes is missing or reduced in effectiveness and when neural processing differs from that subsumed for people with normal color vision. These deviations are of three kinds: anomalous trichromatic vision, dichromatic vision, and monochromatic vision. Their names derive from the minimum number of color stimuli required by an observer to match colors satisfactorily. A person with normal trichromatic vision can match the hues of all stimuli with additive combinations of three appropriately selected lights. Those with anomalous trichromatic vision also require three lights but make different matches from those of normal observers. Dichromatic observers require only two lights, and monochromatic observers are satisfied with a single light.

The wavelengths at which the opponent response functions of Fig. 1 are zero identify the spectral stimuli that elicit *unitary hues* for normal observers under the viewing conditions represented in the graph. The suprathreshold *r-g* curve is zero at about 475 nm. That leaves only the *b* signal at that wavelength, so it corresponds to the spectral stimulus that elicits a blue color response with no trace of any other hue (for the viewing condition in question). The *y-b* curve crosses the zero line at about 505 nm, leaving only *g*, so that would be the wavelength for a unitary green blue. The *r-g* curve again becomes zero at about 580 nm, so that wavelength corresponds to a unitary yellow hue. Unitary red hue can be produced only by a combination of short- and long-wavelength stimuli for the viewing conditions illustrated. The hues corresponding to all other stimuli contain proportions of two hues. These other perceptions are therefore known as *binary hues*. All hues are either unitary or binary. That is, they may appear red or green (but not both at the same time), yellow or blue (but not both at the same time), yellow-red, yellow-green, blue-red, or blue-green, and in various degrees of lightness or darkness. Even the color normally called brown can be described as a dark yellow-red color. Table 1 lists several relationships between attributes of perceived colors and conditions of the A, C_1, and C_2 neural signals of Eqs. (1)–(3).

Additional elaboration and analysis of neural signals takes place in the thalamus and occipital cortex of the brain, but the general form of color-coded signals seems to be the same as those leaving the retina. These signals are organized into *receptive fields* representing the combined responses of many receptors and interneurons. In this way, stimulation in one area of the retina influences signal responses in adjoining and nearby areas. These interactions give rise to contrast and induction effects. When, for example, a gray paper is viewed against a white background, it appears darker than when it is seen on a dark background. The higher level of activity elicited by the white background inhibits response to the gray paper, making it appear darker. Chromatic induction or contrast may also occur to alter perceived hues and saturations. These kinds of interactions make it difficult or impossible to predict color appearances from measurements or specifications of only single focal stimuli; all stimuli in the field of view must be considered and their interactions must be taken into account.

The quantitative nature of these interactions is not well known. Signal processing is both complex and nonlinear in its effect. For example, although the visual mechanism can respond over a range of luminances (spectrally

TABLE 1. EXAMPLE OF THE WAY IN WHICH ATTRIBUTES OF COLOR PERCEPTION COULD BE RELATED TO NEURAL SIGNALS OF THE VISUAL MECHANISM.

Let:*

$$A = a_{11}\rho + a_{12}\gamma \qquad = w\text{-}bk$$

$$C_1 = a_{21}\rho - a_{22}\gamma \qquad = r\text{-}g$$

$$C_2 = a_{31}\rho + a_{32}\gamma - a_{33}\beta = y\text{-}b$$

Attribute of Color Perception	Symbol	Condition
Achromaticness	A	$C_1 = C_2 = 0,\ A > 0$
Chromaticness	K	$(C_1 + C_2) > 0$
Saturation (relative chromaticness)	S	$0 \leqslant \dfrac{C_1 + C_2}{C_1 + C_2 + A} \leqslant 1$
Brightness	B	$C_1 + C_2 + A > 0$
Lightness (relative brightness)	L	$0 \leqslant \dfrac{C_1 + C_2 + A}{(C_1 + C_2 + A)_w} \leqslant 1$
Constant hue	H_i	C_1/C_2 = constant
Unitary hues	H_r	$C_1 > 0,\ C_2 = 0$
	H_g	$C_1 < 0,\ C_2 = 0$
	H_y	$C_1 = 0,\ C_2 > 0$
	H_b	$C_1 = 0,\ C_2 < 0$

*Where + stands for some unspecified form of combination and w refers to a white reference.

weighted radiances) of about 10^{12}, neural signals are greatly compressed and nonlinearly related to input powers (a range of about 10^2 in the receptors and 10^1 in other neurons). This compression requires that to be effective, the visual mechanism must adjust or adapt the sensitivities of its component processes to suit the level and quality of stimulation provided it. The process of adaptation permits us to see a "white" paper as white by moonlight or bright sunlight and by yellowish incandescent lamp or blue sky illumination.

Color Stimuli Color stimuli have extents (spatial and temporal), intensities, and qualities. Spatial extent (size and location) can be specified by length and its derivative measures or by angular subtense and location in the visual field. Temporal extent can be specified by time and its derivative measures. Intensity and quality are specified by spectral power or radiance concentration.

Normal color stimuli can be sources of direct radiation (lights) or of indirect radiation (e.g., reflecting or transmitting objects). Light can be produced by valence-shell electronic excitations from higher levels back to the ground state. In heated solids, the emission spectra of lights are characteristic of the temperature of the material. In gases, the emission spectra are characteristic of the molecular or atomic structure of the material. In either case, the stimulus function $\Psi(\lambda)$ represents the radiance of the light source: $\Psi(\lambda) = L_e(\lambda)$.

Light can also cause low-energy valence-shell electronic excitations in atoms. Spectral selectivity is produced when molecules selectively absorb certain frequencies of light because of these electronic transitions between quantum electronic states. Both organic and inorganic compounds absorb light frequencies by transition of the molecule from the ground state to an excited state, but the physical phenomena that cause the transition may differ in two cases. In either instance, absorption of a particular frequency of light by excitation of electrons whose energy difference corresponds to that frequency removes light of that wavelength from the spectrum of irradiation. Selective alteration of light can also occur by other physical phenomena such as polarization and Rayleigh scattering and by fluoresence and photophorescence. The light which is not absorbed (scattered or re-emitted) is reflected or transmitted. In these cases, the color stimulus function is designated by the product of the irradiance function and the reflectance function $[\Psi(\lambda) = \rho(\lambda)E(\lambda)]$ or the transmittance function $[\Psi(\lambda) = \tau(\lambda) \cdot E(\lambda)]$. In the general case, the product of the relative radiance of a medium with the irradiance of the light source defines the color stimulus function $[\Psi(\lambda) = \beta_e(\lambda)E(\lambda)]$. When $L_e(\lambda)$ is expressed in $W \cdot m^{-2} \cdot sr^{-1}$ or $E(\lambda)$ in $W \cdot m^{-2}$, then $\Psi(\lambda)$ specifies both intensity and quality of the color stimulus. When those values are expressed relative to the corresponding value for some standard of reference (e.g., the Lambert reflector or a specified thickness of air) then $\Psi(\lambda)$ specifies only the quality of the spectral stimulus.

Color Measurement Color measurements may be classed in three broad categories: *color matches*, *color differences*, and *color appearances*. In all three, an atempt is made to relate $\Psi(\lambda)$ or its derivative expression to some invariant criterion of color perception.

The criterion for color matching (upon which colorimetry is based) is the invariance of perceptual identities. The amounts of three reference stimuli or *primaries* that are required to produce the same color appearance as that of some sample are specified as a color match by *color mixture*. Because of the principle of univariance combined with the fact that there are but three kinds of cone receptors, a minimum of three primaries can be used to match the colors of all stimuli, provided that the primaries are perceptually *independent* (i.e., none of them can be matched in color by any mixture of the other two). Certain conventions have been adopted internationally to simplify the practice of colorimetry and enhance communication. The spatial extents of stimuli are restricted to about 2° and 10° diameter in visual subtense centered on the visual axis. Certain geometric conditions are also specified for $\rho(\lambda)E(\lambda)$ and $\tau(\lambda)E(\lambda)$. In order to avoid dealing with the nonlinear complexities of the visual mechanism, only color matches (conditions of equal quantum catches by the receptors) are addressed by CIE conventions adopted in 1931. These colorimetric conventions lead to specifications of the conditions for color matches in terms of the amounts of standard primaries required by a standard observer; they do not specify color perceptions or differences among them. Color matches for stimuli subtending 1-2° diameter have been found to hold over a range of luminances from about 1-2 $cd \cdot m^{-2}$ to around 1,000-2,000 $cd \cdot m^{-2}$ and over changes in chromatic adaptation among daylight sources or Planckian radiators whose spectral radiance functions are not greatly different from that of average daylight. Over these ranges, the nominal process of color matching is *linear* (stimulus radiances can be increased or decreased by any positive factor and the match will continue) and *persistent* (the match holds over changes in sensitivity occasioned by variations in chromatic adaptation). Therefore, any set of color mixture primaries that is a linear transform of some appropriate set will serve as a standard. The CIE has selected a set for the *CIE 1931 Standard Colorimetric Observer* (for 2°) and a second set for the *CIE 1964 Supplementary Standard Colorimetric Observer* (for 10°) and has specified the amounts required of them for the standard observer to match the colors of spectral components of an equi-energy spectrum. These amounts are symbolized as $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ [or $\bar{x}_{10}(\lambda), \bar{y}_{10}(\lambda), \bar{z}_{10}(\lambda)$ for the CIE 1964 observer]. The color mixture coefficients at each wavelength ($\bar{x}_\lambda$, $\bar{y}_\lambda$, $\bar{z}_\lambda$) represent the tristimulus values of the components of the equi-energy spectrum and are illustrated in Fig. 2. When these color mixture coefficients are used, the condition of color match for two stimuli $\Psi_1(\lambda)$ and $\Psi_2(\lambda)$ can be specified as:

$$k \int \Psi_1(\lambda)\bar{x}(\lambda)\,d\lambda = k \int \Psi_2(\lambda)\bar{x}(\lambda)\,d\lambda \tag{4}$$

$$k \int \Psi_1(\lambda)\bar{y}(\lambda)\,d\lambda = k \int \Psi_2(\lambda)\bar{y}(\lambda)\,d\lambda \tag{5}$$

$$k \int \Psi_1(\lambda)\bar{z}(\lambda)\,d\lambda = k \int \Psi_2(\lambda)\bar{z}(\lambda)\,d\lambda \tag{6}$$

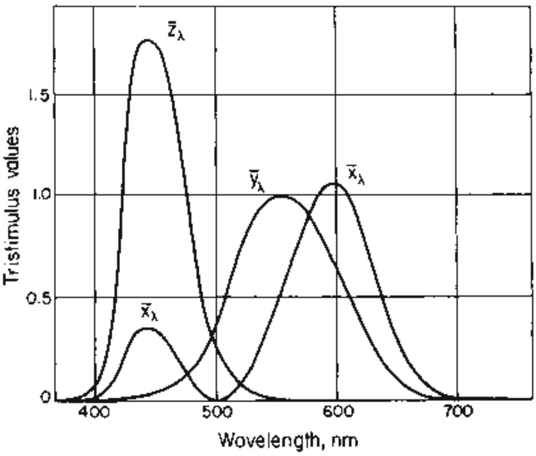

FIG. 2. CIE 1931 Standard Colorimeteric Observer's color mixture functions.

or similarly for the CIE 1964 observer [using $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, $\bar{z}_{10}(\lambda)$]. The limits of integration are usually 380 nm to 780 nm. The integrals of Eqs. (4)-(6) are called *tristimulus values* and symbolized X, Y, and Z. The scale factor k may have any convenient value but most often is assigned one of two values: $k = 680$ lumens · W^{-1} (which yields tristimulus values that are consistent with luminance since $\bar{y}(\lambda) = V(\lambda)$, the CIE 1924 luminous efficiency function) or $k = 100 \left[\int E(\lambda)\bar{y}(\lambda)\, d\lambda \right]^{-1}$ (which yields tristimulus values consistent with luminance factor).

If $\Psi_1(\lambda) \equiv \Psi_2(\lambda)$ (the spectral distributions of both stimuli are identical), then Eqs. (4)-(6) will be satisfied for all observers under all illuminants; such matches are sometimes said to be *isomeric*. If Eqs. (4)-(6) are satisfied but $\Psi_1(\lambda) \neq \Psi_2(\lambda)$, then the match is a *metameric* one that may not satisfy observers whose color mixture functions differ from those of the CIE standard observer, and the match may not hold for the standard observer under a different illuminant.

It is often convenient to plot the *relative* amounts of tristimulus values. They are called *chromaticity coordinates* and are derived from the tristimulus values as follows:

$$x = \frac{X}{X+Y+Z} \tag{7}$$

$$y = \frac{Y}{X+Y+Z} \tag{8}$$

$$z = \frac{Z}{X+Y+Z}. \tag{9}$$

Since $x + y + z = 1$, only two are needed for a complete specification of chromaticity; x and y are conventionally used. When the chromaticity coordinates of the components of the equi-energy spectrum are plotted in a diagram of y versus x, and the chromaticity coordinates for the extremes of wavelength integration are joined together, the roughly "horseshoe" area of Fig. 3 results. The diagram is called a *chromaticity diagram*, and the area depicted contains chromaticities corresponding to all color stimuli.

When a normal trichromatic observer matches the color of any one color stimulus many times, a distribution of chromaticities results representing the variability of determination. Figure 4 illustrates bivariate normal ellipses representing such variability for 25 different color stimuli; the ellipses are plotted as approximately $\frac{10}{3}$ the size of the threshold of perceptibility. The ellipses differ in size and orientation. If a threshold color difference is assumed to be perceptually equal everywhere in color space, then the chromaticity diagram of Fig. 4 must be judged

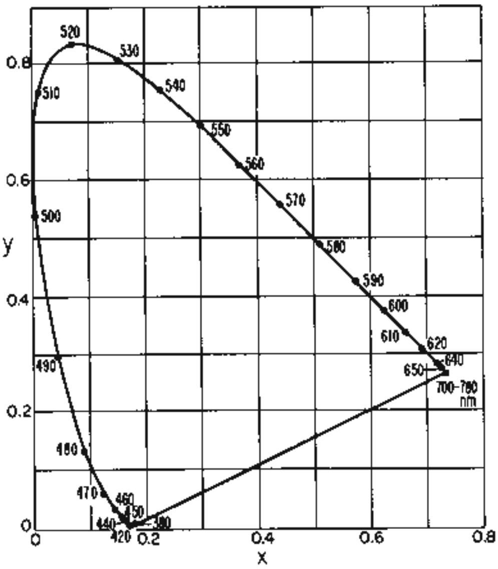

FIG. 3. CIE 1931 chromaticity diagram with coordinates y versus x. Locus of chromaticities corresponding to spectral color stimuli is shown by the curve, along which wavelengths are indicated, and the locus of nonspectral mixtures of additive combinations of spectral stimuli having wavelengths of 380 and 780 nm is shown by the line connecting the ends of the spectrum locus.

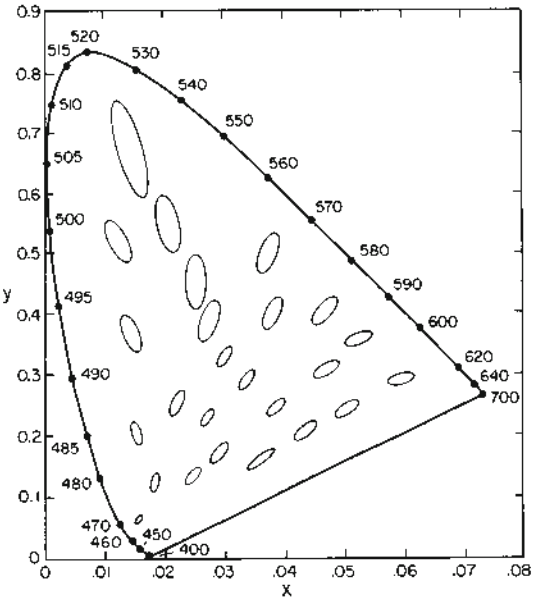

FIG. 4. Bivariate normal ellipses representing $\frac{10}{3}$ of the threshold variability of color matching for 25 color stimuli. [Based on data reported by MacAdam, D. L., "Visual sensitivities to color differences in daylight," *J. Opt. Soc. Am.*, **32**, 247-274 (1942).]

to be nonuniform. A uniform chromaticity diagram would be one in which the distributions of color matches are represented as circles of constant diameter throughout the graph. Straight lines in such a diagram would represent *geodesics*, lines depicting the relative sizes of perceived color differences. The (constant) distances corresponding to threshold differences in color might be taken to represent the additive unit of such a color metric.

Many attempts have been made to derive such a *uniform chromaticity diagram* or scale (*UCS*). None have been completely successful. In 1976, the CIE provisionally recommended two transformations of CIE 1931 tristimulus values as approximations to a uniform color metric: *CIE 1976 L*u*v** and *CIE 1976 L*a*b** diagrams. They are related to the tristimulus values X, Y, Z as follows:

$$L^* = 116(Y/Y_w)^{1/3} - 16 \qquad (10)$$

$$u^* = 13L^*(u' - u'_w) \qquad (11)$$

$$v^* = 13L^*(v' - v'_w) \qquad (12)$$

where

$$u' = (4X)(X + 15Y + 3Z)^{-1}$$

$$v' = (9Y)(X + 15Y + 3Z)^{-1}$$

and

$$L^* = 116(Y/Y_w)^{1/3} - 16 \qquad (13)$$

$$a^* = 500[(X/X_w)^{1/3} - (Y/Y_w)^{1/3}] \qquad (14)$$

$$b^* = 200[(Y/Y_w)^{1/3} - (Z/Z_w)^{1/3}]. \qquad (15)$$

The subscript w refers to a "white" achromatic reference stimulus. The coordinates u', v' form a supplementary chromaticity diagram since they can be defined for a plane of constant luminance; the $L^*a^*b^*$ metric does not have planes of constant luminance and, therefore, has no associated chromaticity diagram. Color differences (constrained to small or near-threshold in size) are specified in the two color spaces of Eqs. (10)-(15) as the Euclidean distances:

$$\Delta E_{uv} = [(\Delta L^*)^2 + (\Delta u^*)^2 + (\Delta v^*)^2]^{1/2} \qquad (16)$$

and

$$\Delta E_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}. \qquad (17)$$

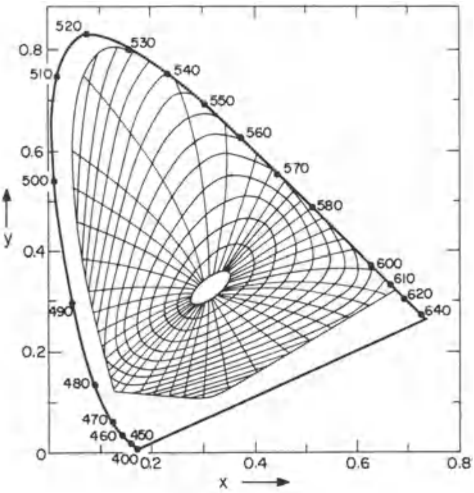

FIG. 5. Loci of constant Munsell hue (approximately radial lines) and chroma (approximately concentric circles) in a CIE 1931 chromaticity diagram for samples having luminance factors of 0.1977 (a Munsell value of 5).

CIE has not yet recommended a method for specifying large differences in color or magnitudes of color appearances. In practice, any of a number of *color order systems* are used for such specification. A color order system is a systematic structure, usually represented by material standards, that attempts to array color stimuli according to some plan. The *Optical Society of America uniform color order system* arrays color stimuli approximately according to geodesics of suprathreshold color differences. The *Swedish natural color system* arrays color stimuli according to the magnitudes of their relative hues, saturations, and lightnesses. The *Munsell notation* arrays samples according to a combination of their hues, chromas (a form of relative chromatic content), and values (a function of lightness), and their differences in color. Figure 5 illustrates the chromaticities of the Munsell notation array for color stimuli having luminance factors of 0.1977. The approximately radial curves represent constant hues, and the approximately concentric circles correspond to constant chromas. These relationships permit specification of differences or magnitudes in terms of CIE tristimulus values. However, all current systems for specifying near-threshold and suprathreshold color differences are inexact to various degrees and, as with conventions for specifying color matches, they should be constrained to certain conditions to be useful.

COLOR CENTERS

Color center is a generic term first coined to characterize the entity responsible for the colored appearance of alkali halide crystals after exposure to x-rays. Today this term is broadly used to describe the microscopic defects that are responsible for the optical property changes throughout the ultraviolet, visible, and infrared regions of the spectrum that occur in irradiated or chemically treated materials. Although impurities may associate with color centers to produce optical absorption or emission bands, color centers are generally defined as vacancies, interstitials, or clusters of these types of defects. These defects can be produced in transparent insulator-type crystals. Recent studies have emphasized both oxide and fluoride materials, but the great wealth of experimental information and tradition still resides within the alkali halide crystal series. For a number of years it was thought that color center research would only yield prototype information for more complex materials with application potential. In the last few years, however, it has been acknowledged that color center research is important in such diverse applied projects as nuclear waste disposal and tunable infrared *F*-center lasers.

The *F* center is the best characterized color center. This center is formed when a negative ion is displaced from a lattice site into an interstitial position in the lattice or to the surface of the crystal. The displacement of this negative ion results in a potential well formed by the next neighbor positive ions that surround the negative ion site. This potential well traps an electron and forms the *F* center—a negative ion vacancy with a trapped electron for charge compensation. Both the "particle-in-the-box" and "hydrogenic" models can be used as crude approximations to determine the energy levels for the *F* center. The former model predicts that the absorption energy of *F* centers is inversely proportional to the square of the lattice constant (potential well size). This approximation is surprisingly accurate in predicting the absorption energies of *F* centers in alkali halides and is helpful for other materials such as MgO, MgF_2, and CaF_2. However, much more sophisticated theoretical treatments are necessary to understand the width of the absorption bands, the temperature dependence of these bands and the lifetimes of the transitions. Table 1 lists the energy for the maximum of the *F*-center absorption in a number of materials.

Although the negative ion vacancy is a "good" electron trap only about 80% of the electron charge is centered within the vacancy. This means that the electron spends most of its time in the potential well interacting with next neighbor positive ions, but for a significant amount of time the electron interacts with other neighbors as well. Since the motion of the surrounding ions continually changes the dimensions of the potential well for the electron, the *F* band absorption is very broad. Of course, as the temperature of a sample is lowered and the ion motion is decreased the width of the absorption band is also decreased. At very low temperature (less than -200°C) ion motion is almost entirely the result of zero-point vibrations and the width of the absorption remains constant.

TABLE 1. COLOR CENTER ABSORPTION IN SELECTED MATERIALS.

	Wavelength of the Maximum of the Absorption Bands (nm) at 300K		
	F	F_2 (*M*)	F_3 (*R*)
LiF	250	447	310 380
NaF	340	499	450
KCl	560	822	680 740
KI	660	1010	810 905
RbBr	680	957	805 860
MgF_2	260	322 355 370	300
$RbMgF_3$	290 340	387	300
$KMgF_3$	270	446	396

When an F center absorbs a photon of the appropriate energy the electron is promoted to an excited state. For device applications how this electron returns to the ground state is most important. For example, the electron can return to the ground state by interacting with neighboring ions to give up its excess energy as heat to the crystal lattice. This is referred to as a *nonradiative* transition and can be highly temperature dependent. The electron can also pass to the ground state through the emission of a photon (luminescence). This emission is especially important for phosphor applications or for laser action. The emission band is broad for the same reason that the absorption is broad. Since in every instance some energy is shared with the lattice neighbors while the electron is in the excited state, there is an energy difference between the absorption and the emission. This is known as the *Stokes shift*. The emission for most alkali halide F centers occurs in the near infrared where tunable lasers are sorely needed. Such lasers have been constructed using F centers and impurity perturbed F-cluster centers. Long-term stability at room temperature is the most serious deficiency of these small solid state lasers.

In some materials the excited state of the F center is close to the conduction band in energy. Thus, at higher temperatures it is possible under light excitation for the excited state electron to move into the conduction band. This results in ionization of the F center, and photoconductivity is observed. The last method of deexcitation of the excited electron which will be considered is energy transfer. It is possible when other defects with similar energy levels are nearby for energy to be transferred from one defect to another. This mechanism has been most thoroughly studied for impurities, but pertains to color centers as well when the concentration of such centers is high. Clearly, the understanding of optical properties of materials is necessary for the development of practical applications. Because of the ease of growth and preparation of alkali halide crystals and the atomic simplicity of these materials, numerous experimental and theoretical advances have occurred through the study of color centers. The great number of high technology techniques which have been developed for detailed investigation of color center phenomena are now being applied to more complex materials such as quartz.

Although the F center is the best known and understood color center, a number of defects have been observed and characterized. A partial list of these defects is given below. Table 1 lists the absorption energy for these defects in several types of crystals:

1. The F center. In a monovalent anion material such as KCl or MgF_2 the F center consists of an electron trapped at a negative ion vacancy (charge compensation is essentially complete). In the case of a divalent anion material such as MgO, the F center consists of two electrons trapped at the negative ion vacancy (charge compensation is again essentially complete). When charge compensation is not complete, e.g., one electron trapped at a divalent anion site, the center is referred to as an F^+ center, indicating a net positive charge at this site. F centers may also be trapped by impurities. When this occurs the notation F_A center is utilized.

2. F-center aggregates. In many instances F centers aggregate to form clusters. The simplest such cluster is the F_2 or M center, which consists of two F centers in neighboring positions. This center resembles a hydrogen molecule and its optical properties have been approximated using such a model. When the two negative ion vacancies share only one electron the center is referred to as an $F_2{}^+$ center. This center can be approximated as an $H_2{}^+$ molecule. Because of the stability and optical properties of these centers, a number of infrared laser system using them have been constructed. When three F centers occupy next neighbor positions the complex is given the notation F_3 or R center. As with the F_2 centers, because of the planar nature of these defects nonequivalent dipoles exist and more than one absorption band is associated with these defects.

3. Hole traps. In addition to electron centers, certain defects can trap holes and give rise to optical absorption and emission. The two best studied such centers are the $X_2{}^-$ or V_K center and the so-called H center. The $X_2{}^-$ center is formed in highly ionic crystals such as the alkali halides and alkaline earth flourides. This defect has not been detected generally in oxide materials. The V_K center consists of a hole trapped between two negative halide ions. It may be pictured as a $X_2{}^-$ molecule that occupies two normal halide sites in a crystal in which X^- denotes the negative ion halide. The H center consists of a hole that is shared by four negative ion halide ions occupying three normal halide ion lattice sites in a crystal. The H center forms an interstitial defect. Since the halide is interstitial, a negative-ion vacancy must exist elsewhere in the crystal. H centers are stable only at low temperature. As the temperature of a material is increased, the H centers aggregate to form interstitial clusters or dislocation loops.

There are a number of ways to produce color centers. The most generally used methods involve irradiation with x-rays, electrons, protons, or neutrons; the use of chemical heat treatment; or the passage of a dc electrical current through the sample while it is at a high temperature. The latter two treatments generate mostly F-type centers without introducing interstitials. When crystals are irradiated both interstitials and vacancies are formed. In highly ionic materials photochemical production of these defects occurs during irradiation. Vacancy-interstitial pairs are produced with as little as

20 eV energy expenditure. The production of electron-hole pairs in the crystal is sufficient to form X_2^- centers which then degenerate into *F* centers and *H* centers. In the photochemical process one 1 MeV electron can produce as many as 10,000 *F* centers. For those materials in which X_2^- centers are not easily formed, such as oxide crystals, this type of damage mechanism is negligible. Instead the impinging radiation has the same effect as in metal crystals. Interstitial-vacancy pairs are produced when the impinging particle has sufficient energy to displace an ion into an interstitial position. In MgO the required energy is about 60 eV so that electrons with a minimum energy of 330 KeV are required to produce ionic damage. These materials are much more difficult to damage by irradiation than are the more ionic halides. Typically about one stable *F* center is produced for every ten 1-MeV electrons.

The thermal, electrical, mechanical, and optical properties of most crystals are changed considerably when color centers are present. Only a few parts per million of interstitial type color centers can change the hardness of a material appreciably. Because of these changes, the study of color centers in those materials with potential for practical applications is particularly important. Oxide materials such as MgO, Al_2O_3, and quartz have been studied as have most flouride systems. New work is progressing on wide band gap semiconductors and even more complicated mixed crystals.

COMPRESSIBILITY, GAS

(a) The *compressibility* of a gas is defined as the rate of volume decrease with increasing pressure, per unit volume of the gas. The compressibility depends not only on the state of the gas, but also on the conditions under which the compression is achieved. Thus, if the temperature is kept constant during compression, the compressibility so defined is called the isothermal compressibility β_T:

$$\beta_T = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial P}\right)_T. \quad (1)$$

If the compression is carried out reversibly without heat exchange with the surroundings, the adiabatic compressibility at constant entropy, β_S, is obtained:

$$\beta_S = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_S = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial P}\right)_S. \quad (2)$$

The two compressibilities are related by

$$\beta_S/\beta_T = C_V/C_P. \quad (3)$$

Here P is the pressure, V the volume, ρ the density, T the temperature, S the entropy, and C_V, C_P specific heats at constant volume and pressure, respectively.

The *compressibility factor* of a gas is the ratio PV/RT (cf. GAS LAWS). This name is not well chosen since the value of the compressibility factor is no indication of the compressibility.

(b) The *experimental behavior* of the compressibility as a function of pressure and temperature is as follows: dilute gases obey the laws of Boyle and Gay-Lussac, $PV=RT$, to a good approximation. The compressibilities β_T and β_S of a dilute gas are then given by

$$\beta_T = \frac{1}{P}; \beta_S = \frac{(C_V/C_P)}{P}. \quad (4)$$

Compressed gases, however, show large deviations from the behavior predicted by Eq. (4). This is demonstrated in Fig. 1, where the isothermal compressibility of argon, divided by the corresponding value for a perfect gas at the

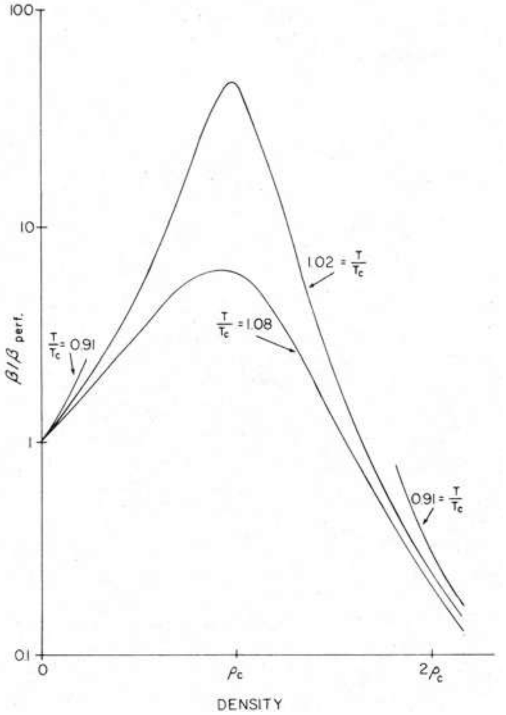

FIG. 1. The ratio $\beta/\beta_{\text{perf.}}$ of the isothermal compressibility of argon to that of a perfect gas at the same density, as a function of the density, at 0.91, 1.02, and 1.08 times the critical temperature. The critical density is indicated by ρ_c.

same density, Eq. (4), is pictured as a function of density for various temperatures. At all temperatures the compressibility at high densities falls to a small fraction of the value for a perfect gas. As the critical temperature is approached from above, a large maximum occurs in β_T at densities near critical. The isothermal compressibility diverges strongly at the critical point (just like C_P, see Ref. 1d) and is infinite everywhere in the two-phase region, where the pressure does not rise on isothermal compression. The adiabatic compressibility, however, diverges only weakly (like C_V, see Ref. 1d) when the critical point is approached, and it is finite in the two-phase region.

(c) Simple notions taken from *molecular theory* can be used to explain the general features of the compressibility in its temperature and density dependence. The pressure of the gas is caused by the impact of the molecules on the wall. If the volume is decreased at constant temperature, the average molecular speed and force of impact remain constant, but the number of collisions per unit area increases and thus the pressure rises. If the gas is compressed adiabatically, the heat of compression cannot flow off, thus the average molecular speed and force of impact increase as well, giving rise to an extra increase of pressure. Therefore $\beta_S < \beta_T$. The actual magnitude of the temperature rise depends on the internal state of the molecules; the more internal degrees of freedom available, the more energy can be taken up inside the molecule and the smaller the temperature rise on adiabatic compression. If molecules have many internal degrees of freedom, the difference between β_T and β_S, just like the difference between C_P and C_V, becomes small.

Molecular theory also shows that if the molecules have negligible volume and do not interact with each other, the gas follows the perfect gas laws of Boyle and Gay-Lussac so that Eq. (4) holds for the compressibilities β_T and β_S. However, in real gases the molecular volume is not negligible. Consequently, in states of high compression little free space is left to the molecules and thus the real gas and the liquid have low compressibilities as compared to the perfect gas (Fig. 1). On the other hand, the mutual attraction molecules experience as they approach each other makes a real gas easier to compress than a perfect gas. This explains the initial rise of $\beta_T/\beta_{\text{perf.}}$ at temperatures not too far above critical.

(d) *Experimental values* for the compressibility could be obtained in principle by measuring the pressure increase on a small volume decrement. In practice a measurable pressure increase is obtained only in regions of low compressibility, i.e., in the dense gas. Usually, compressibilities are determined in indirect ways. Thus, the isothermal compressibility, being proportional to $(\partial V/\partial P)_T$, can be deduced from experimental *PVT* data if these data are sufficiently accurate and densely spaced. For obtaining the adiabatic compressibility from *PVT* data, some additional information is needed, for instance SPECIFIC HEAT data in the perfect gas limit. For reviews of experimental methods for determining *PVT* relations and deriving thermodynamic properties see Refs. 1a, b.

The adiabatic compressibility is readily obtained from speed-of-sound data through the relation

$$v^2 = \frac{1}{\rho\beta_S} \tag{5}$$

Eq. (5) is valid only when compressions and expansions of the sound wave are truly reversible and adiabatic, i.e., if the frequency is low and the amplitude small. Experimental techniques for determining the speed of sound are discussed in Ref. 1c.

The isothermal compressibility, through the fluctuation theorem of statistical mechanics, is related to the density fluctuations in the system.[2,3] These density fluctuations are responsible for the scattering of light. Thus, the isothermal compressibility, in principle, could be directly obtained from the intensity of scattered light.[2,3] In gases, sufficient intensity is obtained only in regions of large density fluctuations, i.e., near the critical point. Experimental methods and results are discussed in Refs. 1d, 3.

(e) *Theoretical predictions* for the isothermal compressibility are obtained from evaluation of the statistical-mechanical partition function or the radial distribution function. In either case, a model for the intermolecular potential is required. An approximate calculation of the partition function valid at low densities leads to the virial expansion;[2] this expansion expresses PV/RT in a power series in density, the coefficients being related to the interactions of two, three, etc. particles; the compressibility then follows straightforwardly.

The virial expansion is not useful for dense gases, because convergence is slow and higher virials are hard to calculate. For dense systems, methods have been developed for evaluation of the radial distribution function $g(r)$, which is the ratio of the average density of molecules at a distance r from any given molecule to the average density in the gas. The compressibility is related to $g(r)$ by the fluctuation theorem

$$kT\,\beta_T = 1/\rho + \int [g(r) - 1]\; 4\pi r^2 dr \qquad (6)$$

Integral equations for $g(r)$, relating it to the molecular potential, its derivatives, and higher-order distribution functions, have been developed. They can be solved after approximations about the form of these higher-order distribution functions are made. These solutions are hard to obtain for any but spherical interactions, and invariably suffer from internal inconsistency. For systems of hard spheres, good solutions are available that have been verified by comparison with results from computer simulation.

The most promising route toward predicting the equation of state of dense fluids of nonspherical molecules has been the approximate evaluation of the partition function by the so-called *perturbation method*. Here it is assumed that the partition function is known for a reference system, which may be a system of hard spheres. The departure of the real interaction from that in the reference system is then treated as a perturbation in a high-temperature expansion of the partition function. Considerable progress has been made in recent years with the prediction of properties of systems of molecules with nonspherical hard cores, "soft" repulsions, dipolar and quadrupolar interactions, etc. Validation of the results of the perturbation method is increasingly performed by comparison with the results of simulation of molecular systems on high-speed computers. Ref. 4 gives a complete survey of and references to the more successful integral equation and perturbation methods.

Many semiempirical equations of state with varying degrees of theoretical foundation have been developed and can be used with Eq. (1) to calculate the compressibility. Van der Waals' equation, a two-parameter equation which gives a qualitative picture of the PVT relation of a gas and of the gas-liquid transition, is an example. For surveys of useful semiempirical equations see Refs. 1b, 2 and 4.

COMPTON EFFECT

Introduction The Compton effect refers to the collision of a photon and a free electron in which the electron recoils and a photon of longer wavelength is emitted as indicated in Fig. 1. It is one of the most important processes by which x-rays and γ-rays interact with matter and is also one which is accurately calculable theoretically.

A discussion of the effect is found in most textbooks on atomic physics. Particularly complete presentations have been made by Evans.[1,2]

History Barkla and others (1908) made many observations on the scattering of x-rays by different materials. The diffuse scattering was interpreted qualitatively by J. J. Thomson in terms of the interaction of electromagnetic waves with electrons which he had shown to be a constituent of all atoms. As more experiments were carried out with light elements, it was established by J. A. Gray (1920) that the diffusely scattered x-rays were less penetrating. This implied that the scattered radiation had a longer wavelength than the incident radiation. This could not be reconciled with Thomson's theory which represented x-rays as continuous electromagnetic waves with wavelengths unchanged by scattering.

The effect which now bears his name was established quantitatively by Arthur Holly Compton (1923) when he published careful spectroscopic measurements of x-rays scattered at various angles by light elements. He found that x-rays scattered at larger angles had systematically larger wavelengths. In searching for an explanation of the data, he discovered that the observations were accounted for by considering the scattering as a collision between a single photon and a single electron in which energy and momentum are conserved.

The important place which the effect occupies in the development of physics lies in his interpretation of the effect in terms of the newly emerging quantum theory. The essential duality of waves and particles was demonstrated in an especially clear way, since the collision conserved energy and momentum while both the incident and scattered x-rays revealed wave-like properties by their scattering from a crystal. In recognition for this contribution, Compton was awarded the Nobel Prize in 1927.

A complete theory for the effect was worked out in 1928 by Klein and Nishina using Dirac's relativistic theory of the electron. The calculation was one of the brilliant successes of the Dirac theory. It represents quantitatively, within the experimental uncertainties, all phenomena associated with the scattering of photons by electrons for energies up to several billion electron volts. Because of the confidence with which photon interaction with electrons can be interpreted, the Compton effect has been important in the analysis of the energy and the polarization of gamma rays from many sources.

Kinematics The relations between the energies and directions of the incident and scattered photons and the recoil electron are determined by the conservation of energy and of the components of momentum parallel and at right angles to the incident beam. In the usual case, where the electron is initially at rest and the energy and momentum of the incident photon are $h\nu$ and $(h\nu/c)$, the equations are:

$$h\nu = h\nu' + T \qquad (1)$$

$$\frac{h\nu}{c} = \frac{h\nu'}{c}\cos\theta + p\cos\phi \qquad (2)$$

$$0 = \frac{h\nu'}{c}\sin\theta - p\sin\phi \qquad (3)$$

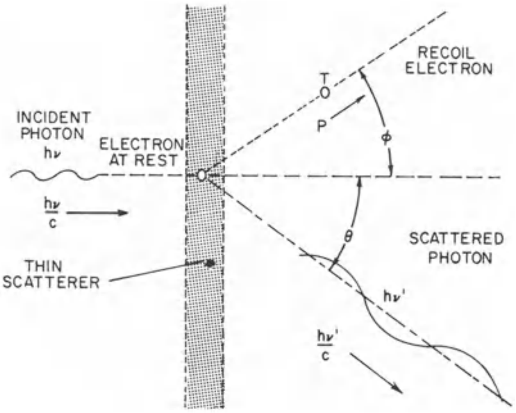

FIG. 1. Diagram showing the initial and final energies and momenta for Compton scattering.

where c is the velocity of light, h is Planck's constant, and the angles are those indicated in Fig. 1. The relativistic relation between the kinetic energy T of the recoiling electron and its momentum p is

$$pc = \sqrt{T(T + 2mc^2)} \qquad (4)$$

where m is the mass of the electron. These equations can be combined to obtain relations which are useful in the interpretation of data. The Compton shift is

$$\lambda' - \lambda = \frac{c}{\nu'} - \frac{c}{\nu} = \frac{h}{mc}(1 - \cos\theta) \qquad (5)$$

This relation was first found experimentally by Compton, who noted that the shift in wavelength $(\lambda' - \lambda)$ depended on the angle, but not on the wavelength, of the incident photon. The quantity (h/mc), which is the shift at 90°, is called the Compton wavelength of the electron and is one of the useful constants $(2.4262 \times 10^{-10}$ cm).

$$h\nu' = \frac{mc^2}{1 - \cos\theta + \dfrac{mc^2}{h\nu}} \qquad (6)$$

In this form, the energy of the scattered photon is seen to vary from that of the incident photon at 0° to less than $(mc^2/2)$ at 180°. At high energies the angle θ for which $h\nu'$ is $(h\nu/2)$ is approximately $2(mc^2/h\nu)$ radians.

The kinetic energy of the recoiling electron is

$$T = \frac{h\nu(1 - \cos\theta)}{(1 - \cos\theta) + \dfrac{mc^2}{h\nu}} \qquad (7)$$

The relation between the scattering angles of the electron and photon is

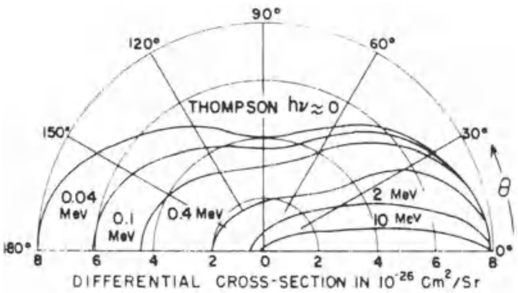

FIG. 2. Differential cross section for photons scattered at angles, θ, for a number of incident energies.

$$\cot \phi = \left(1 + \frac{h\nu}{mc^2}\right)\left(\frac{1 - \cos\theta}{\sin\theta}\right) \qquad (8)$$

Graphs of these kinematic relations and of the scattering cross section are given by Evans[(2)] and by Nelms[(3)].

Scattering of Unpolarized Radiation The differential cross section for the scattering of unpolarized radiation at an angle θ is given by the Klein and Nishina equation.

$$\frac{d\sigma}{d\Omega} = \frac{r_0^2}{2}\left(\frac{\nu'}{\nu}\right)^2\left(\frac{\nu}{\nu'} + \frac{\nu'}{\nu} - \sin^2\theta\right) \qquad (9)$$

where r_0 is the electron radius $= e^2/mc^2 = 2.8177 \times 10^{-13}$ cm, and ν' is obtained from Eq. (6). The cross section is shown as a function of θ for several energies in Fig. 2. The classical Thomson cross section $r_0^2\ (1 + \cos^2\theta)/2$ can be seen to hold for low energies where $\nu' \approx \nu$.

The total cross section obtained by integrating this cross section over angle is important in the attenuation of well-defined beams in passing through a material. The relative importance of Compton scattering as compared to the photoelectric effect and pair production is illustrated for aluminum in Fig. 3 where the attenuation coefficient α is shown as a function of energy. The fraction of the photons surviving without an interaction upon passing through x g/cm^2 of aluminum is $e^{-\alpha x}$. The Compton effect is the major one between 0.5 and 2 MeV. Extensive tables and graphs for other elements are available.[2,4]

In detectors whose response is proportional to the energy deposited by the recoil electrons, the distribution of electron energies associated with a photon of known energy is of interest: The distribution is given by the relation

$$\frac{d\sigma}{dT} = \frac{\pi r_0^2 mc^2}{(h\nu)^2}\left\{2 + \left(\frac{T}{h\nu - T}\right)^2\left[\frac{(mc^2)^2}{(h\nu)^2} + \frac{h\nu - T}{h\nu} - \frac{2mc^2(h\nu - T)}{h\nu T}\right]\right\}$$

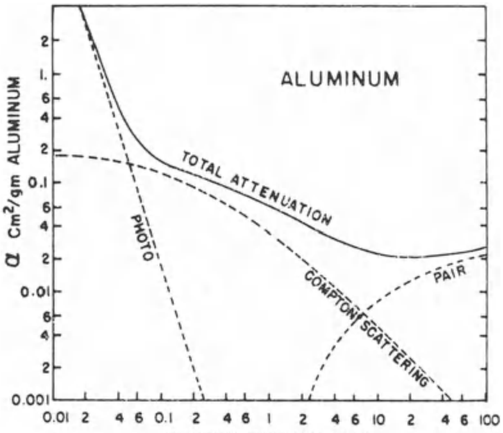

FIG. 3. The attenuation coefficients, α, for the absorption of photons in aluminum as a function of energy. The broken lines represent the separate contributions of the photoelectric effect, the Compton effect, and pair production to the absorption.

where T varies from 0 to $T_{\max} = 2(h\nu)^2/(2h\nu + mc^2)$. A number of these distributions are shown in Fig. 4.

Scattering of Plane Polarized Radiation The differential cross section for the scattering of plane polarized radiation by unoriented electrons was also derived by Klein and Nishina. It represents the probability that a photon, passing through a target containing one electron per square centimeter, will be scattered at an angle θ into a solid angle $d\Omega$ in a plane making an angle η with respect to the plane containing the electric vector of the incident wave.

$$\frac{d\sigma}{d\Omega} = \frac{r_0^2}{2}\left(\frac{\nu'}{\nu}\right)^2\left(\frac{\nu}{\nu'} + \frac{\nu'}{\nu} - 2\sin^2\theta\cos^2\eta\right) \qquad (10)$$

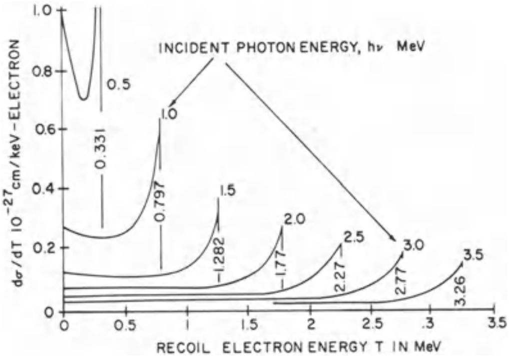

FIG. 4. The energy distribution of the Compton recoil electrons for several values of the incident photon energy $h\nu$. Based on figure in "Compton Effect" by R. D. Evans in "Handbuch der Physik," Vol. XXXIV, pp. 234–298, 1958, J. Fluge, Ed., by permission of Springer-Verlag, publishers.[2]

The cross section has its maximum value for $\eta = 90^\circ$, indicating that the photon and electron tend to be scattered at right angles to the electric vector of the incident radiation.

This dependence is the basis of several instruments for determining the polarization of photons. For example, it was used by Wu and Shaknov[5] to establish the crossed polarization of the two photons emitted upon the annihilation of a positron electron pair; by Metzger and Deutsch[6] to measure the polarization of nuclear gamma rays; and by Motz[7] to study the polarization of bremsstrahlung.

Scattering of Circularly Polarized Radiation The scattering of circularly polarized photons by electrons with spins aligned in the direction of the incident photon is represented by

$$\frac{d\sigma}{d\Omega} = r_0^2 \left(\frac{\nu'}{\nu}\right)^2 \left[\left(\frac{\nu}{\nu'} + \frac{\nu'}{\nu} - \sin^2\theta\right) \pm \left(\frac{\nu}{\nu'} - \frac{\nu'}{\nu}\right)\cos\theta\right] \quad (11)$$

The first term is the usual Klein-Nishina formula for unpolarized radiation. The + sign for the additional term applies to right circularly polarized photons. The ratio of the second term to the first is a measure of the sensitivity of the scattering as a detector of circularly polarized radiation and is shown in Fig. 5.

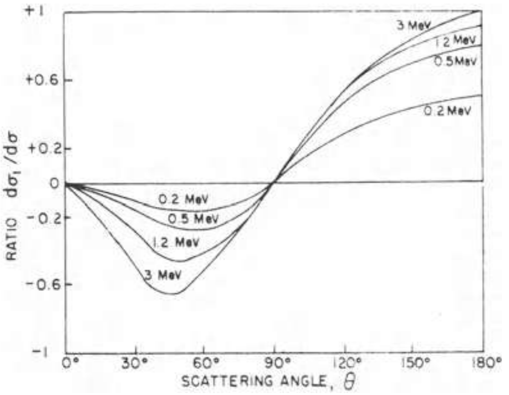

FIG. 5. The ratio of the partial cross section dependent on the spin orientation of the electrons to the average cross section as represented by the second and first terms of Eq. (10). Based on figure in "Compton Effect" by R. D. Evans in *Handbuch der Physik*, Vol. XXXIV, pp. 234-298, 1958, J. Fluge, Ed., by permission of Springer-Verlag, publishers.[2]

In practice, the only source of polarized electrons has been magnetized iron where 2 of the 26 electron spins can be reversed upon changing its magnetization. Although the change in the absorption or scattering is usually only a few per cent, this is often sufficient to get accurate and reliable measurements of circular polarization.

Cross sections for some practical arrangements and discussions of earlier work are presented by Tolhoek.[8] Applications to the determination of the helicities of photons, electrons, and neutrinos in confirming the two-component theory of the neutrino are reviewed in considerable detail by L. Grodzins.[9]

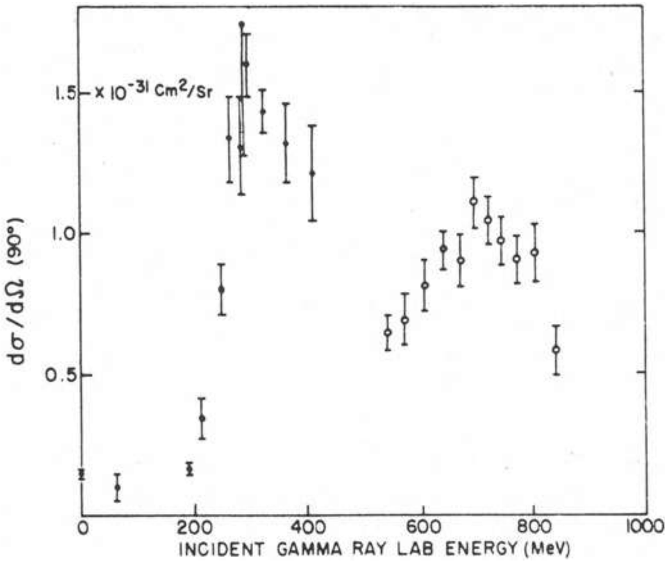

FIG. 6. The differential cross section for the scattering of high-energy photons by protons at 90° in the center of mass system. Based on figure in Steining, Loh and Deutsch, *Phys. Rev. Letters*, **10**, 536 (1963).[10]

Scattering from Moving Electrons Compton backscattering of low-energy photons by high-energy electrons can produce photons with energies comparable with those of the electrons. Milburn[10] and Arutyunian et al.[11] pointed out that backward scattering of an intense polarized laser beam by a beam of high energy electrons could produce a useful beam of monoenergetic photons of intermediate energy. The maximum energy of the backscattered photons is given by

$$h\nu' = h\nu \frac{4(E/mc^2)^2}{1 + 4h\nu E/(mc^2)^2} \tag{12}$$

where E is the total energy of the electron. For photons from a ruby laser ($\lambda = 6943$ Å, $h\nu = 1.79$ eV) the photons backscattered from 6-GeV electrons will have energies of 848 MeV. Photons from a ruby laser interacting with the electron beam at the Stanford Linear Accelerator Center produced monoenergetic polarized photons of 1.44, 2.8, and 4.7 GeV for the study of photon interactions in a hydrogen bubble chamber.[12] Higher-intensity facilities for producing intermediate-energy photons for photonuclear research has been proposed by Italian and U.S. groups.[14] These facilities would use photons from high-intensity lasers interacting with 1.5 GeV and 2.5 GeV electron beams in storage rings.

Proton and Deuteron Compton Effect Particle-like scattering of high-energy photons by protons and deuterons has been observed and has been referred to as the proton and deuteron Compton effect. The kinematic equations are identical to those for electrons except that the mass is that of the proton or deuteron.

Although the cross sections are smaller than that for electrons, by the square of the ratio of the masses, the scattering is easily distinguished by the characteristically higher energy of the radiation at large angles. At energies above the pion threshold, the cross section is dominated by pion nucleon resonances. The experimental cross sections for the scattering by protons, as presented by Steining, Loh, and Deutsch,[15] are shown in Fig. 6. Some experimental results and calculations on the coherent scattering from deuterium are described by Jones, Gerber, Hanson, and Wattenberg.[16]

Measurements at photon energies up to 7 and 16 GeV and comparisons with theoretical predictions of the vector dominance model have been reported by groups from Hamburg[17] and Stanford.[18]

COMPUTERS

Introduction A computer may be defined as a device capable of solving problems by accepting data (input), performing prescribed operations on the data (processing), and providing the results of these operations (output). The basic distinction between electronic calculators, which also fit this definition, and computers is that the latter provide speed in performing complex operations, virtually infinite program and data storage, and the ability to interact with the environment (including other computers) on a real time basis.

Computers may be hydraulic, mechanical, electromechanical, or electronic devices. They are broadly classified as being *digital*, *analog*, or *hybrid*, i.e., analog and digital linked together. The first two types differ fundamentally in the manner in which data are stored and operated upon. Analog computers operate on continuous variables, in the form of voltage or current (the electrical analog of a number or physical quantity), that represent continuous data. Digital computers operate on discrete numerical data represented by a series of binary digits. The data and instructions are stored internally and are indistinguishable in memory. Digital computers perform calculations by adding binary numbers according to instructions derived from coding an arithmetical expression or series of expressions (an algorithm) that represent the problem to be solved. Even though the problem may include differential or trigonometric expressions, each is reduced to simple addition or subtraction (addition of the complement) since addition is the only direct operation a digital computer can perform. Instructions, which are written sequentially, are executed sequentially (one at a time). Calculations usually culminate in a numerical display or graphical representation of the results. Because of the sequential nature of the digital process, the amount of time spent in solution is proportional to the problem complexity. Analog computers, on the other hand, are composed of elements which perform summation, integration, multiplication and differentiation directly. Rather than a serially coded algorithm, the instructions are in the form of basic modifications of the analog computer's circuitry by a user-wired patch board panel. There is no internal data or program storage as such. Instructions are executed effectively simultaneously (in parallel) while the solution is displayed in graphical form in continuous fashion. Since operations are performed in parallel, increased problem complexity demands more computer components, not more time. Solution time is therefore a function of the time characteristics of the problem, not the machine. The speed of the analog computer, therefore, is orders of magnitude faster than the digital computer in solving complex problems that involve calculus. This speed is paid for by a precision of results that is orders of magnitude less than for a digital computer. Hybrid computers attempt to combine the best features of both types i.e., the speed of the analog with the precision of a digital. This is brought about through a digital "front-end" which is used to set up and check out the analog computer and its program. The actual computation time is equivalent to that of a pure analog machine, but the total time (including set-up time) is significantly reduced. Indeed, problems may be solved that would be cost prohibitive on a digital computer and, for all practical purposes, impossible to set up on an analog computer.

As described below, in physics all three types of computers are utilized. Digital computer applications range from theoretical calculations to pure data collection and experiment control. Applications of analog computers involve primarily solutions of differential equations which serve as models of physical systems. Hybrid systems come into play for extremely complex simulation. Examples include determination of tactical envelopes for missiles, optimization of control settings in a nuclear power plant, and development of chemical kinetic models. Whatever the branch of physics, one can be sure that computers today play some significant role.

Computers of the Past The abacus has been

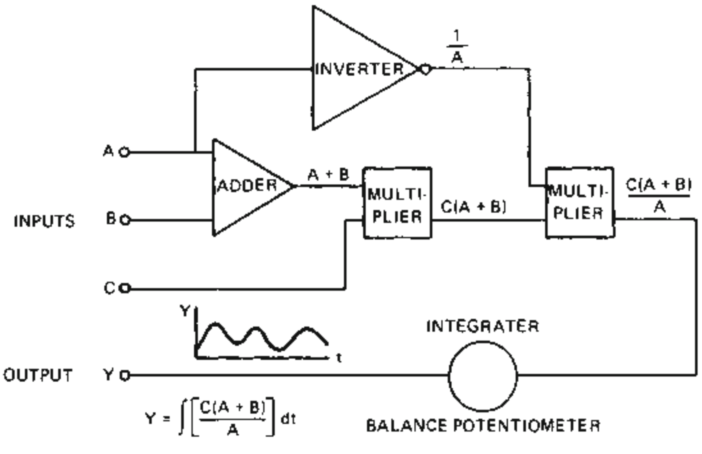

FIG. 1. Typical analog computer configuration to solve the equation for *y*. Requires: 1 adder, 1 inverter, 2 multipliers, 1 integrator.

called the earliest computing machine. For more than 3000 years after the recording of its invention, this was the sole device available to aid in arithmetic calculations. Finally, in the year 1642, a Frenchman, Blaisé Pascal, invented the first mechanical adding machine. His stylus operated "arithmetic machine" had the ability to handle carry overs from one column to the next. Nearly 200 more years elapsed before C. X. Thomas, also a Frenchman, working on a concept proposed by the German, Gottfried Wilhelm Leibniz, built an "arithmometer" in 1820 which, besides addition and subtraction, could perform multiplication and division using the concept of repeated addition and subtraction.

While this was going on, an independent development in the weaving industry saw Frenchmen Jacques de Vaucanson, in 1741, and Joseph Marie Jacquard, in 1804, use holes punched, first in metal drums, later in punched cards, as the control or programmer for textile looms. On a more esoteric plane, Englishman Charles Babbage, in 1823, began construction of his "difference engine." This device, based on the fact that an equation of degree *n* will have a constant *n*th difference, was used to make calculations for trigonometric and logarithmic tables. Babbage succeeded in constructing a machine to solve a second degree equation. But his "analytical engine," which had a memory, control, an arithmetic unit, and an input/output section could not be built at that time with sufficient precision to produce reliable results. Earliest analog computers of the type designed by Vannevar Bush and others in the 1930's actually followed these same mechanical principles until electronics began to take over in the late forties. This activity was culminated perhaps by the Maddida, which appeared in 1951. Analog computers since that time have differed mainly in the application of advanced modular electronics and in linkages with digital computers. Developments of calculators after Pascal and Thomas are not reliably documented. Two American mechanical adders, which spawned present day companies, are worthy of mention, however. These include the Felt "macaroni box" made in 1885 by a firm which later became the Victor Comptometer Corporation, and the "listing accountant" made by a forerunner of the Burroughs Corporation.

The real push behind the development of modern digital computers came about because of U. S. Government requirements, first to count people and tabulate corresponding data; later, during World War II, for developing artillery trajectory tables and performing calculations for the Manhattan project. In preparation for the 1890 census, it became clear that, using available counting and sorting techniques, it would be nearly time to perform the 1900 census before 1890 figures could be determined. Herman Hollerith, who had worked for the census office and was a mechanical engineer, solved the problem by devising a punched card, which could contain all pertinent data, and a series of machines for punching, counting and sorting. Using this equipment, census figures were published in less than three years with unheard-of accuracy. Hollerith revised his punched cards in 1894. They contained 80 columns, each with holes for 0 through 9; this is exactly the format in predominant use today. Hollerith's efforts eventually led to the formation of the International Business Machines Corporation, the world's largest manufacturer of computers. Tremendous quantities of work have been accomplished and are still possible using punch card techniques. However, this methodology is practical only for sorting, counting and selecting in a limited number of ways.

Electronic and electrical techniques were required to make practical, accurate computations of the vast quantities of data to solve problems and prove theories which today serve as the cornerstone of modern science. These machines are based upon the foundations laid by George Boole, who pioneered in the field of symbolic logic, and Allan Turing, who hypothesized a universal computer. George Boole's algebra provides a mechanism for representing logic in mathematical symbols and rules for calculating the truth or falsity of statements. Digital computers carry out these operations an infinite number of times. Allan Turing's paper, "Computable Numbers," in 1937, described a hypothetical Turing machine that can solve any type of mathematical problem which can be reduced to coding in a given set of commands within the memory capacity of the machine.

First application of these principles resulted in the Bell Telephone Laboratories relay computer in 1939. Five years later, in 1944, the second significant relay computer, which was also the first general purpose digital machine, was constructed at Harvard by Professor Howard Aiken, with funds provided partially by IBM. Known as the Mark I, this machine was really a huge electro-mechanical calculator. The Electronic Numerical Integrator and Calculator, "ENIAC," the first electronic computer, was developed in 1946 by J. P. Eckert and J. W. Mauchly of the Moore School of Engineering in Philadelphia. Funds were provided by the U. S. Army with the promise that the machine would be suitable for calculating ballistic tables. This machine contained 18,000 vacuum tubes which replaced the former mechanical relays as switching elements. As might be expected, it was huge, weighing over 30 tons, and terribly unreliable. Nevertheless, it existed until 1955 after over 80,000 hours of operation had been logged.

Development proceeded thereafter at a much more rapid rate. IBM continued work, producing the Selective Sequence Electronic Calculator

(SSEC) in 1947. The Moore School developed a second machine known as the Electronic Discrete Variable Computer (or EDVAC) which became operational in 1952. EDVAC is accepted as the first stored program computer. Unlike earlier machines which were programmed at least partially by setting switches or using patch boards, this machine and all others which were to follow, stored instructions and data in identical fashion. EDVAC used acoustical delay lines, which were simply columns of mercury through which data passed at the speed of sound, as the main memory. This type of storage has given way to magnetic core memory and semiconductor memory in computers of today.

In 1946, John Von Neumann, a mathematician at the Institute of Advanced Study (IAS), Princeton, New Jersey, presented a paper entitled "Preliminary Discussion of the Logical Design of an Electronic Computing Instrument." This paper, which was prepared jointly under a contract with the U. S. Army, suggested the principles under which all digital computers which followed would be built. This included internal program storage, relocatable instructions, memory addressing, conditional transfer, parallel arithmetic, internal number base conversion, synchronous internal timing, simultaneous computing while doing input/output, and magnetic tape for external storage. An IAS computer, employing most of these concepts, actually went into operation in the early fifties. All machines which followed used virtually the same principles. UNIVAC I (Universal Automatic Computer) was the first commercially available digital computer (circa 1950). This machine was a direct descendent of ENIAC and EDVAC, having been built by Remington Rand following acquisition of the Echert-Mauchly Computer Corporation. Eventually, 48 UNIVAC I's were built making Remington Rand the number one computer manufacturer until International Business Machines (IBM) began in earnest in 1954 with the introduction of its 700 line. This machine and its successor, the 650, made IBM the number one computer manufacturer in the world, a position which it holds today.

Digital Computer Hardware As shown in Figs. 2 and 3, general-purpose digital computers are comprised of four basic components: an arithmetic or computing unit, a high speed internal storage unit, input-output devices, and a control unit. Data and instructions are indistinguishable within the computer; both are represented by binary patterns of semiconductor or magnetic core states. Each binary unit is called a "bit". A fixed number of bits is referred to as a computer "word". A word is, generally, the smallest directly addressable whole unit of memory. The number of bits in the word determines the accuracy of the basic machine and its cost. Small word machines are employed in real world applications to control processes and make basic decisions. These small machines are referred to as minicomputers. Large word computers serve as theoretical number crunchers, often with smaller machines preprocessing input data or controlling output devices. Computer word size ranges from eight bits, or a single word accuracy of one part in 256, to sixty bits for an accuracy of one part in 2^{60} or a maximum positive decimal number of about 1 152 921 504 000 000 000.

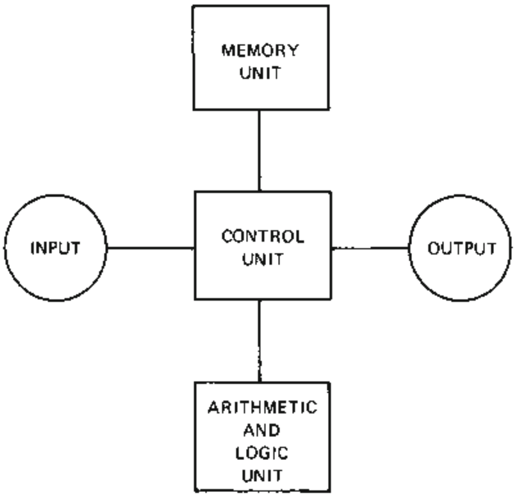

FIG. 2. Basic configuration of a digital computer. Problems are of the form
Input A = 3.0, B = 4.0
Output C = SQRT (A * A + B * B)

In setting (programming or coding) instruction sequences, the user arranges for the control unit to determine, through an instruction decoder, whether the instruction itself refers to some memory location where data resides or calls for some basic arithmetic or logical operation to be performed. These operations are performed between data registers. Registers always provided include: an accumulator, a program counter, a memory address indicator, and an overflow indicator. Operations themselves may modify the stored instructions by performing calculations on them, branch to a new set of instructions, and/or cause the machine to interact with the outside world. Response from this interaction may cause the machine to "decide" what operations to perform next depending upon the options built into the program. The computer can make no decision of its own accord; it is simply directed to "conclude" which one of a given set of alternatives best fits a given situation. This being the case, it is important to remember that computers don't solve problems, people that program them do. The advantage possessed by the computer is speed of operation. Even the slowest machines can perform an addition of two numbers in less

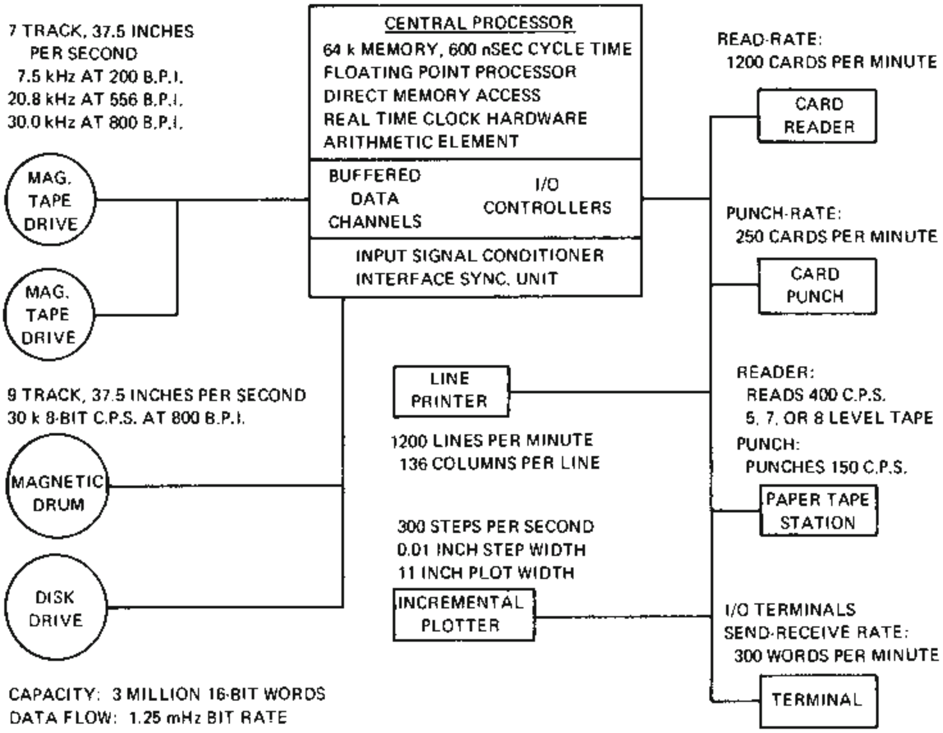

FIG. 3. Typical 3rd generation, medium size computer.

than 3 microseconds. Using special circuitry, multiplication of any two numbers takes less than ten microseconds. These arithmetic functions, plus logical operations like AND, OR, XOR, repeated thousands of times in one second enable the machine to use iterative techniques to do all operations necessary for calculating mathematical tables, as well as to keep up with the real world in monitoring and control applications where data at rates of up to 100,000 characters per second are encountered.

Figure 3 shows the configuration of a typical third generation, medium size machine (first introduced after 1968, and employing medium scale integrated circuitry with a multiprogramming operating system). Its purpose is to show the diversity of peripheral gear which is tied to a computer and the speed at which this equipment operates. The numbers shown are representative and by no means show the highest capacities available. This configuration will support a dedicated operation (one user at a time) or several users simultaneously in a multiprogramming or time shared mode. These latter terms refer to the ability of the system to run more than one user program simultaneously. The difference between time sharing and multiprogramming, as the terms are usually used, is that several users are connected simultaneously to the system in time sharing, while more than one program is run at the same time under multiprogramming. This assumes, of course, that no single program requires total system resources for more than a small time period. Hardware controllers have been optimized to take advantage of this usual case and permit virtually simultaneous user access to the central processor.

Digital Computer Software Computer *software* refers to all programs which direct machine activities. This software can be generally divided into three classes: an operating or executive system; language assemblers, translators and compilers; user applications programs, mathematical program libraries, and data analysis packages. The first class generally goes under acronyms similar to Disk Operating System (DOS), Mass Storage Operating System (MSOS), Real Time Executive (RTE), UNIX, CPIM, or other such names. It is the function of this master software to schedule users and users' programs, allocate processor and peripheral resources, perform internal "housekeeping," and handle emergencies. It is the operating system that permits time sharing and multiprogramming to be carried out. All but the most basic systems offer this software. The second software class operates within or is subject to the OS. It includes such things as FORTRAN (Formula Translator) compilers, BASIC (Beginners All-Purpose Symbolic Instruction Code) interpreters, a system editor, and an assembler.

These and other conversion programs reside within the machine and are used to change English language statements or data to machine bit patterns which are decoded internally. Standards have been devised for FORTRAN, BASIC, ALGOL, COBOL, PL/I and other languages so that a program written on one manufacturer's machine will (almost) run on another. Assembly languages, however, are machine independent and in no way compatible. The final class of software includes those programs designed and written to accomplish a specific task. For example: find the roots of a polynomial expression of a certain type; or given a set of data describing the elongation versus temperature and load of an alloy specimen, as well as known constants, calculate stress and strain values at the break point. On small dedicated computer systems a single application package may be the only software loaded other than input/output drivers which communicate with peripheral devices. This is true of microprocessors, experiment controllers, front-end machines and, in general, all computers that have less than 8000 words of central memory. Software clearing houses that supply computer programs worldwide for exclusive manufacturers, as well as for general use, have gone into business to meet the demand for application programs.

Scientific Applications The evolution of the digital computer and modern scientific knowledge are closely linked. We have seen that development of the ENIAC was the direct result of the need to perform millions of calculations

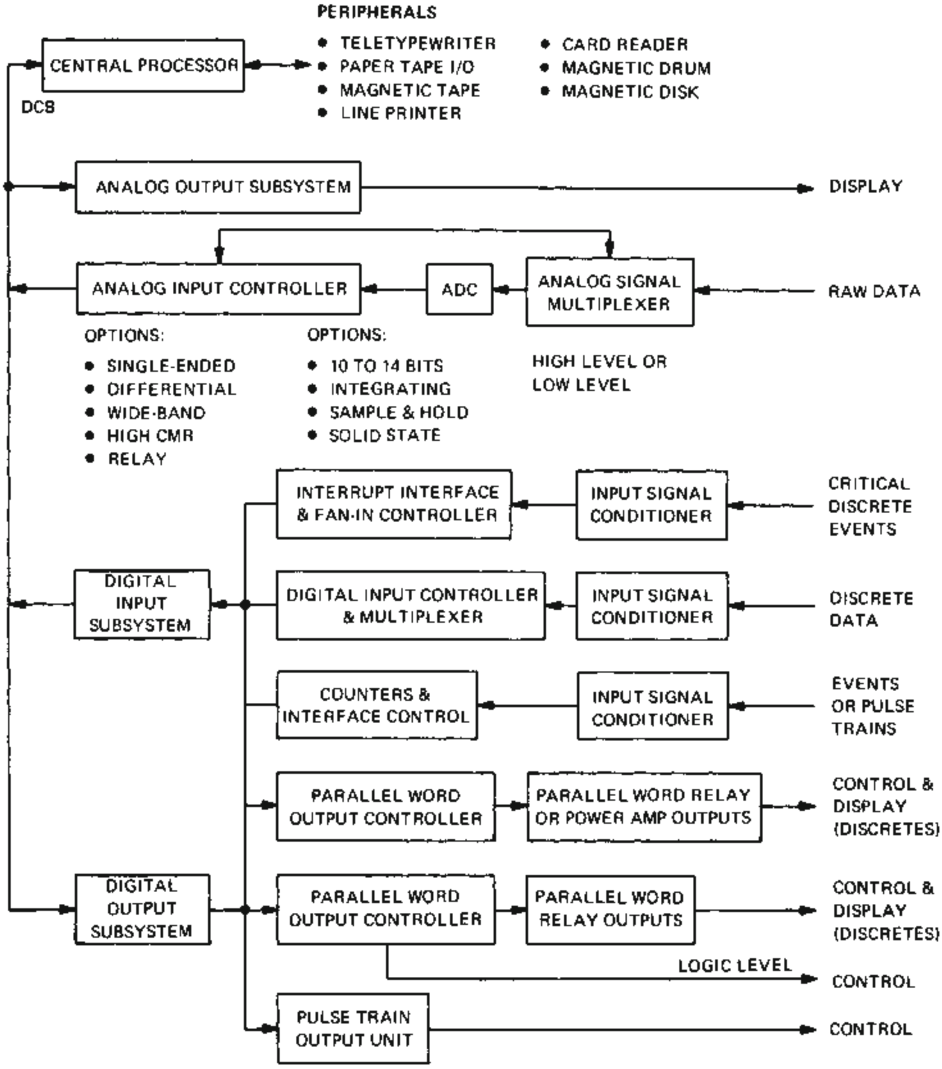

FIG. 4. Typical data acquisition and analysis configuration.

on the Manhattan Project that would have taken years during a time when years were not available. A second example is the fact that no attempt was made to find a rigorous solution of the "3-Body Problem" of celestial mechanics until the advent of the modern digital computer. Today these servants of scientists and engineers are found in their smaller versions in more physics laboratories than not. Theoretical data or that produced by passive data acquisition devices is then transmitted to larger systems for further processing. Where theoretical studies are involved, large systems perform computations that would simply not be practically possible otherwise. Examples of typical applications or user software now in use to solve particular scientific problems include programs to: calculate Cartesian coordinates for all atoms in a molecule, compute numerical eigenvalues and matrix elements for the quantum mechanical radial equation, and determine the coulomb lattice energy of an ionic crystal. There is also a complete system of programs for quantitative theoretical chemistry. In the area of direct data acquisition and instrument control, small computer systems of the configuration shown in Fig. 4 are most often employed. These systems are built as part of electron spin and nuclear magnetic resonance spectrometers, all types of optical spectrophotometers, real time Fourier analyzers, and x-ray spectrometers, to name only a few. They are used to control and acquire data in applications ranging from remote seismic stations to laboratory spark chamber monitoring. In physics education they find uses ranging from teaching basic principles to performing semiautomatic pattern recognition for bubble chamber film data analysis.

Personal Computers The latest entry into the computer industry is the personal computer (PC). In the past eight years, the personal computer has moved from the province of hobbyists to take a place in business offices and private homes. Thousands of people are purchasing personal computers each week, not only low-end microcomputers, but also high-end systems such as the IBM PC. They have proven to be incredibly popular and several hundred thousand of them were sold in only the past three years. Further, for every person who buys a personal computer, two or three more are considering a purchase. This has been attributed to both the videogame explosion and the public's recognition of the power and capability of the microcomputer. These computers are reasonably inexpensive, and designed to allow the average person to learn about the computer and use it to solve everyday problems.

The personal computer is a genuine computer which has most of the features of the big mainframe computers. As computers became smaller, they also became faster, and today processing time is measured in microseconds and nanoseconds (billionths of a second). For example, the IBM PC is four times faster than the IBM 360. It can be equipped with enough capacity to handle the accounting and inventory control tasks of most small businesses. It can also perform computations for engineers and scientists, and it can be used to keep track of home finances, budget management, investment analysis, and many, many other applications ranging from educational to recreational to business functions.

Figure 5 shows the basic configuration of a personal microcomputer. Like other computers it consists of the CPU and the system board that connects the CPU to other devices for input and output (I/O) and storage. There are three basic types of memories: ROM (Read-Only Memory) which is not user-modifiable and which contains programs you would never want to change; RAM (Random Access Memory), in which data can be either written or read and which can be thought of as the microprocessor's work space; the mass storage device, which al-

lows the storing of great quantities of information and programs on magnetic disk or tape outside the computer itself. Parallel and serial interfaces connect the microcomputer to other devices such as printers, keyboards, etc. Early computers had only serial ports that received and returned data serially, or, one bit at a time. Processing time in computers was vastly improved by the development of parallel ports which handle and move large amounts of data simultaneously. The process utilizes electrical conductors (printed circuit boards) that will carry multiple electrical impulses around the innards of the computer. These multiple impulse carriers are known as busses, and several used together are called bus systems.

Although the industry is yet dominated by 8-bit microprocessors, all new systems are 16-bit. Within a few years they will have replaced the 8-bit processors as the brains of medium-priced personal computers. The power of the 16-bit microprocessor—with its ability to address over 1 million characters of computer memory—is needed to run software that is more flexible and easier to use than the software commonly used today. Microprocessor chips (such as Intel Corporation's 8088 and Motorola's MC68000) are already turning up in the more advanced personal computers and manufacturers of the Corvus Concept and the IBM Personal Computer, among others, are putting that power to good use. Further, during 1984 the first 32-bit biped PCs will be introduced. This will put on a desk top computer power of limitless dimensions to most people.

Future Developments As we have shown, the computer industry only recently celebrated its silver anniversary, yet there is almost no area of our life which it has not affected. In terms of dollars, the hardware, software and manpower investment is well over 100 billion. Despite these impressive figures, which point to success, many serious shortcomings in computer technology and its applications are evident. Most experts agree that hardware advances at the component level will slow down. Peripheral devices such as line printers, card readers, etc., appear to be approaching their capacity limits. These devices must give way to new technologies or be reduced in cost to the extent that they can proliferate infinitely. It seems more reasonale that they will give way to more direct user involvement through input/output terminals and direct data transfer. The direction of central and mass memory supports this contention since costs, speed, and density continue to improve drastically. This trend will continue for some time with mechanical devices giving way to new approaches employing chemical and basic molecular phenomena. Real future advances will occur as a result of changes in arithmetic and control elements and in the software systems which drive computers. Micro-processors made possible by large scale integrated circuitry (LSI) will allow "intelligence" to be built into all computer peripherals and make possible special purpose modules to be employed for handling a single arithmetic or control function. This will permit many more operations to be performed in parallel, thus decreasing time to solution. The low cost of these modules will cause them to begin to appear almost everywhere. Few scientific instruments will be built where they are not employed as control elements or to provide at least intermediate results directly. Software development will respond to make use of this distributed internal processing and permit better machine and manpower utilization. More emphasis will be placed on high level languages similar to PL/I and on the development of applications packages which will handle a given problem from start to finish. Less distinction will be made between systems and language routines. A single tool will be available to accomplish a given objective. Problems like code conversions between units will be handled by hardware. Modular programming techniques and top-down software management will harness software development making distributed intelligence and application of automatic data processing a reality in all fields.

CONDENSATION

The condensation of a vapor to form a liquid, amorphous phase, or crystal generally occurs by the mechanism of nucleation and subsequent growth. *Nucleation* is a thermally activated process which leads to a stable fragment of the condensed phase. In the absence of surfaces of certain condensed phases, reactive foreign molecules, or other potent catalysts to the nucleation process, it is usually the slower step and occurs at an appreciable rate only under conditions considerably removed from equilibrium. For the usual case where nucleation catalysts are present, the process is characterized as heterogeneous nucleation, but if there are no such catalysts at all, it is called *homogeneous nucleation.*

In principle, statistical thermodynamics would appear to offer the most attractive approach to nucleation rate theory. For example, Band[1] and Hill[2] have given formal treatments for the equilibrium concentration of clusters of molecules in a vapor. However, the internal partition functions have thus far eluded quantitative evaluation. Further, in the case of metallic systems, there is at present little knowledge of the electronic energy states in clusters containing only a few atoms.

Accordingly, even to the present day, most treatments follow that of Volmer[3] and coworkers, who evaluated the free energy of formation of clusters by ascribing macroscopic thermodynamic properties to them. Thus the free energy of a droplet is described as the sum of a surface term (area times surface tension) and a volume term (volume times the negative bulk free energy change). An attractive feature of this approach is that it permits ready visualization of the origin of the free energy barrier to nucleation in terms of the maximum in the above sum as a function of size. However, a very unattractive aspect is that the calculated size of the critical nucleus, i.e., the cluster size at the top of the free energy barrier, is only about 100 molecules, which leads one to doubt the applicability of macroscopic concepts in the present examples. Nevertheless, following standard methods,[4] this spherical-drop model leads directly to a rather simple expression for the rate of homogeneous nucleation of droplets from supersaturated vapor.

The remarkable agreement[3,5] of this macroscopic theory with observations of the critical supersaturations for appreciable nucleation rate of various liquids in cloud chambers stood for many years as the basis of our knowledge of nucleation. For example, referring to the data of C.T.R. Wilson[6] and of C. F. Powell[7] who reported a "fog limit"* for homogeneous nucleation of water droplets at a supersaturation ratio of about 5.0 at 275 K,† agreement with the macroscopic theory is excellent.[8] However, in recent years it has been pointed out[4,5,8,9,10] that the external partition functions for free translation and rotation had been neglected in the macroscopic theory. When these contributions are included, the theory predicts a critical‡ supersaturation ratio of about 3.0 for water vapor at 275 K, in poor quantitative agreement with Powell's observations. This situation stimulated a great deal of experimental and theoretical work in the field. On the experimental side, two new techniques were developed to measure critical supersaturation ratios for homogeneous nucleation: (1) the diffusion cloud chamber[11,12,13] and (2) the supersonic nozzle method.[14,15] Work is still in progress, but it appears that virtually all substances, with the possible exception of argon[16] and ammonia,[17] follow the original macroscopic theory which ignores the contributions from free translation and rotation. On the theoretical side, much effort has been directed toward ascertaining the magnitude of another correction to the macroscopic theory, which tends to counterbalance the effects of free translation and rotation. This is termed the *replacement partition function*, and it describes the free energy due to the six internal degrees of freedom the isolated cluster does not have because it is not a part of the bulk phase. Efforts to calculate this quantity by classical phase integral methods[18,19,20] have not been entirely successful because of the great difficulty in defining an embedded cluster in a liquid. In fact, some treatments yield large[18,19] replacement partition functions while others give small ones.[20] However, the calculation is somewhat easier for crystals, and the result[20] indicates that the replacement partition function is not large and hence does not appreciably offset the contributions from free translation and rotation in the case of homogeneous nucleation of crystallites from the vapor. Unfortunately, there are very few experimental data for this case, but the theoretical result has been used in astrophysics calculations.[21] In summary, one might con-

*Denoting production of many droplets, i.e., of the order of 10^7 cm^{-3}.

†Meaning the ratio of actual to equilibrium partial pressure of vapor.

‡Critical for a given, usually high, nucleation rate.

clude at the present time that the good agreement between the original macroscopic theory and experiments on liquids is fortuitous and due to (i) a large replacement partition function or (ii) the circumstance that the macroscopic surface tension overestimates the droplet entropy and underestimates the potential energy.[22,23]

One might think that the above issues could be settled by computer calculations using fairly realistic potential functions to calculate the cluster free energies, and much work has been done in this area.[22,24] In one of the more elaborate efforts,[25] Monte Carlo methods were used to calculate the surface tension and chemical potential of bulk Lennard-Jones argon, and these results were applied to estimate the free energy of isolated L-J argon droplets. The resulting free energies of formation were then compared with the actual Monte Carlo free energies of isolated liquid L-J argon clusters. It was found that the contributions from free translation and rotation were required to describe the Monte Carlo cluster data. This means that, unlike the case of physical experiments on real liquids, the original macroscopic theory must be modified by the contributions from free translation and rotation in order to describe L-J argon. However, a major shortcoming of this and other computer calculations is that pairwise potentials were used. This is a serious difficulty in view of the importance of three-body potentials in describing surface properties.

On the other hand, molecular dynamics computer simulations on highly supersaturated L-J vapor have been useful in predicting spinodal decomposition as another condensation mechanism, which is an alternative to nucleation and growth of droplets. Spinodal decomposition has long been recognized[26] as a mechanism of phase separation in binary solid systems in which there is no symmetry change and for which the free energy-composition curve is continuous. At high supersaturations the initial phase is unstable for all infinitesimal density variations having a wavelength greater than some "critical" wavelength. The molecular dynamics work on L-J vapor[27] exhibited the characteristic interconnected structure of vapor and liquid, and the process was consistent with the recognized laws for spinodal decomposition. There are at present few, if any, physical experiments to corroborate this prediction.

A considerable amount of work has been done on the heterogeneous nucleation of metal crystals from thermal vapor beams onto substrates.[5,28,29] Many theoretical approaches follow a macroscopic treatment similar to that outlined above. In view of the high supersaturation ratios, typically 10^6-10^{33}, and resulting small critical nucleus sizes (1 to 5 atoms) involved in this case, an "atomistic" theory[30,31] has been introduced to replace the older macroscopic theory. However, quantitative agreement with observed supersaturations for appreciable nucleation rate is not good for either the old or the new theory. Nevertheless it has been established that in most cases nucleation occurs by the processes of adsorption, surface diffusion, and statistical fluctuation to form the crystalline nuclei. Also, particularly for metals on ionic and semiconductor substrates, many nucleation rates have been quantitatively measured by means of both kinematic and *in situ* transmission electron microscopy. Indeed, within the past 15 years there has been a remarkable increase in the degree of sophistication of such experiments. Ultra high vacua (of the order of 10^{-10} Torr) leading to much greater cleanliness are now common and the characterization of both substrate and deposited crystallites has been greatly enhanced by the application of LEED, Auger spectroscopy, mass spectrometry, transmission electron diffraction and a host of other new techniques. However, interpretation of the rate data is often obscured by ignorance of the actual (often defect) sites for nucleation on the substrate surface. Interestingly enough, it has been possible to demonstrate and measure the mobility of small (10–20 atom) clusters,[32] e.g., of solid gold on the (100) surface of alkali halide crystals. In connection with the above experiments, selected-zone dark-field electron microscopy (SZDF) has been developed[33] to determine the crystal structure, orientation, and degree of perfection (absence of twinning) of each of the myriad of isolated microcrystallites on a substrate surface. SZDF employs annular objective-lens apertures of different geometries to select only a well-defined number of Debye-Scherrer diffraction rings. Thus it is possible to map, within one image, all specimen areas of random azimuthal orientation that diffract into the selected range of Bragg angles.

Historically, field emission microscopy has yielded interesting information on nucleation of metals in deposition from the vapor onto clean tungsten field emitter tips.[34,35] Many metals, e.g., copper and gold, form critical adsorbed coverages of several monatomic layers before nucleation of three-dimensional crystals occurs. This is the Stranski-Krastonow mechanism[36] for deposition of crystals from the vapor and may be expected for situations in which the binding energy of the adatoms to the substrate is high. In some cases the initial monolayers are thought to be pseudomorphic* with the substrate.[37] Another important mechanism for cases of high binding energy is the monolayer-by-monolayer overgrowth (MO) or Frank-van der Merwe mode,[38] which also may occur with pseudomorphism in the initial monolayers. In some cases the monolayers are initiated by nucleation of 2-dimensional discs.[39] Misfit dis-

*Of exactly the same crystal structure and lattice parameter.

locations to accommodate the strain are thought to form at the substrate-deposit interface as the deposit thickens. Ultimately, the deposit becomes noncoherent with the substrate and attains its natural crystal structure. The misfit dislocations even facilitate phase transformation in cases where the bulk deposit and substrate are of different crystal structure. Examples of the MO mechanism are SnSe on (001) SnTe and Pt on (001) Au.[39] Recent studies[39] have provided much quantitative information, such as Burgers vector, spacing and mechanism of origin, on misfit dislocations. Also, they have revealed ordered structures of monolayer or sub-monolayer thickness, e.g., Pb on the (111) Ag surface. This may have a relevance to the preparation of epitaxial thin films.

Growth is the process by which the stable nuclei continue to grow and thereby consume the supersaturated vapor. In general, several mechanisms are involved in the growth process, and some of these are thermally activated. However, the free energies of activation are usually low, and hence most growth processes proceed at an appreciable rate even under conditions close to equilibrium where the gross evaporation flux almost equals the gross condensation flux. The first step in growth from the vapor is thought to be adsorption of the impingent molecule. The bulk of both experimental and theoretical work indicates that the impingent atoms or molecules are in most cases thermally accommodated and adsorbed at the surface before being either re-evaporated or integrated into the liquid or crystalline structure.

In the case of liquids, it is thought that the molecular mobility is sufficiently high that the adsorbed molecules are taken almost immediately into the liquid structure. However, the situation is quite different for crystals, whose surfaces are still most conveniently visualized in terms of the original "atomic building block" model of Kossel[40] and Stranski.[41] Thus, in the case of certain surfaces of high index, the kinks in the steps of the atomically rough surface provide ready sinks for adsorbed molecules. In fact, experiment shows that such planes grow so rapidly that they quickly eliminate themselves from the crystal growth form, leaving the smoother surfaces of low index. These closely packed planes contain no steps and kinks to serve as sinks for the admolecules diffusing on the surface. Accordingly, for a perfect crystal, it is thought that growth can proceed only by nucleation of new monomolecular layers, whose edges provide the sinks, and their lateral propagation. A typical supersaturation ratio for appreciable growth by this mechanism is of the order of 1.5 for molecular substances, and there is a large amount of theoretical and experimental evidence[42] for the general occurrence of this type of growth from the vapor at high supersaturation.

The fact that real crystals do indeed grow at much lower supersaturation ratios, of the order 1.01, continued to present a theoretical problem for many years. Then in 1949 Burton, Cabrera, and Frank[43] showed that certain emergent dislocations of the screw orientation* must provide a source of monomolecular steps for growth at low supersaturations. Further, they demonstrated that the resultant growth form on the close-packed surface, the growth spiral, cannot exterminate itself as do other types of steps or ledges. In the usual case, crystal growth by this mechanism is thought to be controlled by surface diffusion of the admolecules. Experimental verification of these predictions is now voluminous.[44]

Inasmuch as crystal growth from the vapor is linked to the motion of monatomic steps on the surface, it becomes of great interest to describe the step dynamics arising from surface diffusion gradients. Most of the studies thus far have been concerned with the closely related reverse process of crystal evaporation, and the theory of step dynamics has been extended to cover stationary-state evaporation[5] with the steps emanating from crystal edges or from dislocations and the bunching of evaporation steps under transient conditions.[45,46] Recently the evaporatior rate from (100) KCl single crystal surfaces w1s measured as a function of undersaturation under stationary-state conditions,[47] and remarkable agreement with theory was found. In general the evaporation coefficient† will lie between $\frac{1}{3}$ and 1 and the catalytic effect of dislocations in providing additional monatomic steps disappears as the undersaturation ratio rises above 0.9. Similarly, in recent electron microscope work on vacuum evaporated (100) NaCl surfaces,[48] the transient fluctuations in monomolecular step spacing caused by a sudden change in evaporation temperature were quantitatively described by the theory.

Most of the theoretical studies of growth in deposition on substrates have not been in terms of the fundamental microscopic mechanisms, namely, the screw dislocation spiral mechanism and the monatomic disc nucleation mechanism. Perhaps this is because of the experimental difficulty in observing growth rates of the small crystallites on substrates. Rather, the main thrust of the theoretical work on growth thus far has had as its goal prediction of the crystallite number density and size distribution. This is of course a complicated problem affected by nucleation, depletion of the adatom concentration about growing clusters, surface dif-

*Or dislocations with a component of the Burgers vector perpendicular to the surface.

†Ratio of actual to equilibrium gross evaporation flux.

fusion fields, competition between crystallites for the available adatoms and the effect of capillarity[†] in retarding crystallite growth. Most of the studies have confined themselves to the case of incomplete coverage of the substrate. There are many treatments of these phenomena, but one useful approach is numerical integration of the divergence of cluster current in size space with consideration of capillarity in the boundary conditions.[49] The results give a reasonably good description of the observed time evolution of cluster size distribution.[‡]

In the interests of brevity, the complex and interesting effects relating to diffusion in the vapor,[5] adsorption of impurities,[5] chemical reaction,[42] and dissipation of the heat of condensation[8] have been omitted from the above discussion. The subject of crystal growth morphologies is, of course, huge and beyond the scope of the present article.[5,42]

CONDUCTIVITY, ELECTRICAL

The electrical conductivity of a substance is an intrinsic property denoting the ability with which electric charge can flow through the substance. The meaning of a definite conductivity is most commonly associated with solids, although electrical conduction also occurs in liquids, electrolytes, and ionized gases. Electrons are the usual charge carriers in solids, but ionic conduction can be important for some materials, such as the alkali halides and compounds of the KAg_4I_5 class, while proton conduction has been demonstrated for ice.

A suitable definition for the electrical conductivity of an isotropic material is provided by *Ohm's law*. This is the statement that the direct-current density **J** within a conductor is proportional to the dc electric field **E**. At a given temperature and pressure, the constant of proportionality is the electrical conductivity σ, thus:

$$\mathbf{J} = \sigma \mathbf{E}$$

If the material is *anisotropic*, the magnitude of **J** depends not only on the magnitude of **E** but on its direction as well. **J** and **E** are then nonparallel for some orientations of the material, and σ is a tensor of the second rank. Since the ability of a material to conduct electricity is influenced by the mechanisms resisting the flow of charge, it is also helpful to work in terms of the *specific electrical resistivity* ρ, which is the reciprocal of σ.

If a voltage V between the ends of a conductor of length ℓ and uniform cross-sectional area A maintains a current I through the conductor, Ohm's law may be set in a practical form by combining the relations:

$$\mathbf{J} = \sigma\mathbf{E}, \quad \mathbf{E} = \frac{V}{\ell}, \quad \mathbf{J} = \frac{I}{A}, \quad \sigma = \frac{1}{\rho}.$$

Hence, $I/A = (1/\rho)(V/\ell)$ or $V = I(\rho\ell/A)$, so that $V = IR$. The ratio $\rho\ell/A$ is called R, the *electrical resistance* of the conductor. It is a property of a particular sample because it involves the dimensions A and ℓ, whereas ρ and σ are intrinsic properties of the constituent material. With V in volts and I in amperes, R is measured in ohms. The electrical resistivity $\rho = RA/\ell$ is then given in ohm-meters if A is in square meters and ℓ in meters, while σ is given in $(\text{ohm-meters})^{-1}$ or mhos per meter.

The major factors determining the magnitude of the electrical conductivity for a material are the conduction electron, or ion, density, and the nature of the interatomic forces (which decide the mobility of the charge carriers). The actual current flow also depends on the size of the electric field. Part of the energy carried by the current is inevitably consumed as Joule heat, but there are many commercial devices in which such heat or light conversion is put to good use (electric fires, toasters, cookers, light filaments, fuses, etc.). The rate per unit volume at which energy is converted is I^2R or VI, in units of watts or joules per second. Where it is required to add resistance to an electrical circuit, resistors made of carbon, graphite, or metallic alloys are often selected. When wires of low resistance are needed, copper is the most common material ($\rho \sim 1.7 \times 10^{-8}$ Ωm) although at ordinary temperatures silver is the best conductor ($\rho \sim 1.6 \times 10^{-8}$ Ωm).

In alternating current circuits, the conductivity or resistivity depends on the frequency of the applied electric field. Deviations from the dc value are not appreciable at low frequencies but may become significant for microwave or higher frequencies.

Gases can conduct electricity if they are ionized. Practical applications include discharge tubes, electronic vacuum tubes, and the arc discharge. Natural ionization of the atmosphere results from cosmic rays or radioactive sources in the ground. The conductivity of the atmosphere is quite low at ground level but it increases rapidly with altitude up to 50 km because of the greater cosmic radiation and the lower density of scattering centers.

Many liquids or solutions known as electrolytes (besides a few solids) can be decomposed by an electric current into charged particles called anions and cations. Such processes involve a transfer of matter through the conductor. The conductance of a solution is defined as the current flowing per unit charge applied to the electrodes immersed in the solution and per unit concentration of electrolyte between the electrodes. It is dependent on the number and mobilities of the ions in the solution. In geophysics there is an important field of activity involving electrical conductivity measurements of the surface layers of the crusts of the earth and the moon. But in laboratory physics a principal area of activity lies in solid-state physics, and the remainder of this article will be devoted to such work.

Solids may be classified in various ways (according to their binding, ductility, crystalline or amorphous nature, etc.) but a particularly convenient one considers their conduction properties. Two distinctive qualities are of interest: (i) the magnitude of σ or ρ at a suitable comparison temperature (say, room temperature), and (ii) the temperature variation of σ or ρ. Three broad classes of solids may thus be characterized:

(1) *Metals* having high conductivities (when pure) with specific resistivities at room temperature lying in the range 1.6×10^{-8} Ωm (for silver) to 140×10^{-8} Ωm (for manganese and plutonium). Less pure metals and alloys may have resistivities up to 1000 times bigger than these, while very pure metals at liquid helium temperatures may have resistivities 10^5 times smaller. In general, the resistivities of metals increase with temperature. Also the effect of adding small amounts of impurities is that of adding a temperature-independent contribution to the resistivity (*Matthiessen's rule*). If ρ_T is the thermal resistivity and ρ_0 is the impurity contribution, the total resistivity $\rho = \rho_T + \rho_0$.

(2) *Semiconductors* which have much lower conductivities than do metals, with resistivities in the range 10^{-5} to 10^5 Ωm. In contrast to metals, their resistivities decrease with rising temperature and very rapidly with the addition of impurities.

(3) *Insulators* whose electrical conductivities are lower still, with resistivities ranging from 10^6 to 10^{16} Ωm. The feeble conductivity is little affected by impurity additions, but it improves rapidly as the temperature is raised.

The basic differences between these classes can be understood in terms of atomic and quantum-mechanical principles which explain the varying degree of availability of free electrons or mobile ions for conduction purposes. The main features are outlined below. An additional distinct class, that of superconductivity, which is a spectacular quantum situation in which the low-temperature state of a number of metals and a few semiconductors is one of zero resistance, is not dealt with here (see SUPERCONDUCTIVITY).

Metals are characterized by their high density of free conduction electrons which transport negative charge ($-e$) through the interstices of the crystal lattice composed of positive ions. The origin of the conduction electrons is some or all of the valence electrons from the previously neutral atoms. In the absence of an electric field the conduction electrons have high-speed random motions ($\sim 10^6$ ms^{-1}), and there is no directed charge flow in any particular direction. But when a field is applied, they acquire a steady net drift, of much lower speed than their kinetic speeds, in exactly the opposite direction to the field. Part of the kinetic energy gained in this way is just as steadily returned to the lattice as Joule heat via collision processes with it. The current density **J** is then $-ne$**v** for an electron density of n per unit volume and drift velocity **v**. The mean-free path between collisions commonly exceeds 100 interatomic spacings at room temperature, or even 10^7 spacings in pure metals at low temperatures. An assumption that the collisions are elastic permits the use of a relaxation time τ, at least under the conditions pertaining at high temperatures for thermal scattering or at low temperatures for impurity scattering. τ is a quantity inversely related to the probability per unit time of an electron undergoing a collision. A basic equation of the form $\rho = m/(ne^2\tau)$, in which m is closely related to the electron mass, can be derived without undue difficulty, so that the major barrier to calculating the magnitude of ρ or σ of a metal revolves about understanding and evaluating τ and its temperature dependence.

A conceptual hurdle here is how can an electron proceed more than a few atomic spacings without being scattered by the massive, closely spaced lattice ions? The reason is that the lattice is the source of a periodic electrostatic field and that the electron waves are modulated by a function having the same period. It can then be shown that such waves are propagated with no loss of energy if the lattice is perfectly periodic. In practice, the lattice potential is never perfect, for it is disturbed by both thermal vibrations and impurity atoms or physical defects. The thermal vibrations are quantized with discrete energy values called *phonons*. For temperatures exceeding the Debye temperature, the phonon density and hence the electron-phonon scattering and the resistivity increase almost in proportion to T. At very low temperatures, $\rho_T \propto T^5$. This is directly related to the T^3 variation in the Debye phonon spectrum which gives a T^3 specific heat at low temperatures. Obtaining realistic estimates of the resistivity magnitudes for metals other than the alkali metals remains a matter of considerable complexity. A useful semiempirical equation is the Grüneisen-Bloch relation because it facilitates the analysis and discussion of experimental data. It represents the variation of the thermal resistivity of a wide selection of metals rather well. In some multivalent metals, but more importantly in semiconductors, electrons behave in a way which can be described by the displacement of positive charge carriers called *holes*. Experimental results are sometimes discussed as if the current arises from the flow of electrons and holes.

Magnetic metals have additional resistive effects due to scattering from localized-spin assemblies. An important field is *dynamic cooperative phenomena* using the divergence of $d\rho/dT$ at magnetic critical points as a tool. Another active field is the *Mott transition* whereby certain materials can be switched from a metallic to an insulating condition using small changes of pressure, temperature, or electron-to-atom ratio. Resistivity is also used to study atomic order-disorder and crystal phase transitions, and in the study of defect production and migration. Its temperature dependence is used for *thermometry* and its strain dependence for strain gauges. Its magnetic-field dependence is the basis of the major field of *magnetoresistivity*. When used together with the related Hall effect, valuable information is provided on the effective sign, number, and mobility of the charge carriers in semiconductors, while in metal single crystals certain details of the FERMI SURFACE can be deduced.

Insulators and *pure semiconductors* have no free electrons available at 0 K for conduction. Diamond, silicon, and germanium are typical examples. All their four valence electrons are fully occupied in forming chemical bonds in the solid. Raising the temperature energizes, and frees for conduction duties, a small fraction of these electrons. The empty energy states left behind (holes) also aid in conduction. The fraction of carriers is ~ 1 in 10^9 for Si and Ge at room temperature; the number varies approximately as $T^{3/2} \exp(-\Delta E/2kT)$ where ΔE is the energy to excite a bound electron and k is the Boltzmann constant. ΔE is ~ 5.2, 1.2, and 0.75 eV for diamond, silicon, and germanium respectively. The chief difference between the behavior of diamond (a typical insulator) and pure Si and Ge (typical semiconductors) is the greater ease with which temperature can induce conduction in the latter. The conduction of semiconductors, but not of insulators, is readily improved by adding certain impurities. This has the effect of introducing electrons (n-type) or of producing holes (p-type). Such materials are termed *extrinsic*, or *impurity, semiconductors*. Their great practical application is in transistors and diodes. (See SEMICONDUCTORS and SOLID-STATE PHYSICS.) Conduction in many semiconductors and insulators is also increased by the photoelectric action of incident light radiation (see PHOTOCONDUCTIVITY).

CONSERVATION LAWS AND SYMMETRY

Among the most basic of the laws of nature are the conservation laws. A conservation law is a statement saying that in a given physical system under specified conditions, there is a certain measurable quantity that never changes regardless of the actions which go on within the system. One of the tasks of physics is to determine which properties of a given system are actually conserved during the course of specific types of interactions.

In classical (pre-quantum and pre-relativity) physics the following conservation laws were known:

(1) *Conservation of Mass.* In a closed system the total mass is constant.

(2) *Conservation of Energy.* In a closed system the total amount of energy is constant. (In relativistic physics these two laws are identical due to the equivalence of mass and energy.)

(3) *Conservation of Momentum.* The total momentum of a system is constant if there is no outside force acting on the system. (The momentum of an object is defined as the mass multiplied by the velocity; the total momentum of a system is the vector sum of all the individual momenta of the parts.) This means that the internal forces within the system have no effect on the total momentum.

(4) *Conservation of Angular Momentum.* The total angular momentum of a system is constant if there is no torque acting on the system from without. (The angular momentum of an object relative to a point O is its momentum multiplied by the perpendicular distance between its line of travel and the point O.)

Historically these laws arose out of a philosophical belief that the universe was created with a definite amount of motion which remained unchanged following the original creation. As a result of the attempt to clarify what kind of "motion" was conserved, the concepts of momentum and kinetic energy were developed. As early as the seventeenth century Huygens recognized that both momentum and kinetic energy were conserved in the collisions of elastic balls. During the nineteenth century the existence of various "forms" of energy was recognized, and the more general law of conservation of energy arose out of measurements involving reactions in which energy was transformed from one form to another (e.g., mechanical, thermal, electrical). The measurements showed that within certain limits of accuracy, the total amount of energy in a closed system was unchanged by any of the reactions tested.

From the modern point of view, it is not necessary to make measurements involving large-scale systems, for the macroscopic behavior of matter results from the interactions between relatively few types of elementary particles. Therefore it is sufficient to investigate the conservation laws as they apply to the basic interactions between fundamental particles.

At present only four fundamental types of interactions have been recognized: the gravitational, the weak nuclear, the electromagnetic, and the strong nuclear force. Each of these interactions individually obeys the classical conservation laws. As a result those laws must be obeyed in any kind of action involving interactions between particles. This rule, of course, applies to every activity in the universe.

For example, when we compress a spring, the potential energy of the spring is increased. The modern picture visualizes the energy as stored in the electric fields between the atoms of the spring as they are pushed closer together. Thus, the spring's potential energy is ultimately of an electrical nature.

The development of a conservation law is seen to depend on a combination of theoretical concept and experimental measurement: The scientist forms in his mind an abstract concept of a physical quantity such as energy which can be measured by a given set of operations. Measurements then show that (within limitation of error) this quantity is conserved under a given set of conditions. Modern measurements have been able to verify the conservation laws to very high degrees of accuracy. Conservation of energy has been verified to within 1 part out of 10^{15}, using the Mössbauer effect. (See Reference 1.)

An important function of the conservation laws is that they allow us to make many predictions about the behavior of a system without going into the mechanical details of what happens during the course of a reaction. They give us a direct connection between the state of the system before the reaction and its state after the reaction. In particular we can say that any action which violates one of the conservation laws must be forbidden. For example, many problems involving rotational or orbital motion are solved very simply by noting that the motion must be such that the angular momentum of the system remains constant. No further information concerning the forces or accelerations are required.

With the development of the Hamiltonian method of solving physical problems, and particularly with the growth of importance of quantum mechanics, it has become clear that the conservation laws are closely connected with the concept of symmetry in nature. This is based upon the fact that the interaction between two or more objects can be described in terms of a potential energy function (more precisely a mathematical function called the Hamiltonian of the system). If the potential energy of the system is known for any position of these objects in space, then we can predict the future motion of the objects in the system.

A detailed solution of the equations of motion will describe the position and velocity of each particle in the system at any time during their interaction. However, certain general predictions can be made without going through the complete solution of the problem, if there exist certain symmetries of space and time. The following examples illustrate the various geometrical or space-time symmetries encountered in classical physics.

(1) If the potential energy function does not depend explicitly on one of the space coordinates, then the component of momentum associated with that coordinate never changes—it is a constant of the motion, and thus obeys a conservation law. Particular situations most frequently encountered are as follows:

(a) An object moves in a three-dimensional space where its potential energy is a constant. That is, the expression describing the potential does not explicitly contain the coordinates x, y, or z, so it does not make any difference where the origin of the coordinate system is located. This means that the description of the system is invariant with respect to a translation of the origin of the coordinate system in any direction. As a result of this symmetry the momentum of the object in all three dimensions is constant. In technical terms, conservation of linear momentum is associated with translational symmetry (or homogeneity) of space.

(b) An object moves in a world which is flat, so that the force of gravity is in the vertical (z) direction. The potential energy depends on the height of the object above the ground, but does not depend on its location in the horizontal plane. That is, the description of the system is invariant with respect to a translation of the coordinate system in the x-y plane. Since there is symmetry in the x-y plane, the object's momentum is conserved as far as motion in that plane is concerned, but is not conserved in the z direction.

(c) Two spherical bodies interact in such a way that the potential energy depends only on the distance between the two bodies. This interaction has spherical symmetry, and the system is invariant with respect to a rotation of the coordinate system about any axis; i.e., it is isotropic. In spherical coordinates there are two angle variables, so there are two components of angular momentum to be conserved. As a result the two bodies orbit around their common center of mass in such a way that the magnitude of the total angular momentum is constant, while the plane of the orbit in space never changes. In other words, conservation of angular momentum is due to the isotropy of space.

(2) If the interaction between two objects

does not depend explicitly on the time coordinate, then the actions which take place do not depend on when we start measuring time. That is, the properties of the system are invariant with respect to a translation of the origin along the time axis. As a result of this symmetry it is found that the total energy of the system is conserved. In other words, conservation of energy is associated with a symmetry in the time dimension.

Use of a four-dimensional coordinate system in accordance with Einstein's principle of relativity allows us to combine both space and time symmetries into a single space-time symmetry. With this scheme the three dimensions of space and the one dimension of time make up a single four-dimensional space. Analogously, energy is regarded as the fourth component of a four-dimensional vector whose first three components are the three components of momentum. The symmetries associated with translation and rotations in this space-time continuum are called Poincaré symmetries.

With the rise in importance of elementary particle physics, a new type of symmetry has proven very valuable. These are "internal symmetries"—symmetries involving the internal properties of particles. The general philosophy underlying the study of elementary particle interactions is that anything can happen as long as it is not expressly forbidden by a law of nature. Among elementary particles there are a vast number of conceivable reactions that might take place. However, most of these reactions are forbidden by "selection rules," which are essentially conservation laws. For example, the total electric charge during any reaction cannot change. This rule immediately forbids such reactions as the conversion of a neutron into a proton plus a neutrino. An electron must also be created to balance the charge.

The study of symmetries and conservation laws is especially important in elementary particle physics because the exact nature of the strong and weak nuclear interactions is not known, so one cannot make detailed predictions concerning the results of reactions involving these forces. However, a knowledge of symmetry principles gives one a great amount of general information concerning these reactions, so one can estimate the probability of each reaction taking place.

While a law such as conservation of energy is true for all interactions, a number of the internal symmetries lead to conservation laws that do not apply to all of the four fundamental interactions. Such symmetries are therefore called "approximate" or "broken" symmetries. The implication of the term is that undistorted nature would be completely symmetrical, but that the presence of certain forces leads to an asymmetry, or breaking of the symmetry.

One important class of conservation laws has to do with the constancy of certain essential numbers during the course of particle reactions. These "number laws" are as follows:

(1) *Conservation of Electric Charge.* If P is the number of positive charges in a system, and N is the number of negative charges, then $Q = P - N$ is the net number of charges. The charge number Q is unchanged by any reaction. For example, the creation of a positive charge must always be accompanied by the formation of an equal negative charge (e.g., an electron-positron pair is created by a high-energy photon). Conservation of electric charge is associated with a symmetry property of Maxwell's equations known as gauge invariance, which states that the absolute value of the electric potential (as opposed to the relative value) plays no part in physical processes. In quantum field theory conservation of electric charge is connected with the fact that the properties of a system of particles do not depend on the phase of the wave function describing the system.

(2) *Baryon Conservation.* Baryons are a class of elementary particles including the proton, the neutron, and several heavier particles such as the lambda, the sigma (plus, minus, and neutral), and the omega (minus). Baryons are particles that interact with the strong nuclear force. Each baryon is given a baryon number 1, each corresponding antibaryon is given a baryon number −1, while the light particles (photons, electrons, neutrinos, muons, and mesons) are given baryon number 0. The total baryon number in a given reaction is found by algebraically adding up the baryon numbers of the particles entering into the reaction. During any reaction among particles the baryon number cannot change. This rule ensures that a proton cannot change into an electron, even though a neutron can change into a proton. Similarly, to create an antiproton in a reaction, one must simultaneously create a proton or other baryon. Baryon conservation ensures the stability of the proton against decaying into a particle of smaller mass. Both conservation of charge and baryon conservation are absolute selection rules.

(3) *Lepton Conservation.* Leptons are a class of light particles that include electrons, neutrinos, and muons, as well as their antiparticles: the positrons, antineutrinos, and antimuon. Each lepton is assigned a lepton number +1, while each antilepton has a lepton number −1. All other particles have lepton number zero. In any reaction the algebraic sum of lepton numbers is conserved. This rule determines the course of beta decay, muon decay, and other reactions governed by the weak interaction.

(4) *Isospin Conservation.* Since the strong nuclear force acting between two neutrons is found to be the same as the force acting between two protons, as well as between a neutron and a proton, it is found useful to consider the neutron and proton as two states of the same

particle (the *nucleon*). These two states are considered to differ only by the different positions of a vector property called the *isospin* (or isotopic spin). This concept arises by analogy from the fact that two electrons in an atom can exist in a state of spin "up" and spin "down." These two states are indistinguishable in the absence of an external magnetic field because of symmetry of space with respect to rotations around an arbitrary axis. Similarly, a proton is a nucleon with isospin "up" and the neutron is a nucleon with isospin "down." In particle physics, whenever a system can exist in a discrete state, characterized by a definite quantum number, there exists a property (in this case isospin) that is conserved. In the absence of electromagnetic interactions there is no difference between the two isospin states because of symmetry with respect to rotation in "isospin space." Electromagnetic interactions make a difference because of the charge on the proton. Isospin conservation implies equality of *p-p*, *n-n*, and *n-p* forces, except for the effect of the electromagnetic force. Thus isospin conservation is only an approximate symmetry.

(5) *Strangeness Conservation. Strangeness* is a property of elementary particles found useful to classify hyperons (particles more massive than nucleons) into families. Each particle is assigned a strangeness quantum number S which is related to the electric charge Q, the isospin number T, and the baryon number B by the formula $Q = T + (S + B)/2$. ($T = \frac{1}{2}$ for a proton and $-\frac{1}{2}$ for a neutron; other particles may have $T = 0$ or 1, depending on the type.) Strangeness is conserved in reactions involving the strong interaction. The selection rules resulting from strangeness conservation are very important in explaining why some reactions take place much more slowly than others.

A very important set of conservation laws is related to symmetries involving parity (P), charge conjugation (C), and time reversal (T). Parity is a property that is important in the quantum-mechanical description of a particle or system of particles. It relates to the symmetry of the wave function that represents the system. If the wave function is unchanged when the coordinates (x, y, z) are replaced by $(-x, -y, -z)$ then the system has a parity of +1. If the wave function has its sign changed from positive to negative (or vice versa) when the coordinates are reversed, then the system is said to have a parity of −1. During a reaction in which parity is conserved, the total parity number does not change.

Changing the coordinates (x, y, z) into $(-x, -y, -z)$ converts a right-handed coordinate system into a left-handed coordinate system. In terms of symmetry, the meaning of conservation of parity is that in any situation where parity is conserved, the description of the reaction will not be changed if the word "left" is changed to the word "right" and vice versa. This means that such reactions can provide no clue that will distinguish between the directions right and left.

Prior to 1956 it was believed that all reactions in nature obeyed the law of conservation of parity, so that there was no fundamental distinction between left and right in nature. However, in a famous paper by C. N. Yang and T. D. Lee it was pointed out that in reactions involving the weak interaction, parity was not conserved, and that experiments could be devised that would absolutely distinguish between right and left. This was the first example of a situation where a spatial symmetry was found to be broken by one of the fundamental interactions.

The principle of charge conjugation symmetry states that if each particle in a given system is replaced by its corresponding antiparticle, then nobody will be able to tell the difference. For example, if in a hydrogen atom the proton is replaced by an antiproton and the electron is replaced by a positron, then this antimatter atom will behave exactly like an ordinary atom, if observed by people also made of antimatter. In an antimatter universe the laws of nature could not be distinguished from the laws of an ordinary matter universe.

However, it turns out that there are certain types of reactions where this rule does not hold, and these are just the types of reactions where conservation of parity breaks down. For example, consider a piece of radioactive material emitting electrons by beta decay. The radioactive nuclei are lined up in a magnetic field which is produced by electrons traveling clockwise in a coil of wire, as seen by an observer looking down on the coil. Because of the asymmetry of the radioactive nuclei, most of the emitted electrons travel in the downward direction. If the same experiment were done with similar nuclei composed of antiparticles and the magnetic field were produced by positron current rather than an electron current, then the emitted positrons would be found to travel in the upward, rather than in the downward, direction. Interchanging each particle with its antiparticle has produced a change in the experiment.

However, the symmetry of the situation can be restored if we interchange the words "right" and "left" in the description of the experiment at the same time that we exchange each particle with its antiparticle. In the above experiment, this is equivalent to replacing the word "clockwise" with "counterclockwise." When this is done, the positrons are emitted in the downward direction, just as the electrons in the original experiment. The laws of nature are thus found to be invariant to the simultaneous application of charge conjugation and mirror inversion.

Time reversal invariance describes the fact that in reactions between elementary particles, it does not make any difference if the direction of the time coordinate is reversed. Since all reactions are invariant to simultaneous application of mirror inversion, charge conjugation, and time reversal, the combination of all three is called *CPT* symmetry and is considered to be a very fundamental symmetry of nature.

A new type of space-time symmetry has been proposed to explain the results of certain high-energy scattering experiments. Called "scale symmetry," it pertains to the rescaling or "dilation" of the space-time coordinates of a system without changing the physics of the system. (See Reference 5.) Other symmetries, such as chirality, are of a highly abstract nature, but aid the theorist in his effort to bring order into the vast array of possible elementary particle reactions.

It is a temptation to say that "nature likes symmetries" in order to prove the theoretical necessity of a conservation law. However it must be realized that only human beings can like anything. The search for symmetries in nature leads to experiments that test the theory. While a symmetry idea may suggest a conservation law, the conservation law must be tested by experiment to see if nature really behaves that way in a given situation.

CONSTANTS, FUNDAMENTAL*

Perhaps the basic concept of modern physical theory is that there are fundamental entities underlying the structure of the universe, that the atoms and molecules which make up the universe are the same and that they obey the same physical laws in the farthest galaxy as they do on earth. One of the goals of science then, is to determine the relationships that exist among these entities so that the set of independent fundamental quantities may be reduced to a minimum. Thus, 19th Century chemistry led the way to the understanding of the vast complexity of matter in terms of less than a hundred "irreducible" chemical elements. In the first half of the 20th Century physics expanded the realm of chemistry by the discovery of isotopes and increased the number of atomic elements to perhaps a thousand, but at the same time reduced the number of fundamental entities to three—the proton, the neutron and the electron—out of which the thousand different isotopes and billions of different molecules are built. Physics is now undergoing a similar simultaneous expansion and reduction. The electron has been joined by the muon, tauon, and neutrinos (and their anti-particles) and the proton and neutron are now associated with pions, kaons, and an array of "strange" and "charmed" mesons and baryons. On the other hand there are emerging theories of a more elementary particle—the quark—out of which the observed particles are "constructed," and the "grand unification," which will describe gravitation, electromagnetism, and the strong and weak nuclear forces as manifestations of a single entity.

It is this universality that makes it meaningful to attempt to measure the properties of these fundamental entities with all possible precision. Although the numerical values of such quantities as the mass and electric charge of a proton, or the velocity of propagation of electromagnetic waves are expected to be constant in time and space, our knowledge of those values is variable and in general changes with each new measurement. There is no valid evidence however, at the present time, that these quantities are not indeed constant. It may be that the values of the fundamental constants are changing over time scales comparable to the age of the universe and that this so-called "age" is not the indication of a time of beginning but is instead the time constant describing the rate of change of an ever-existing, unending universe. Should such a model indeed prove correct, it would not in principle change the concept of fundamental, invariable constants of nature. Although it would fundamentally alter our theoretical understanding, and change the models one uses for the description of the universe, these changes would still be described in terms of fixed parameters, which are then the fundamental constants.

Fundamental Units The existence of fixed, constant values associated with atomic and molecular physics has important implications for metrology and the establishment of units and standards. By the end of the nineteenth century it had already been suggested that basic

*Preparation of this article supported in part by National Bureau of Standards (US), Grant NB81-NADA2087.

physical processes could be used to establish standards for units of measurement. Since atomic processes are uniquely reproducible and universally available they can be better standards than arbitrary artifacts such as a metre bar or a prototype kilogram. Artifacts can change or be damaged. Does the build-up of a surface film or the absorption of atmospheric gases on the prototype kilogram change the size of the international unit of mass? How can we know? On the other hand the mass of a proton, or of a carbon atom in its ground electronic state, is invariant, the same everywhere and at all times. Similarly, one may consider the Bohr radius or the Compton wavelength of an electron as a fundamental atomic unit of length. Because of the limitations of measurement, the use of such microscopically small standards of length would sacrifice accuracy in the comparison of the standard with macroscopic lengths. The optical interferometer, however, allows one to compare lengths in terms of the wavelength of a monochromatic light source. Therefore in 1960 the platinum-iridium prototype metre bar in use since 1889 was replaced by the definition of the metre as the length equal to 1650763.73 wavelengths in vacuum of the electromagnetic radiation arising from the optical transition $2p_{10}$-$5d_5$ in the isotope of krypton of mass 86.

The unit of time (the second) is ordinarily defined as 1/86400 of a day. As the available precision of measurement and the demands of science and technology increased, this definition proved inadequate, since the period between two successive noons changes throughout the year due to the nonuniform speed of the earth in its orbit around the sun. The specification was made more precise, and the "day" was defined for time-keeping purposes to be the mean length of the day averaged over a full year. However, this definition also proved inadequate because the rotation of the earth on its axis is not constant: as a result of tidal forces between the earth and the moon and of physical changes in the distribution of mass over the earth's surface during the year, the rate of rotation is decreasing by 0.03% per million years and varying seasonally by as much as a part in 10^7. In 1960 the international General Conference on Weights and Measures therefore adopted a definition of the second as "the fraction 1/31556925.9747 of the tropical year for 1900 January 0 at 12 noon ephemeris time." This definition directly demonstrates one of the problems associated with nonatomic standards. The year (the time between successive vernal equinoxes) is not a constant so that the mean motion of the earth in its orbit must be specified at a specific instant. With the development of atomic clocks and the ability to make accurate and precise measurements of frequency it was clear that such clocks could provide convenient and reproducible standards for the measurement of time. Following the recommendation of the General Conference in 1964 an atomic definition of the second was internationally adopted in 1967: "the second is the duration of 9192631770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom" ($F = 4$, $m_F = 0 \leftrightarrow F = 3$, $m_F = 0$).

In the decade between 1972 and 1982 intercomparisons of the wavelengths of many absorption-stabilized gas lasers demonstrated their reproducibility at the level of parts in 10^{10} with stability of parts in 10^{11}. During the same period it became clear that the ^{86}Kr transition defining the metre could not provide an unambiguous standard of wavelength, because of its inherent spectral profile and lack of spectral purity, beyond the order of several parts in 10^9. At the same time, nonlinear optical techniques were being developed that provided efficient microwave harmonic generation. These, coupled with frequency synthesis developments and the inherent monochromaticity and stability of absorption-stabilized lasers, made possible the direct comparison of the frequency of optical transitions ($\lambda \sim 10^{-4}$ cm) with that of the cesium clock ($\lambda = 3.26$ cm). When both the frequency and wavelength of a wave are known its velocity is simply $c = \lambda f$. In this way the velocity of light was found to be $c = 299792458 \pm 1.2$ m/s. The precision of this result is limited not by the measurements themselves but by the inherent uncertainties associated with the krypton lamp. Such a situation implies that the wavelength standard should no longer be krypton but should instead be a much more reproducible and monochromatic laser. If, however, one can transfer frequency (or wavelength) measurements from the optical region to the microwave region and hence know the wavelength of the radiation used to define the duration of the second, or the frequency of the radiation used to define the length of the metre, is it necessary to have two separate standards? Should one not use a single atomic transition to define both the unit of length and the unit of time? In essence, why not define the metre in terms of the second and an accepted value for the velocity of light? This is exactly what has now been done and in October 1983 the metre was redefined by adopting $c = 299792458$ m/s as an exact quantity.

The unit of temperature is related in a less direct manner to atomic processes, but since the liquid or gaseous state of matter is a result of intermolecular forces, the realization of the international temperature scale is in principle also atomic, defined by fundamental constants, and reproducible without reference to a specific arbitrary artifact, by chosing the triple point of water to have an assigned temperature of 273.16 degrees Kelvin, exactly.

Only the unit of mass is defined on the basis of a man-made object; the kilogram is nothing more than the mass of the prototype platinum-iridium kilogram kept in the laboratory of the

Bureau International des Poids et Mesures in Paris.

These units and standards, which define the international metric system of units ("Système International" or SI), are not without significance to those English-speaking nations who have not yet adopted the metric system. There is no independent English system; the foot is internationally defined as 0.3048 m and the pound is exactly 0.45359237 kg (see Table 1).

Universal Constants In view of the attempts to replace arbitrary or man-made standards of measurement with standards based on atomic phenomena it is appropriate to ask whether there is a truly universal set of fundamental units of length, mass and time. The so-called Planck units are based on a recognition that the existence of the universe itself provides a basis for constructing such quantities. We may postulate that the universe contains matter and energy. The Newtonian constant of gravitation, G, is the fundamental quantity defining the interaction between matter in the large—without bringing into question its composition or internal structure. Similarly, Planck's constant (divided by 2π), $\hbar$, and the speed of electromagnetic radiation, c, are the fundamental quantities associated with light and electromagnetic energy. A more fundamental basis can indeed be found. In the special theory of relativity the constant c appears as a factor which unifies the description of space and time. Its numerical value depends on the units in terms of which one measures length and time. It has the dimensions of a velocity (length/time) but its identification with the velocity of electromagnetic radiation is a consequence of the theory and the fact that the photon has zero rest-mass. In the general theory of relativity the fundamental constant is G/c^4, determining the extent to which the energy density produces a curvature of space. The fundamental constant of the Planck radiation law (describing the distribution of electromagnetic energy and how it changes with temperature) is hc. In fact, the thermodynamics of black-body radiation requires, solely on the basis of dimensional analysis, that the constant hc must exist independently of quantum theory. From these three constants one may construct a quantity with the dimensions of a mass, $m^* = (\hbar c/G)^{1/2} = 21.8\ \mu g$, a quantity with the dimensions of length $l^* = (\hbar G/c^3)^{1/2} = 1.62 \times 10^{-35}$ m, and a quantity with the dimensions of time, $t^* = l^*/c = (\hbar G/c^5)^{1/2} = 5.38 \times 10^{-44}$ s. The physical significance of these quantities is not clear. The length l^* and the time t^* may be related to an ultimate quantization of space and time and may represent inherent limits of measurement, so that it would be impossible to distinguish two points which are closer together in space or time as separate points. The same kind of interpretation cannot be given to m^*, an object of that mass is within the range of size visible to the eye, certainly easily seen in a microscope of even low magnification, and would contain the order of 10^{17} atoms! It remains for future theorists to provide a meaning to these fundamental quantities.

Experimental Determinations The only test one has of validity of physical theory is the agreement between the results of measurements and the predictions of the theory. Discrepancies between theory and experiment may be due to experimental errors or to misinterpretation of the experimental results, or they can demonstrate the need for revision or rejection of the theory and its replacement by a new theory. The difficulties inherent in measuring physical constants to an accuracy of a few parts per million are great. Direct measurements of the mass of the electron or of the electronic charge are not as accurate as measurements which determine instead various combinations of these quantities. Whereas R. A. Millikan was able to measure the elementary charge on an electron in 1912 to one part in a few thousand (and this experiment can hardly be improved upon today), our current knowledge of the electronic charge, with an accuracy of approximately 1 part in 500,000, comes from combining the ratio of the Faraday constant to the Avogadro constant with measurements of the Sommerfeld fine structure constant, the gyromagnetic ratio of the proton, the Josephson effect, the realization of the SI ohm, the magnetic moment of the proton relative to the Bohr magneton, and a half-dozen or so other measurements which affect the final result to a greater or lesser degree. In fact, the present knowledge of the numerical values of all of the so-called fundamental constants of physics come from such indirect measurements. Of these physical constants, only the universal gravitational constant G is measured independently of the others. In the first place, no theoretical relation is known which relates G to the other physical constants,

TABLE 1. METRIC EQUIVALENTS.

1 inch	0.0254 m 2.54 cm
1 foot	0.3048 m
1 mile	1609.344 m
1 pound (avdp)	0.45359237 kg 453.59237 g
1 ounce (avdp)	28.349523125 g
1 pound (troy)	373.2417216 g
1 ounce (troy)	31.1034768 g
1 gallon (231 in^3)	3.785411784 L*
1 quart	0.946352946 L
1 ounce (fl)	29.5735295625 cm^3

NOTE These numbers are exact by definition. For most calculations they may be rounded off considerably.

The legal definition of length is in terms of the yard. 1 yard = 0.9144 m.

*L ≡ litre = 1 dm^3 = 1000 cm^3.

and in the second place, the accuracy with which G is known is at least an order of magnitude poorer than the accuracy of the atomic constants.

With the growth in our knowledge of natural laws and of the technical means of making precise physical and chemical measurements, an increasing number of relationships have been discovered between the fundamental constants of physics and chemistry. The situation regarding our knowledge of these constants is a spiderweb of interconnected data which can be visualized as a bridge truss made up of elastic members, or, more simply, an interconnected network of springs, in which the length of each member represents the experimentally measured relationship between constants, and the stiffness is a measure of the accuracy of this measurement. The problem is to determine the positions of the nodes of this network. One recognizes that the alteration of any one member will produce an effect which will be transmitted throughout the entire structure. This will be true whether we change the length of a member, or its stiffness, or remove it entirely.

In order to determine the values of the physical constants from such an overdetermined set of data, it has become common to use the method of least squares. This can be considered as equivalent to the problem of minimizing the stored potential energy in our multidimensional network. The fundamental requirement, however, is basically one of establishing a method of analysis which is consistent and independent of the choice of variables used to describe the situation. The method of least squares not only does this but also provides a procedure which yields "best" estimates for the values of the constants in the sense that these estimates are the most accurate. For these reasons, least squares adjustment has been used for all of the significant determinations of the values of the fundamental physical constants over the past 35 years.

Numerical Values The numerical values given in Tables 2 and 3 are based on the most accurate and consistent measurements available as of June 1982. Significant measurements are the frequency-voltage relation in a superconducting Josephson junction which determines the ratio $2e/h$; the Faraday constant, $N_A e$; the ratio of the magnetic moment of the proton to the magnetic moment of the electron μ_p/μ_e, or to the magnetic moment of the muon, μ_p/μ_μ; the proton magnetic moment measured in units of the Bohr magneton μ_p/μ_B, or in units of the nuclear magneton $\mu_p/\mu_N = (m_p/m_e)\mu_p/\mu_B$; the quantized Hall effect in semiconductors which yields e^2/h; and the Avogadro constant N_A. The spectroscopy of the energy levels of one-electron atoms (positronium, muonium, hydrogen, and deuterium) and of two-electron helium provide the basis for determining the Ryberg constant and the Sommerfeld fine structure constant. An accurate determination of the fine structure constant may also be obtained from the observed anomalous magnetic amount of the electron and (with less precision) from the anomalous magnetic moment of the muon. On the other hand, the agreement of the observed magnetic moment of the muon with that predicted by the theory of Quantum Electrodynamics (QED) and the value of α derived from the electron magnetic moment provides perhaps the most accurate verification of QED, and may be considered as providing a probe of the elec-

Second radiation constant	hc/k	$0.014388\ \mathrm{m \cdot K}$
	$N_{\mathrm{A}}hc$	$0.1196266\ \mathrm{J \cdot m^1 \cdot mol^{-1}}$
Gas constant	R	$8.3145\ \mathrm{J \cdot K^{-1} \cdot mol^{-1}}$
Boltzmann constant	k	$1.38066\ \mathrm{J \cdot K^{-1}}$

[a] Based on an analysis of the data available June 1982. The numerical values are expected to be accurate to within one or two units in the last digit given. All quantities are in SI (Systeme International) units:

C = coulomb	N = newton
G = gauss	T = tesla
Hz = hertz (cycles per second)	u = atomic mass unit
J = joule	W = watt
K = kelvin (degrees)	Wb = weber

tromagnetic interaction to distances as small as 10^{-20} m.

CORIOLIS EFFECT

A marksman fires his rifle due north. In the absence of wind, he might well expect it to travel in a straight line and land due north of him. But will it? The physicist would, in general, answer no on the basis that the earth is rotating and is not, therefore, an inertial frame of reference (see ROTATION—CIRCULAR MOTION). G. G. Coriolis first analyzed this effect in 1844, and he is acknowledged in its name. For large artillery projectiles this effect may be significant, but for hand carried weapons it is usually negligible. For instance, a typical .22-caliber rifle bullet might be horizontally deflected 0.2 meter in traveling one kilometer.

That a projectile will normally follow a path which is curved in the horizontal leads conversely to the idea that to follow a straight path over the rotating earth requires the application of a sidewise force. Even though this appears to violate Newton's first law (see DYNAMICS), it is perfectly true in a non-inertial system—hence, the reason that this force is sometimes called "fictitious."

A body which is moving with constant speed in a straight line in an inertial system is not accelerating and is subject to no net force. An observer in a rotating coordinate system will, however, observe the same object to follow a curved path. The observer may treat this apparent deflection from a straight line as an acceleration which is always perpendicular to the path of the object. It is called the Coriolis acceleration. The apparent force applied to the body to cause the deflection from a straight path into a curve is called the Coriolis force.

The true acceleration of a body moving with constant speed in a straight line in a rotating coordinate system is equal in magnitude to the apparent acceleration just described. An expression for it may be derived simply and quite rigorously, but not generally, for the case of a body moving with constant radial speed in a rotating system. It consists of two distinct components both easily evaluated for the case mentioned. One component arises from the change in direction of the radial velocity of the body, the other from its change in tangential velocity due to changing distance from the center of rotation (see ROTATION—CIRCULAR MOTION).

Suppose the rotating system has a constant angular velocity ω, and the body moves radially with constant speed v. It is initially at distance r_1 from the center of rotation with velocity $\bar{v}_1$. After a small time interval Δt, it is at distance r_2 with velocity $\bar{v}_2$ (see Fig. 1). The two velocities $\bar{v}_1$ and $\bar{v}_2$ are related since the final velocity $\bar{v}_2$ is the vector sum of the initial velocity $\bar{v}_1$ and the change in velocity $\Delta\bar{v}$. Refer to Fig. 2 for a vector diagram of the preceeding statement (see STATICS). If we consider instantaneous values, Δt approaches zero, the angle $\omega\Delta t$ approaches zero, and the chord Δv approaches its arc in length. We may then use the well known angle-arc relationship (arc length) = (radius) (angle in radians), and write

$$\Delta v = v\omega\,\Delta t, \text{ or } \Delta v/\Delta t = \omega v$$

Now $\Delta v/\Delta t$ is the acceleration component (a_1) resulting from the change in direction of $\bar{v}$.

The tangential velocity of a body equals the product of its angular velocity and its radius of rotation. Equating changes in these quantities yields

$$\Delta v_t = \omega(r_2 - r_1) = \omega\,\Delta r$$

Or, dividing by Δt

$$\Delta v_t/\Delta t = \omega\,\Delta r/\Delta t$$

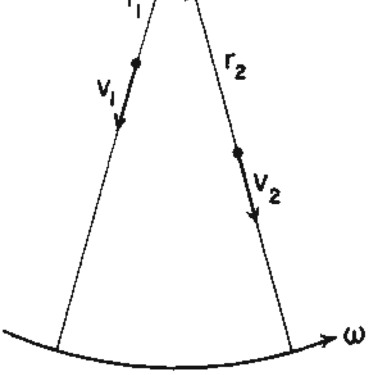

FIG. 1

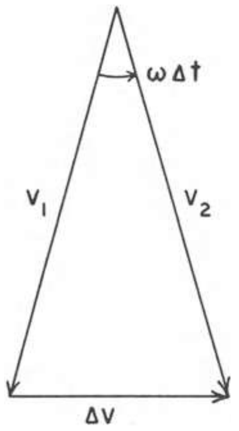

FIG. 2

Now $\Delta v_t/\Delta t$ is the acceleration component (a_2) arising from changing tangential velocity, and $\Delta r/\Delta t$ is the radial speed v. Hence a_2 also equals ωv.

Since both a_1 and a_2 lie in the same direction, being perpendicular to the radial velocity and to the right in the figure, their magnitudes may be added together with the sum equaling the magnitude of the Coriolis acceleration a_c

$$a_1 + a_2 = a_c = 2\omega v$$

Using Newton's second law $F = ma$, the Coriolis force is

$$F_c = 2m\omega v$$

The earth is not, of course, a rotating plane. The Coriolis acceleration reaches a maximum at the poles and vanishes at the equator. If v_h denotes horizontal velocity on the earth's surface, the resulting Coriolis acceleration may be evaluated by reference to Fig. 3 where ϕ is the latitude and v is the true radial speed with respect to the earth's axis.

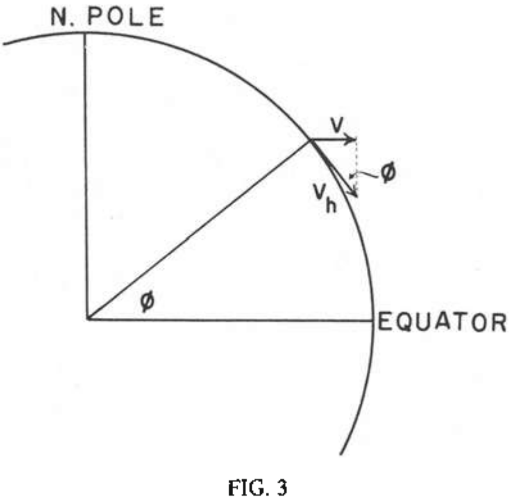

FIG. 3

$$v/v_h = \sin \phi$$

$$v = v_h \sin \phi$$

and the Coriolis acceleration becomes

$$a_c = 2\omega v_h \sin \phi$$

and the Coriolis force is

$$F_c = 2m\omega v_h \sin \phi$$

The Coriolis effect applies to any object moving on the surface of the earth, and a more general treatment will show it to be completely independent of the direction of motion. The quantity $2\omega \sin \phi$ is commonly known as the Coriolis parameter. Since the earth rotates 2π radians in 24 hours, or at a rate of 7.27×10^{-5} radians/sec, the parameter is quite small, and equals exactly 10^{-4} sec^{-1} at about $43\frac{1}{2}°$ latitude. This small value for the Coriolis parameter means that in everyday life its effects are small and go largely unnoticed. For instance, the Coriolis force on an automobile driving at turnpike speeds might typically be five newtons. The acceleration can cause considerable deflection of long range artillery, however, and appropriate corrections must be made.

The Coriolis effect plays a large role in the great mass movements of the oceans and atmosphere. In the northern hemisphere, the apparent deflection is always to the right of the direction of motion. For example, air drawn toward a center of low pressure is deflected to the right and eventually flows *around* the low pressure area in a counterclockwise motion. This motion characterizes frontal storms typical of temperate climates. If the pressure force and Coriolis force are equal, the resulting wind velocity is said to be geostrophic (i.e., "turned by the earth"). Above one kilometer, the winds are closely geostrophic.

Though it has been only a little over a century since the first analysis of this effect, the Coriolis force has through the centuries influenced man's environment through its control of the motions of winds and waters, and hence the distribution of the sun's heat over the earth. Ancient man, not aware of the motion of his planet, was nevertheless profoundly influenced by it.

COSMIC RAYS

Cosmic rays are high energy subatomic particles which populate the interstellar space within galaxies, and to some extent between galaxies. The primary cosmic rays are atomic nuclei and electrons which have been accelerated by the action of electric and magnetic fields in a hierarchy of astrophysical processes. Only a few of these processes have been clearly identified. The primary particles produce secondary cosmic rays in collisions with other forms of matter.

The kinetic energy of these particles is typically 1–10 GeV; they have far more energy than the alpha, beta, and gamma rays emitted by radioactive atoms. Collisions between cosmic rays and target nuclei release enough energy to create mesons, both directly and via decay. Most of the cosmic rays which reach the earth's surface are in fact muons from the decay of charged pions. The pions are produced high in the atmosphere by collisions between primary cosmic rays and the nuclei of oxygen and nitrogen atoms.

Investigations of the unexpected behavior of these muons, and of other cosmic-ray phenomena, stimulated the development of large machines for producing "artificial cosmic rays," and evolved directly into the discipline now called elementary particle physics. Many of the experimental devices that are used in this new field were originally developed to study cosmic rays. They include Geiger-Muller and proportional counters, and devices for delineating tracks, descendents of the Wilson cloud chamber. Positrons, muons, charged pions, kaons, the first hyperons—all were discovered using cosmic rays.

Because the cosmic-ray energy spectrum extends, roughly as an inverse power law, to energies much greater than accelerating machines can duplicate, a good deal of activity still centers on the use of cosmic rays for studying elementary particle physics. With the advent of proton-antiproton colliders achieving TeV center-of-mass energies, this kind of work will be restricted henceforward to cosmic-ray energies greater than 10^{15} eV. The intensity of such cosmic rays is so small that it will be difficult indeed to do worthwhile experiments. At the present time much cosmic ray work is devoted to a second application, obtaining information about the astrophysical setting in which cosmic rays are produced and propagate.

Cosmic rays provide the only directly accessible sample of matter from outside the solar system. Hence the chemical composition (nuclear charge spectrum) of this material has been studied extensively, using detectors carried to great heights by means of balloons, rockets and spacecraft. The charge spectrum of "normal" (solar system) material, accounted for by nucleosynthesis in the big bang followed by processing in stars, is characterized by strong contrasts. The odd-Z elements are much less abundant than those with even Z, the light elements Li, Be, and B are practically absent, and so forth. The cosmic-ray charge spectrum shows much less contrast. The differences can largely be accounted for by spallation of primary heavy nuclei in collisions with interstellar hydrogen. The path length required to explain the anomalous composition of the nuclei arriving at the earth (the so-called "escape length") is about 7 g/cm^2 below 1 GeV per nucleon, decreasing to less than 1 g/cm^2 above a few hundred GeV per nucleon. The abundances of the primary elements (those which are actually accelerated) show a suggestive correlation with the first ionization potential of the atoms. Studies carried out by measuring artificial etch-pits in meteoritic crystals have shown that the cosmic-ray charge spectrum extends beyond Fe at least to Z about 80, the vicinity of Pt and Pb in the periodic table. These "ultra-heavy" nuclei are especially interesting probes since their interaction mean free paths are much shorter than the escape length. The conditions they require in order to be synthesized are also more restrictive than for lighter nuclei. Large counter systems and large sheets of etchable plastic are now being used to study the ultra-heavy component.

Measurements have also been made of isotopic abundances in cosmic rays. In case of primary constituents it is expected that the results will provide especially clear evidence regarding the varieties of nuclear processing that the cosmic-ray material has been through prior to its acceleration. One of the first findings is that the abundance ratio ^{22}Ne/^{20}Ne (extrapolated to the source) is significantly greater than for solar system material. However in other cases (^{26}Mg/^{24}Mg and ^{30}Si/^{28}Si) the abundances are not dissimilar.

The stable isotopes of secondary constituents provide information on the escape length and its energy dependence. The unstable isotopes provide a clock for measuring the average time spent in traveling from the sources to the solar system. By combining the lifetime with results on the path length one can obtain the density of the scattering material, averaged over those parts of the galaxy through which the cosmic rays have propagated. Results of this kind have come mainly from the isotope ^{10}Be (half-life 1.6×10^6 years), and they are limited thus far to energies less than 1 GeV per nucleon. They indicate that the lifetime is at least 10^7 years. This value, which is supported by data on the electron and positron energy spectra, described below, is unexpectedly large. It implies a mean density of scattering material equal to 0.3 g/cm^3, substantially less than the accepted value for interstellar matter in the galactic disk. These results indicate that cosmic rays spend much of their lifetime in regions of lower than average density, perhaps outside the disk.

Attempts to detect nuclei of antimatter in cosmic rays have shown that for charge numbers $Z \geqslant 3$ their abundance is less than 10^{-4}. Antiprotons have been found in two different energy bands. They appear to be secondaries produced in the sources or in passage through the interstellar medium. If the anomalously high intensity in the lower of these bands is confirmed it may indicate that cosmic-ray protons have a different life history than the heavier nuclei.

About 1% of the cosmic rays that strike the earth are electrons. High energy electrons have difficulty in propagating very far in the galaxy because they lose energy in producing synchrotron radiation under the influence of the magnetic fields that are present. On the other hand, the fact that they do produce this radiation has made it possible to show that cosmic-ray electrons (and presumably nuclei) are present in large numbers in supernova remnants such as the Crab Nebula, and in curious structures (jets and radio lobes) associated with unusually active external galaxies. Observationally, synchrotron radiation is distinguished by its nonthermal spectrum and high degree of polarization. From the intensity of this radiation one can deduce the amount of power that must be supplied to electrons in these sources. It proves to be a significant fraction of the visible power, indicating that the mechanism by which cosmic rays are accelerated is remarkably efficient.

If the electrons were a secondary component, produced by nuclear collisions, half of them would be positively charged. Measurements show that positrons make up only one-tenth of the total, so most of the electrons must be directly accelerated. Since the positrons are secondary and are subject to the life-shortening synchrotron process, measurements of their energy spectrum afford an alternative approach to determining the cosmic-ray lifetime.

Cosmic γ-rays and neutrinos with energies less than 10 or 20 MeV are a mixed bag. Some of these γ-rays come from nuclear reactions in stellar atmospheres and some from $e^{\pm}$ annihilation, others are thermal radiation from accretion on neutron stars and black holes; some of these neutrinos come from nuclear reactions inside stars. But γ-rays and neutrinos with higher energies are true cosmic rays, albeit secondary.

High energy neutrinos produced locally, by cosmic rays striking the earth, have been observed in deep mines. Initial steps have been taken toward construction of DUMAND, a deep underwater muon and neutrino detector. Having a target mass of order 10^9 tons (target volume ~ 1 km^3), it will be capable of detecting high energy neutrinos from distant events such as supernova explosions.

Work on cosmic γ-rays is further advanced. One of the original objectives was to determine the spatial distribution of cosmic-ray flux in this galaxy, using the γ-rays from decay of π^0 mesons produced by collisions of nuclei with interstellar gas and dust. Progress has been made, but this is proving to be more difficult than expected because of competition from γ-rays produced by cosmic-ray electrons. Two mechanisms are involved, bremsstrahlung and collisions with low energy photons (microwave through infrared to visible). It is found that the disk-shaped region in which electrons are present is considerably thicker than the disk containing most of the gas and dust of the galaxy. With their limited angular resolution, the instruments used to date respond mainly to the electron-initiated γ-rays. However these γ-rays are themselves a source of important astrophysical information.

The most abundant cosmic rays, having energies on the order of 1–10 GeV, are strongly affected by magnetic fields within the solar system. The first proof that the bulk of cosmic rays are charged particles rather than γ-rays was provided by the latitude effect, a reduction in cosmic-ray intensity at low latitudes resulting from the shielding effect of the earth's dipole field. Experiments detecting an east-west asymmetry in the intensity of obliquely incident cosmic rays proved, on the basis of geomagnetic theory, that primary cosmic rays have predominantly a positive charge.

The weaker but more extensive fields in interplanetary space show their influence in more subtle ways, through time variations correlated with solar activity. The effects range from an 11-year periodicity in the local cosmic-ray intensity to sudden intensity modulations associated with individual solar flares. The equipment used to study these variations ranges, in turn, from networks of earth-based monitors to satellites and interplanetary probes. Both the short term and long term variations are understood in terms of an interaction between cosmic rays and the "solar wind." The solar wind, an extension of the sun's corona, consists of outward-streaming plasma carrying with it a magnetic field that is partly regular, resulting in convection, and partly turbulent, resulting in diffusion. At the boundary where the solar wind meets the interstellar medium some particle acceleration seems to take place, making that region an important plasma physics laboratory. Particle acceleration also occurs from time to time near the sun's surface, in flares. Many cosmic-ray investigations are aimed primarily at deriving information about the sun and the interplanetary medium.

It is important for use of the ^{14}C radiocarbon dating technique in archaeology to know whether the intensity of cosmic rays reaching the earth has varied appreciably over the past 10^4 years. This unstable isotope, generated in the earth's atmosphere mainly through the reaction $^{14}N(n, p)^{14}C$, is one of several produced by cosmic-ray bombardment. By comparing ^{14}C dates with those determined by counting tree rings it has been found that the apparent production rate of ^{14}C has varied by some 20% over the past 3000 years. However, carbon participates in complex exchanges between the atmosphere, biosphere, and hydrosphere. It is not clear what relative importance should be given, therefore, to variations in the earth's magnetic field, in solar activity, or in climate, when interpreting these data. Extensive measurements of cosmogenic radionuclides in meteorites indicate that the intensity of cosmic radiation in interplanetary space has been constant within experimental error (about a factor of 2) for the past 100 million years.

Below 1 GeV per nucleon the energy spectra of the various cosmic-ray constituents are increasingly affected by the solar wind. Below 100 MeV per nucleon, corrections for the residual solar modulation, even for quiet-sun data, are so great that the shapes of the spectra in interstellar space are uncertain. For at least 3 decades above 1 GeV per nucleon the energy spectra have approximately inverse power-law form. The exponent has about the same value, 2.6, for all primary nuclei. The spectra of elements that are wholly or predominantly secondary, such as Li, Be, B, are somewhat steeper. These differences are successfully explained by models that properly take into account fragmentation during propagation from the source or sources to the solar system. By inverting the calculation one obtains "source abundances," for comparison with solar system material, for example. It is found that for self-consistency in these results the path length should decrease with increasing energy, as remarked above.

Above 10^3 GeV per nucleon the evidence from "direct" experiments, those in which the primary nuclei are identified by measuring their charge, is still scanty. Such experiments must be carried out above the atmosphere using balloons or spacecraft, but the particle energies must be measured calorimetrically, using thick absorbers. The two requirements combine to limit the product of area, time and solid angle, and hence the total count for a given intensity. Ground based experiments can have much larger sensitive areas and can use the atmosphere as an absorber, but they must rely on indirect evidence for identifying the primary particles.

The ground-based experiments are of two types, those which detect unaccompanied high energy muons, and those which detect air showers. The muons arise from the decay of charged pions (and kaons) produced when the primary cosmic rays collide with air nuclei, high in the atmosphere. In the same collisions, neutral pions are produced which give rise, by their decay, to photons, which in turn produce electromagnetic cascades via pair production and bremsstrahlung. The colliding nuclei retain half of their energy, on the average, so this process repeats for several generations. At high enough energies many of the charged pions collide before decaying, because of relativistic time dilation, further augmenting the hadronic cascade. The composite cascade, consisting of hadrons, muons, and electrons (plus γ-rays) is called an air shower.

The cosmic radiation observed at ground level consists largely of muons from very small air showers whose electron and hadron components have been absorbed in the upper atmosphere. Above 10^{11} eV primary energy the electromagnetic cascades can be detected at ground level by means of atmospheric Čerenkov light collected with large mirrors. This light is very faint, so the observations must be made on clear, moonless nights. The same technique applies, of course, to showers produced by γ-rays. Cosmic γ-rays from several pulsars have been detected in this way.

When the primary energy reaches about 10^{14} eV the electrons reaching mountain altitude are numerous enough to be detected at distances of order 100 m from the shower core, or axis. This marks the beginning of a new experimental regime in which large counter assemblies are used to make detailed measurements, preferably on several components, of individual showers. The equipment used includes ionization calorimeters for studying the high-energy hadrons, counters deep underground for detecting "hard" (high energy) muons, counters with smaller amounts of shielding to measure "soft" (~1 GeV) muons, unshielded counters for registering the total number of particles at ground level (most of which are electrons), and detectors of atmospheric Čerenkov light accumulated over the growth and decay of the shower above ground level. The simpler and less costly of these detectors are deployed in large numbers, forming arrays with collecting areas ranging from a small fraction of a square kilometer to several tens of square kilometers. Using electronic coincidence circuitry, the array counters select the events to be measured. Commonly they are given the added task of determining the trajectory of each selected shower: the core location from the intensity pattern, the direction from the timing pattern. Aside from the trajectory requirements, which determine the geometrical factor of the experiment, the selection depends primarily on the shower energy being greater than some threshold. The actual energies of the individual selected showers are calculated after the fact, in most cases using data from additional detectors over and above those which produced the trigger.

Large air shower arrays, operating continuously for many years, have measured the cosmic-ray energy spectrum over a range extending from about 10^{17} eV to more than 10^{20} eV per particle, while smaller arrays, operating at high mountain altitudes, have covered the range from 10^{14} to 10^{17} eV. This spectrum can be extended to lower energies by adding together the low energy spectra described above for all values of Z. The result exhibits several features. The (integral) slope, which at 10^{12} eV has become 1.7, a trifle greater than at lower energies, first decreases to ~1.5 and then, above the so-called "knee" at a few times 10^{15} eV, increases rather abruptly to ~2.0. After this rapid fall has continued for 3 decades the spectrum again flattens, having an "ankle" at ~10^{19} eV, above which the slope is only ~1.6.

Air shower experiments also explore the directional characteristics of high energy cosmic rays. At low energies, disregarding effects of the geomagnetic field and solar wind, cosmic rays are remarkably isotropic in direction. This is understood as resulting from repeated magnetic scatterings as the cosmic rays diffuse through the interstellar medium. Up to energies corresponding to the knee, the magnitude and direction of the small observed anisotropy (<0.1%) is explained by the motion of the solar system relative to its surroundings (the Compton-Getting effect) and a tendency of cosmic rays to stream outward from the denser parts of the galaxy in the direction of the local interstellar magnetic field. At energies corresponding to the knee the anisotropy begins to increase. The direction of the maximum intensity begins to change, becoming perpendicular to the galactic disk at about 10^{17} eV. At that point the anisotropy is several percent. As the energy increases further, so does the anisotropy, but no clear pattern emerges until the highest energies are reached. Above 5×10^{19} eV, where the Larmor radius of a proton in a regular magnetic field of reasonable strength (3 microgauss) is greater than the size of the galaxy (20 kiloparsec), the arrival directions are predominantly perpendicular to the plane of the galactic disk. It is generally believed that these cosmic rays must be extragalactic. But they cannot come from the extreme depths of space. Because of the Doppler effect, photons of the 2.7° microwave background radiation will appear to a 10^{20} eV proton to be 100 MeV γ-rays capable of producing photopions. The resulting energy loss sets a limit of about 30 megaparsec on the range of such protons. Photodisintegration imposes a similar limit on the range of heavier nuclei.

The identity of the particles that produce large air showers must be deduced from secondary features of the showers, such as the "elongation" (atmospheric depth of maximum development) or the ratio of muons to electrons. But these secondary features also depend on the character of elementary particle collisions at energies where direct evidence is unobtainable. The extreme proposals can be ruled out by rather general arguments: practically none of the large air showers are initiated by relativistic dust grains, and few if any by neutrinos or γ-rays. Just as at low energies, most of the very high energy cosmic rays are atomic nuclei.

The preponderance of indirect evidence on the composition of these nuclei (for equal energy) indicates that from 10^{12} eV to the knee of the energy spectrum the average mass increases. It then appears to decrease markedly over the next 1.5 to 2 decades. After that it seems to remain constant. At the knee, where the average mass seems to be greatest, the fraction of Fe nuclei may be 50-100%; at the highest energies the fraction of protons is at least 50%, probably greater.

Seventy years have passed since the balloon flights by Victor Hess which established the existence of cosmic rays. Except for small contributions from solar activity, there is still no clear evidence of where or how they are produced. It is becoming more and more difficult to account for the nonsolar cosmic rays reaching the earth by means of a single source or class of sources. There is much to be said in favor of an association between supernovae and the bulk of galactic cosmic rays, those with energies not much higher than 10^{15} eV, but even in that domain alternative models have some support. The possibility of accounting for the knee in terms of a "pulsar bump" made up of particles enriched in heavy nuclei cannot yet be ruled out. It is very probable but not absolutely certain that the highest energy particles are extragalactic. Does the ankle at 10^{19} eV mark a transition from predominantly galactic to extragalactic? Alternatively, if the knee marks the onset of enhanced leakage from the galaxy, one might expect the extragalactic component to become dominant within a couple of decades, by a few times 10^{17} eV, but there the spectrum seems to be smooth.

In the highest energy region, at least, the study of cosmic rays remains a frontier, both in physics and in astrophysics.

COSMOLOGY

The Size and Shape of the Universe Although philosophical speculations about the origin, structure, and evolution of the Universe have continued since the time of the ancient Greeks, the observational basis for scientific cosmology has only recently been obtained. For nearly two centuries, the universe was, for example, thought to be limited to a finite, static system of stars which make up our Milky Way Galaxy. Observations supporting a finite stellar Universe with an observable edge were presented by William Herschel in the late eighteenth century and reaffirmed by Jacobus Kapteyn in the early 20th Century. By assuming that all stars shine with roughly the same intrinsic brightness, they could use counts of the number of faint stars in different directions to determine the structure of the stellar system. In this way both Herschel and Kapteyn concluded that the stars are concentrated in a flattened disk with the Sun at the center and with the greatest extent in the plane of the Milky Way. Herschel was unable to provide a distance scale for his picture, however, and it remained for Kapteyn to specify that the edges of the stellar Universe are located at about 1,500 pc in the direction perpendicular to the galactic plane and at about 8 times that distance in the direction of the plane. (One parsec, or pc, is equal to ten thousand billion kilometers, or 10^{13} km.)

One of the first objections to the Sun-centered Universe was provided by Harlow Shapley in the early 1920s. His observations indicated that the globular clusters outline an immense galactic system that is nearly a factor of ten larger than the visible stellar system. According to this scenario, the Kapteyn Universe is simply a local star cloud located in the outer regions of the grander Milky Way structure. Although Shapley did not realize it at the time, interstellar dust absorbs the light of distant stars, and for this reason the star counts vastly underestimated the scale of the stellar system. This was not all, for it was soon realized that the entire system of stars is rotating like a gigantic pinwheel about a remote, massive center. For instance, the investigations of Bertil Lindblad and Jan Oort, in 1925 and 1927 respectively, demonstrated that the Sun is located about 10,000 pc from the galactic center, and that the Sun revolves around this center at a very rapid speed of about 250 kilometers per second. In addition the enormously massive center, which contains a mass equivalent to about 100 billion stars, gravitationally controls the motion of the Milky Way, producing differential rotation in which the more remote stars move at slower speeds. In any event, Harlow Shapley's arguments for a dramatically larger size for the Milky Way were correct. The known Universe had to be centered far from the Sun, and its boundary had to be increased by a factor of ten. As it turned out however, Shapley was decidedly incorrect in arguing that the so-called spiral nebulae belong to the Milky Way. When it was realized that the spiral nebulae are actually extragalactic "island universes" containing literally billions of stars, the known size of our Universe had to be increased by factors of hundreds and then thousands, and even tens of thousands.

Although the once-fashionable island universe theory of spiral nebulae went into decline after the spectroscopists demonstrated the gaseous nature of certain diffuse nebulae, the extragalactic interpretation of the spirals revived its popularity after Vesto M. Slipher serendipitously discovered their large radial velocities. In the early twentieth century there was a widespread belief that the spiral nebulae are primitive solar systems in the making, and Percival Lowell asked Slipher to use the instruments at the Lowell Observatory to investigate their expected rotations. As a result, in 1914 Slipher "accidentally" discovered their astonishingly high velocities which sometimes exceeded 1,000 kilometers per second. Because it was hard to believe that objects with such enormous speeds could long remain a part of the Milky Way system, these observations proved to be a major impetus for reviving the island universe theory. In other words, the velocities of the spiral nebulae exceeded the escape velocity of the Milky Way, and they were therefore probably extragalactic objects which lie outside the gravitational control of our Galaxy.

This was nevertheless, a controversial conclusion, for it seemed to contradict Adrian van Maanen's measurements of the proper motions of spiral nebulae. If these objects lie well outside our Galaxy, then their angular motions correspond to absurdly high linear speeds approaching the velocity of light. Van Maanen's observations were simply incorrect, however, and it was eventually shown that the spiral nebulae lie at the enormous distances suggested by their high radial velocities. The great debate over the extragalactic nature of spiral nebulae was, in fact, finally settled in 1925 when Edwin Hubble announced the discovery of Cepheid variable stars in the Andromeda nebula (M 31) and the great spiral in Triangulum (M 33). The observed period and apparent brightness of these stars could be combined with the period-luminosity relation to infer a distance of about 480,000 pc for these two nebulae. This meant that they are considerably more distant than the most remote parts of our own Milky Way Galaxy. In fact, we now know that all of the spiral nebulae are remote galaxies, or island universes of stars, which are scattered throughout extragalactic space at distances as large as 10 billion pc.

Hubble next embarked on a survey of the realm of the nebulae. Just as the counts of stars as a function of brightness and direction in the sky had been used to show that the Milky Way is a finite disklike system, nebula counts could be used to explore how the nebulae, or galaxies, are distributed in space. As Hubble probed deeper into space to fainter and fainter magnitudes, the number of galaxies increased proportionally just as would be expected for a uniform distribution of galaxies in ordinary flat Euclidean space. Expressed algebraically, the number $N(m)$ of nebulae per unit solid angle brighter than visual magnitude m was:

$$N(m) = 1.43 \times 10^{-5} \times 10^{0.6m} \text{ galaxies per steradian.} \qquad (1)$$

(Astronomers use a logarithmic scale of brightness, or magnitudes, in which larger apparent magnitudes refer to apparently fainter objects.)

Although some galaxies are aggregated into groups or clusters, Hubble found that they are uniformly distributed when viewed on very large scales. That is, the counts of faint galaxies in different directions and to different depths in the same direction indicated that there is a homogeneous and isotropic distribution of galaxies. This meant that we are not in a privileged position in the Universe, and that the Universe has no preferred shape or center. The distribution of galaxies would appear the same, apart from small scale fluctuations, when studied from any galaxy. In addition, there was no sign of the number of galaxies thinning out as Hubble looked further into the depths of space. There simply was no indication of an edge of the Universe. In fact, observations with the most powerful modern telescopes have reaffirmed Hubble's basic conclusions about the large scale structure of the Universe. It has a nearly homogeneous distribution of mass with no visible edge and no preferred center.

The Redshift-Distance Relation As early as 1914 Vesto M. Slipher had published the radial velocities for fifteen spiral nebulae or galaxies, noting that most of them are moving away from the Earth at velocities which exceed those of any other known astronomical object. According to Slipher, this indicated "a general fleeing from us or the Milky Way." To be precise, Slipher actually measured the difference between the wavelengths λ_0 of the spectral lines of the galaxies and the wavelengths λ_L of the same lines observed in terrestrial laboratories. This difference specifies the redshift z through the relation

$$z = \frac{\lambda_0 - \lambda_L}{\lambda_L}. \qquad (2)$$

The most straightforward interpretation of the redshift is in terms of the Doppler effect due to the recession of the galaxies. According to this interpretation, the galaxies are moving away from the Earth with radial velocities V_r along the line of sight given by

$$V_r = c \times z \quad \text{for} \quad V_r \ll c \qquad (3)$$

where $c = 2.99792456 \times 10^5$ kilometers per second is the velocity of light, and it is assumed that V_r is much smaller than c. In any event, seven years after Slipher's pioneering work, C. Wirtz looked for correlations between these velocities and other observable properties of the galaxies. Wirtz found that, when suitable averages of the available data were taken, "an approximate linear dependence of velocity and apparent magnitude is visible. . . . The dependence of the magnitudes indicates that the spiral nebulae nearest to us have a lower outward velocity than the distant ones." Thus, both Slipher and Wirtz were remarkably close to "discovering" the expanding Universe; but it remained for Edwin Hubble to provide the data which conclusively indicated that the most distant galaxies are rushing away from us the fastest.

It actually was not until 1929 that Hubble provided better quantitative data for the distances of the spiral nebulae and mentioned somewhat incidentally the linear correlation of distance D and redshift. Because he was primarily interested in determining the solar motion with respect to the distant nebulae, he did not specifically state the now-famous Hubble law

$$cz = V_r = H_0 \times D. \qquad (4)$$

(The parameter H_0 is now called Hubble's constant.) Hubble's first formulation of this redshift-distance relation referred only to relatively nearby galaxies (velocities less than 1,000 kilometers per second and distances less than 2 megaparsecs or 2 million parsecs), but he initiated a program to explore the relation to the largest distances possible. By the early 1930s Milton Humason had extended the spectrographic observations to the limits of the 100-inch telescope at Mount Wilson, and together Humason and Hubble found the redshift-distance relation to hold for velocities as large as 20,000 kilometers per second and for distances as large as 32 megaparsecs. This was done by reformulating Hubble's law in the form:

$$\log (cz) = 0.2m + B, \qquad (5)$$

where m is the apparent magnitude of the object and the constant B depends on Hubble's constant H_0 and the intrinsic brightness of the galaxy. Because of the impossibility of measuring the distances to the weaker nebulae, Hubble and Humason assumed that all nebulae have the same intrinsic brightness and inferred a velocity-distance relation from the log redshift-apparent magnitude relation given in Eq. (5). They were also able to derive the value of Hubble's constant H_0 = 558 kilometers per second per megaparsec. This work was then amplified and extended by Humason, Nicholas Mayall, and Allan Sandage. In 1956 they published the log redshift-apparent magnitude relation for 474 extragalactic nebulae, using data obtained during a 25-year period at the Mount Wilson, Palomar, and Lick Observatories. Within the accuracies of the data, the relation is linear and the slope has a value of 0.2, which is the expected value for a homogeneous, isotropic expanding Universe. Moreover, by this time Walter Baade had shown that the period-luminosity relation for Cepheids in spiral arms is quite different from that for Cepheids in galactic nuclei or in globular clusters. When this difference was taken into account, the extragalactic distance scale was revised, and Hubble's constant was revised downward to about 180 kilometers per second per megaparsec. (During the past 15 years Allan Sandage and his colleagues at the Mount Wilson and Palomar Observatories have published at least five successively smaller values for Hubble's constant, the most recent value being about 50 kilometers per second per megaparsec.)

The log redshift-apparent magnitude relation was extended much deeper into space and further into the past when radio galaxies and quasi-stellar objects, or quasars, were discovered. Although normal galaxies like the spiral nebulae emit most of their radiation at optical wavelengths in the visible part of the spectrum, the radio galaxies and quasars emit tremendous amounts of energy at radio wavelengths. In fact, these objects were first discovered by radio astronomers who measured their angular sizes and determined their positions in the sky using interferometric techniques. These positions were then used to locate optical counterparts whose redshifts could be measured. Thus, for example, the first known radio galaxy, Cygnus A, was identified with an extragalactic object in 1954. Its redshift was 0.057, at the time one of the largest known. Nearly a decade later the first two quasars, 3C 273 and 3C 48, were identified with blue objects with starlike images and redshifts of 0.16 and 0.37, respectively. In retrospect, the designation quasi-stellar object appears to this writer a misnomer, however, for most quasars are comparable to galaxies in overall extent, and their starlike images are actually due to their enormous distances.

These were mind boggling discoveries, for the quasars had to be receding from our Galaxy at speeds which are a substantial fraction of the velocity of light, and both radio galaxies and the quasars had to be intrinsically much brighter than the nearby spiral galaxies. Although Nobel prize winner Martin Ryle once reasoned that the discrete radio sources are stars located within the Milky Way, and Geoffrey Burbidge once argued that quasars do not participate in the expansion of the Universe, there is now a general consensus that both of these superluminous objects are the active nuclei of young galaxies whose remote distances are specified by Hubble's law. Even their unusually bright radiation seems to be explained by a central energy source involving a massive black hole. At any rate, the extragalactic radio objects have approximately the same intensity over a wide range of wavelengths, in contrast to the spectrum of the normal galaxies. As a result, the radio galaxies and quasars can be used to probe the remotest regions of the Universe. In fact, quasars with redshifts as large as 3.5 have been discovered, corresponding to a distance of about 10 billion pc. These quasars are so far away that they emitted the radiation we now detect when the Universe was less than 20% of its present age. Moreover, their radial velocities are so large that astronomers must use the relativistic expression

$$V_r = c \times \left[\frac{(z+1)^2 - 1}{(z+1)^2 + 1}\right] \qquad (6)$$

to infer a radial velocity V_r from the measured redshift z. As illustrated in Fig. 1, the quasars and radio galaxies nevertheless exhibit a log redshift-apparent magnitude relation which is consistent, within the errors, with that expected for a homogeneous, isotropic expanding Universe. Unhappily, the great dispersion in the observed data makes it impossible to determine the details of the expansion. The data suggest instead that the distant quasi-stellar objects are about a factor of 10 brighter than the nearer radio galaxies, which are in turn about a factor of 10 brighter than the very nearby normal galaxies. Because the light with which we view distant objects left them some time ago, this change in brightness suggests that younger extragalactic objects are brighter than older ones.

The Expanding Universe: Origin and Evolution The most obvious and simplest interpretation of the observed galaxy redshifts is that they are due to the Doppler effect of receding galaxies, and that the Universe is therefore expanding. Nevertheless, there was initially quite a different explanation, for the Universe was still believed to be limited to the Milky Way system of stars. Around 1917 theoreticians were trying to find a solution to Einstein's gravitational theory which would keep this finite, static system from collapsing under its own weight. Willem de Sitter showed that there is one solution in which the redshifts of galaxies increase with the square of their distance, but in this case the finite Universe remains static and the galaxies do not move apart. That is, the redshift-distance relation becomes a mathematical curiosity of the General Theory of Relativity, and has nothing to do with an expanding Universe. Curiously enough, Hubble at first attributed his linear redshift-distance relation to this so-called de Sitter effect. Most astronomers, including Hubble, eventually accepted the expanding Universe, whose observed properties can be explained by simple Newtonian gravitation, but additional astronomical evidence was at first required to "prove" that the Universe is expanding.

Indirect evidence for an expanding Universe is provided by the fact that the sky is dark at night. If a static Universe is composed of a uniform and infinite distribution of stars, the night sky should be about as bright as the Sun. This so-called Olbers' paradox arises from the

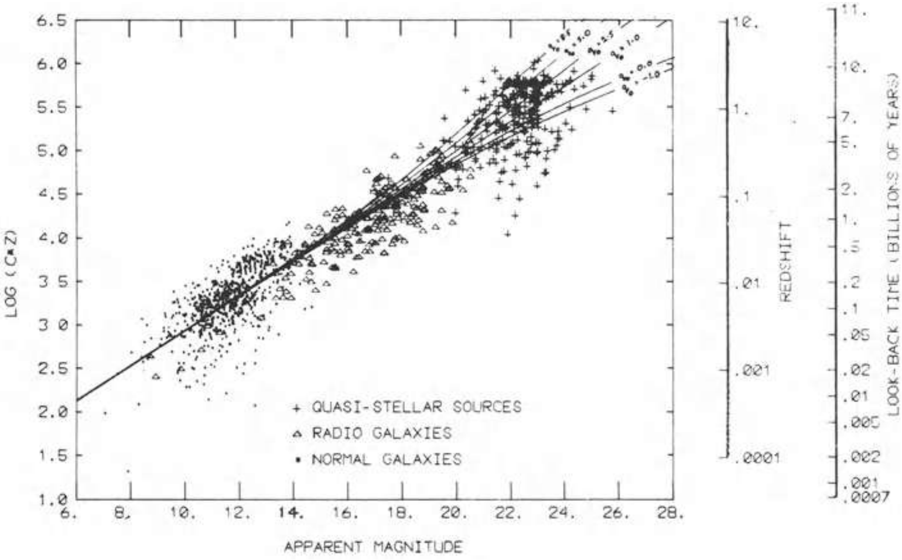

FIG. 1. The author's composite Hubble diagram, in which are plotted 663 normal galaxies, 230 radio galaxies, and 265 quasi-stellar objects. The vertical axis at right gives the look-back time in billions of years, calculated on the assumption of a Hubble constant of 50 kilometers per second per magaparsec. The solid lines denote the theoretical log redshift-apparent magnitude relations for a homogeneous isotropic Universe with different values of the deceleration parameter q_0. Because of the wide range in the intrinsic properties of these extragalactic objects, the observations provide no definitive statement about the value of q_0 and the fate of the expanding Universe.

fact that every line of sight in a static infinite Universe will eventually intersect the surface of a star, and the sky should therefore be as bright as a typical star's surface. This paradox is resolved in an expanding Universe in which the redshift moves the starlight of distant galaxies out of the visible optical wavelengths and into the larger invisible wavelengths. In fact, in order to avoid a theoretically bright night sky, astronomers have been compelled to conclude that the radiation from energetic young galaxies has to be greatly redshifted, and that an expanding Universe is therefore required.

If we accept the notion of an expanding Universe, the redshift-distance relation provides a method for studying the past history of the Universe, while also providing a time scale for creation in an evolving Universe. For instance, the light we detect from radio galaxies and quasars was emitted during past epochs, or higher redshifts, when the Universe was comparatively young. The fact that these objects are more abundant at higher redshifts provides support for the idea that we live in an evolving Universe that changes with time. In fact, a backwards extrapolation of the presently observed expansion indicates that there must have been a time in the past when all of the matter in the Universe was highly compressed and extremely hot. This was the time of the big bang which gave rise to the expanding Universe. For example, in a Universe which expands forever in flat Euclidean space, the big bang occurred at a time

$$t_0 = \frac{2}{3H_0} = 13 \text{ billion years ago,} \qquad (7)$$

where Hubble's constant $H_0 = 50$ kilometers per second per megaparsec. The astrophysically determined ages of the oldest stars agree, within a factor of two, with this estimated time since the big bang. This agreement therefore provides additional evidence for an expanding Universe which originated in a big bang.

During the early stages of the expanding Universe, thermal radiation provided the dominant form of mass-energy, and the expansion was therefore gravitationally controlled by the radiation. As shown by George Gamow in the 1940s, the temperature $T(t)$ at time t since the big bang is, under these conditions, given by

$$T(t) = \left[\frac{c^2}{32\pi G a t^2}\right]^{1/4} \approx \frac{10^{10}}{t^{1/2}} \,{}^\circ\mathrm{K}. \qquad (8)$$

Here, c is the velocity of light, G is the Newtonian constant of gravitation, a is the radiation constant, and in the numerical approximation the time t is in seconds. As Gamow realized, the temperatures during the first few minutes are hot enough for protons and neutrons to combine to form helium nuclei. The amount of helium synthesized is about 27% by mass, and this abundance agrees with that observed in various spots in our Galaxy, in nearby galaxies and in quasars. Moreover, the observed abundance of helium in our Galaxy far exceeds the amount which would be synthesized in all of the stars in our Galaxy over its entire lifetime. On the other hand, the observed abundance of the heavier elements in our Galaxy shows appreciable variation, and the much lower abundances can be synthesized within stars. In other words, the observed abundance of helium cannot be produced within the stars, and even if it was there would be an excessive abundance of the heavier elements. We can only conclude that the observed helium originated in the early stages of the expanding Universe before galaxies and stars were formed. As a matter of fact, detailed calculations indicate that the amount of helium produced depends upon the "frozen-in" proton-neutron ratio, and that this ratio is very sensitive to the rate of expansion. If this rate differed by even 50% from the accepted value, the helium abundance would disagree with that observed.

Direct astronomical evidence for the expanding Universe was provided in 1965 when Arno Penzias and Robert Wilson accidentally detected the 3°K microwave background radiation that proved to be the relic radiation of the big bang. When testing the microwave (or short wavelength radio wave) receiving system intended to be used for measurements of the high-latitude continuum radiation of our Galaxy, Penzias and Wilson found a few degrees of unexpected noise temperature. Because the excess noise showed no sidereal, solar, or directional variation, they first supposed that is arose in the receiving antenna itself, but they concluded that there remains an external noise contribution with an antenna temperature of 3.5 ± 1.0°K at the wavelength of 7.3 centimeters. In a companion letter in the same issue of the *Astrophysical Journal*, Robert Dicke and his colleagues explained the excess 3°K radiation as the residual temperature of the primeval explosion that initiated the expansion of the Universe. This concept had nevertheless already been developed by George Gamow, Ralph Alpher, and Robert Herman in the late 1940s, when they showed that a present temperature of about 5°K results when the 10 billion degree primeval fireball has been cooled by expansion in the enlarging cavity of the world. In any event, if the cosmic noise discovered by Penzias and Wilson is the relic fireball radiation, it should have a thermal spectrum. Because of the interactions of matter and radiation, the primeval radiation will very rapidly reach thermodynamic equilibrium, and the resulting thermal spectrum will be preserved for all time as the Universe expands and cools. The expected thermal spectrum was promptly confirmed, and the microwave background was additionally shown to be extremely isotropic. In fact, the most precise measurement of the large-scale isotropy of the Universe now comes from the microwave background, which is isotropic to better than 0.1% on angular scales greater than one minute of arc. (An anisotropy of a few millidegrees has been attributed to either the motion of our Galaxy and its neighbors relative to the background radiation at a velocity of 500 kilometers per second, or to a Universe which is anisotropic at the 0.1% level.) At any rate, the high energy density, thermal spectrum, and isotropy of the 3°K microwave background cannot be explained by the radiation of conventional astronomical objects, and it must be attributed to the relic radiation of a denser, hotter epoch. This discovery therefore provides unambiguous evidence for the singular origin of the expanding Universe, while also providing an important constraint on the radiation temperature throughout the evolution of the Universe.

The radiation temperature $T_r(t)$, the radiation energy density $\rho_r(t)$, and the matter density $\rho_m(t)$ at any time t can, for example, be inferred using the boundary conditions

$$\begin{aligned} T_r(t_0) &= 3 \text{ degrees Kelvin} \\ \rho_r(t_0) &= 4 \times 10^{-34} \text{ grams per cubic centimeter} \\ \rho_m(t_0) &= 1 \times 10^{-31} \text{ grams per cubic centimeter} \end{aligned} \tag{9}$$

where the time $t_0 = 13$ billion years and the mass density is for galaxies. For a Universe of radius $R(t)$ at time t we have

$$\begin{aligned} \rho_m(t) &\propto [R(t)]^{-3} \\ \rho_r(t) &\propto [R(t)]^{-4} \\ T_r(t) &\propto [R(t)]^{-1} \end{aligned} \tag{10}$$

so that

$$\frac{\rho_m(t)T_r(t)}{\rho_r(t)} = \text{constant for all times.} \tag{11}$$

We are presently in a matter dominated era in which ρ_m exceeds ρ_r. At the decoupling time these two forms of energy density were equal, and before that time radiation dominated matter.

Fate of the Universe What is the fate of the Universe? Will it continue to expand forever, or will it stop its expansion in the future and begin to contract? The answer to this profound question is found by considering the condition for which the outward motion of a remote galaxy is just balanced by the inward gravitational pull of all of the other galaxies in the Universe. This critical condition occurs when the velocity of the remote galaxy is just equal to the escape velocity of the rest of the Universe. When Hubble's Law is used to specify the galaxy's velocity and the galaxy's kinetic energy is placed equal to the gravitational potential energy resulting from the gravitational tug of all the other galaxies, we obtain a critical mass density:

$$\rho_c = \frac{3H_0^2}{8\pi G} = 4.7 \times 10^{-30} \text{ grams per cubic centimeter,} \qquad (12)$$

where G is the Newtonian gravitational constant and the numerical value corresponds to $H_0 = 50$ kilometers per second per megaparsec.

If the present mass density $\rho_m(t_0)$ of the Universe exceeds ρ_c then the present expansion will eventually reverse, the galaxies and stars being destroyed and finally engulfed in a hot, dense fireball analogous to the one which initiated the present expansion. In other words the Universe will eventually stop its expansion, contract, and undergo another big bang. Alternatively, if the present mass density is less than or equal to the critical value, the Universe will continue to expand forever. The galaxies will disperse and fade into a black void. Will the expanding Universe end with a whimper or a bang? Edwin Hubble answered this question in 1926 when he essentially showed that the mass density of galaxies is less than the critical density, and that the Universe will therefore continue to expand forever.

Of course, we now have greater confidence in the conclusion that the expansion will continue indefinitely. Astronomers have reaffirmed the fact that the mean density of matter in the luminous visible parts of galaxies falls short of the critical value by a factor of about 30. Dark or invisible matter has been inferred from dynamical considerations as well as from radio and X-ray measurements of galactic halos and the intergalactic medium in clusters of galaxies. Nevertheless, when these contributions have been added, the mass density of the Universe is at least 10 times too small to halt its expansion. This has been confirmed by satellite measurements of the abundance of interstellar deuterium, which was presumably created in the big-bang explosion. These measurements indicate that the present mass density of the Universe in both visible and invisible forms is $\rho_m(t_0) \lesssim 5 \times 10^{-31}$ grams per cubic centimeter. Theoreticians will continue to create esoteric theories and observational astronomers will continue to collect uncertain data; but the available evidence indicates that the conclusions will not change. The evolving Universe will continue to expand forever, and the observable properties of this expansion will probably continue to be explainable in terms of Newton's theory of gravity and flat Euclidean space.

CRITICAL MASS*

The mass of fissionable material required to produce a self-sustaining sequence of fission reactions in a system (a reactor, for example) is the *critical mass* for that system.

The chain of reactions will be self-sustaining if, on the average, the neutrons released in each fission event initiate one new fission event. The system is said to be *critical* when that condition exists.

Neutrons released from fissioning nuclei may escape from the system; they may be captured in non-fissioning reactions, or they may produce new fissions. The critical mass depends on the relative probabilities of these processes and on the average number of neutrons released per fission. Evaluation of these probabilities is the concern of criticality calculations which are important in the design of neutron chain reactors.

The escape probability becomes larger for smaller systems, inasmuch as the ratio of surface to volume increases as a system is made smaller. Thus, there is a *critical size* below which the chain reaction in a given system cannot be made self-sustaining. The concept of critical size is often discussed along with critical mass.

Neutrons colliding with non-fissionable nuclei in the system may be absorbed and thus lost to the chain reaction. In fact, not every neutron absorption by a fissionable nucleus results in a fission. Non-fission absorption must be taken into account in calculating the critical mass. For example, a system containing pure ^{235}U can be made to have a low critical mass. If the same

*Research sponsored by the USAEC under contract with Union Carbide Corporation.

configuration were loaded with a sufficient quantity of natural uranium (0.0057 per cent ^{234}U, 0.72 per cent ^{235}U, and 99.27 per cent ^{238}U) to contain the same total amount of ^{235}U, it would not be critical because at certain energies the ^{238}U readily absorbs neutrons without fissioning.

The probability that a neutron striking a fissionable nucleus will cause it to fission depends on the fission cross section (see FISSION) which in turn depends on the energy of the neutron, increasing as the neutron energy gets lower. Thus the addition of a moderator, that is, a material which takes up energy from the neutrons without absorbing them, will lower the critical mass of a system. Water and carbon are good moderators.

The critical mass also depends on the average number of neutrons released per fission. This number changes slightly with neutron energy. For ^{235}U it is about 2.45 for thermal neutrons and about 2.65 for 1 MeV neutrons. The numbers are slightly higher for ^{233}U.

A complete criticality calculation must take into account the fission cross section as a function of neutron energy and the average neutron yield per fission as a function of neutron energy. Also to be considered are the geometrical distributions in the system of the fissionable nuclei, the absorbing nuclei, and the moderator, and how the neutrons scatter from them. Furthermore, the configuration of reflecting material outside of the fuel volume has a marked influence on the critical mass. A complete calculation would construct the spatial and energy distributions of neutrons in the system through the use of a mathematical procedure that models the history of neutrons from their release to their capture or escape. Neutron diffusion theory or transport theory is usually used for such calculations. Actual calculations use idealizations and produce approximate results. Often, criticality experiments are required to verify results.

Finally, as example of critical masses, a sphere 32 cm in diameter containing ^{235}U dissolved in water has a critical mass of about 2.1 kg. The same sphere with ^{233}U has a critical mass of about 1.1 kg.[1] The Oak Ridge National Laboratory graphite reactor was loaded with 31 tons of natural uranium. This contains about 203 kg of ^{235}U.

A thorough discussion of neutron chain reactors is given in reference 2.

CRITICAL PHENOMENA

Introduction The field of phase transitions and critical phenomena has seen extraordinary developments within the past few years,[1] and in this brief account we shall attempt to provide an overview of some of these, concentrating our discussion on the concepts of scaling and universality.

We shall organize the introduction to critical phenomena about three simple questions: (1) "What happens?", (2) "Why study?", and (3) "What do we actually do?"

"What Happens?" What happens near the critical point is easily explained by means of the example of a simple magnet. The most striking macroscopic property of a magnet is that it is in fact "magnetized"—it can, for example, pick up thumb tacks! Suppose we measure the number of thumbtacks or magnetization as we heat the magnet at a uniform rate. As we heat, the tacks fall off one by one, but the rate of falloff suddenly diverges to infinity at a certain temperature (see Fig. 1) and there are no thumbtacks left for temperatures higher than this temperature. We call this temperature the *critical temperature*, T_c, and we call phenomena associated with the critical point *critical phenomena*.

Examples of other critical phenomena are the singularities in two important *"response functions"*:

(1) the constant-field specific heat (see Fig. 2(a))

$$C_H \equiv \text{response in heat content to a change in temperature}$$

$$\equiv T\left(\frac{\partial S}{\partial T}\right)_H, \qquad (1)$$

where here $S = S(T, H)$ denotes the entropy of the system, and

(2) the isothermal susceptibility (see Fig. 2(b))

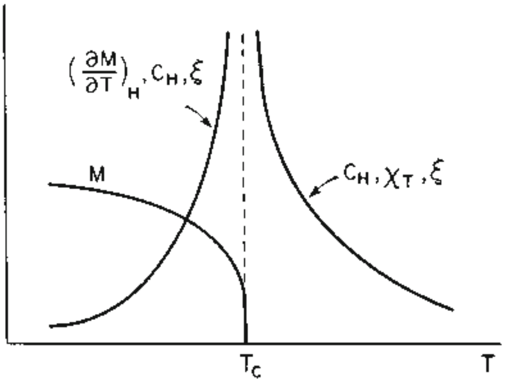

FIG. 1. Behavior (schematic) of some common physical quantities near the critical point.

$$\chi_T \equiv \text{response of magnetization to a change in magnetic field} = \left(\frac{\partial M}{\partial H}\right)_T, \tag{2}$$

where $M = M(T, H)$ is the magnetization and H is the magnetic field.

Thermodynamic functions are *macroscopic* in nature. What is happening at a *microscopic* level to account for the anomalies in the thermodynamic functions? Simply said, the motion of increasing numbers of particles is becoming correlated; e.g., the correlation function,

$$C_2(T, H, \underset{\sim}{r}) \equiv \langle s_0 s_{\underset{\sim}{r}} \rangle - \langle s_0 \rangle \langle s_{\underset{\sim}{r}} \rangle, \tag{3}$$

which describes the degree of correlation among the constituent magnetic moments s_r of our magnet, is becoming long-range. Here the angular brackets denote thermal averages.

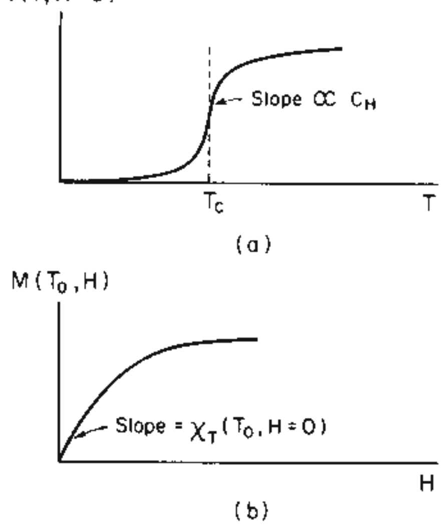
In fact, the "moments" of the correlation function,

$$\mu_a(T, H) \equiv \int |\underset{\sim}{r}|^a \, C_2(T, H, \underset{\sim}{r}) \, d\underset{\sim}{r}, \tag{4}$$

are found to diverge for all positive a and even for a limited range of negative a (roughly $a \gtrsim -2$)! In particular, the zero-field isothermal susceptibility is directly proportional to the zeroth moment

$$\chi(T, H=0) \propto \mu_0\,(T, H=0) = \int C_2(T, 0, \underset{\sim}{r}) d\underset{\sim}{r}, \tag{5}$$

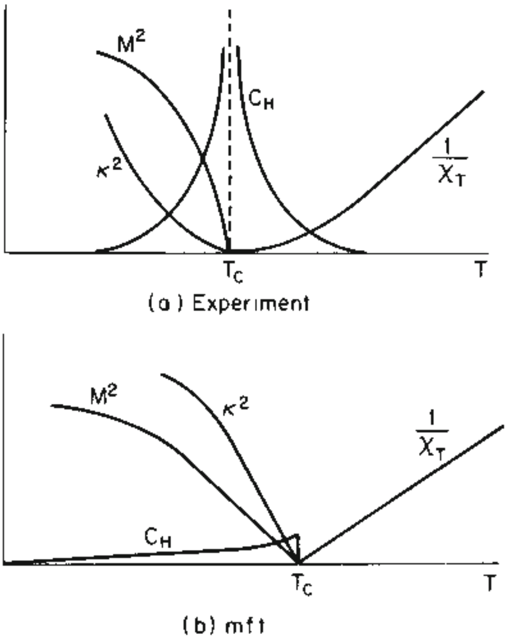
so the divergence of the susceptibility can be seen to be directly related to the increase in range of $C_2(T, H, \underset{\sim}{r})$.



(a)

(b)

FIG. 2. Definitions of two response functions, the constant-field specific heat $C_H(T, H = 0)$, and the isothermal susceptibility evaluated in zero field $\chi_T(T, H = 0)$. Both functions are singular at the critical point of a simple magnet.



(a) Experiment

(b) mft

FIG. 3. Behavior (schematic) of common physical quantities near the critical point, (a), compared with the predictions of the mean field theory, (b). Here $\kappa \equiv 1/\xi$.

A particularly useful measure of the range of the correlation function is the correlation length, $\xi(T, H)$, defined by the equation

$$\xi^2(T, H) = \mu_2(T, H)/\mu_0(T, H) \tag{6}$$

This quantity can be measured experimentally, e.g., by light scattering, and it is found to diverge near the critical point (see Fig. 1).

"Why Study?" There are, of course, many answers to the question "why study critical phenomena," but certainly the simplest answer is that there exist rather striking discrepancies between the predictions of closed-form theories and our findings in the real world. For example, in Fig. 3 we compare, in a qualitative fashion, the experimentally observed temperature dependences of the functions discussed above with the predictions of the *mean field theory* (mft) of cooperative phenomena. The mean field theory corresponds to a model in which each magnetic moment interacts with all other magnetic moments in the entire system with an *equal* exchange interaction. Such a model is unlikely to be a realistic model for the task of describing the effects noted above, and indeed we know that interaction energies in a system fall off with distance between the magnetic moments. Thus one reason for studying critical

phenomena is that it provides a testing ground for theories that concern the microscopic interactions in matter.

A second reason for the burgeoning interest in critical phenomena is that a wide variety of seemingly disparate physical systems are found to behave quite similarly near their "critical points." For example, phenomena analogous to those shown in Fig. 1 are found in a liquid-gas system (see LIQUID STATE), in a ferroelectric, in a superfluid, in a superconductor, and in a binary alloy or mixture. Accordingly, workers from a variety of disciplines have been drawn together by the problem of critical phenomena, adding to the interdisciplinary flavor of the field.

"What Do We Actually Do?" The answer to this question may be given on many different levels, but basically it is that we simply want to understand on a microscopic level what forces exist between the constituent particles in matter, and how they "contrive" to produce the anomalies discussed above and sketched in Fig. 1. As a first step in this direction, it is useful to provide a quantitative measure of the phenomena.

It is found that in almost all systems the limiting behavior of the functions of interest is well described by a simple power law—so that if one plots one's data on log-log paper, the data fall on a straight line sufficiently near the critical point (see Fig. 4). It is important to emphasize that the power law behavior sets in for some systems only quite near the critical point, and when we write

$$f(x) \sim x^{\theta}, \tag{7}$$

meaning "$f(x)$ varies as x to the θ power for x near zero," we mean, formally, that

$$\theta \equiv \lim_{x \to 0} \frac{\log f(x)}{\log x}. \tag{8}$$

There is in general a different exponent for each function and each path of approach to the critical point. The thermodynamic functions considered above all concern approaches to the critical point ($T = T_C$, $H = 0$) in which $H = 0$ and $\tau \equiv T - T_C \to 0$. Accordingly, we define the three exponents α, β, and γ in Table 1 to describe, respectively, the behavior of the specific heat, the spontaneous magnetization, and the isothermal susceptibility along this path.

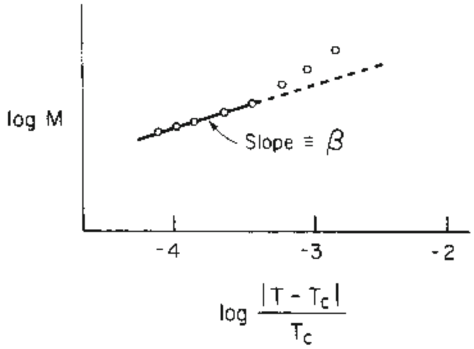


FIG. 4. Sketch of definition of the critical-point exponent β [$M \sim |\tau|^{\beta}$] to illustrate the general definition (8).

The second column gives a typical range of experimental values for the exponents, while the third column gives the values predicted by the mean field theory. The reader would do well to verify from inspection of Fig. 3 that the mean field exponents are correctly listed. That the agreement is far from perfect is consistent with the discrepancies between Figs. 3(a) and 3(b) (experiment and mft).

Theorists have endeavored to calculate the exponents for as many models as possible. For example, the fourth column shows the exponents calculated for the two-dimensional Ising model, for which many of the zero-field properties are known exactly. We see that these exponents agree no better with experiment than do the mean field exponents—in fact, they err in the opposite direction, with the experimental numbers lying in between the mft and two-dimensional Ising predictions.

We shall subsequently argue that the reason that the two-dimensional Ising model disagrees with experiments on three-dimensional systems is that the system dimensionality plays a crucial

TABLE 1. DEFINITIONS AND TYPICAL VALUES OF SELECTED CRITICAL-POINT EXPONENTS FOR A SIMPLE MAGNET.

Exponent	Definition	Experiment	Mean Field Theory (mft)	d = 2 Ising	d = 3 Ising
α', α	$C_H \sim (-\tau)^{-\alpha'}$ $\sim \tau^{-\alpha}$	−0.1 to 0.2	0	0	$\simeq 1/8$
β	$M \sim (-\tau)^{\beta}$	0.2 to 0.4	1/2	1/8	$\simeq 5/16$
γ', γ	$\chi_T \sim (-\tau)^{-\gamma'}$ $\sim \tau^{-\gamma}$	1.1 to 1.5	1	7/4	$\simeq 5/4$
$\alpha' + 2\beta + \gamma'$		$\simeq 2$	2	2	$\simeq 2$

role in determining critical-point exponents. Indeed, the fifth column, showing the results of numerical approximation procedures for the three-dimensional Ising model, is seen to agree rather better with the experimental results.

Scaling Hypothesis One could continue discussing exponents for other systems, for other functions, or for other paths of approach to the critical point. Until a few years ago this discussion would serve to summarize most of the research activity in critical phenomena. However, we are sooner or later going to seek a deeper understanding of the exponents, and this understanding is just beginning to arise. It is coming not from the exact solutions of model systems—for which the complexity of the derivation all but totally obscures any physical insights concerning the magnitude of the exponent obtained—but rather from an altogether different approach.

This approach began historically with the introduction of rigorous relations among the critical-point exponents—these relations took the form of inequalities, and generally involved three exponents. The inequality involving α', β, and γ' is simply

$$\alpha' + 2\beta + \gamma' \geqslant 2, \tag{9}$$

and is generally called the Rushbrooke inequality.[2] That model systems appeared to satisfy Eq. (9) (and most of the other "rigorous" inequalities) as *equalities* (Table 1), and that most experimental systems were not inconsistent with the possibility that (9) is an equality, did not go unnoticed. However, all attempts to rigorously prove (9) as an equality have been singularly unsuccessful.

It is in the finest tradition of theoretical physics that when one cannot solve the original problem, one seeks to replace it with a simpler problem that one can solve. In this instance, the "breakthrough" occurred in 1965—two years after Rushbrooke proposed the Rushbrooke inequality—by many investigators working independently.[3] Their work generally goes by the name of the "*homogeneity*" or "*scaling*" hypothesis, and is perhaps most easily formulated in terms of a class of functions called *generalized homogeneous functions* (GHFs). A function $f(x, y, z, \cdots)$ is a GHF if we can find functions $g_x(\lambda)$, $g_y(\lambda)$, $\cdots$, $g_f(\lambda)$ such that for all positive λ,

$$f[g_x(\lambda)x, g_y(\lambda)y, \cdots] = g_f(\lambda)f[x, y, \cdots], \tag{10}$$

where the functions $g_i(\lambda)$ are arbitrary except that they possess inverses. It is elementary to show[3] that (10) is equivalent to the statement that there exist numbers a_x, a_y, $\cdots$, a_f such that

$$f(\lambda^{a_x} x, \lambda^{a_y} y, \cdots) = \lambda^{a_f} f(x, y, \cdots). \tag{11}$$

The scaling hypothesis is just that—a hypothesis. It involves GHFs, and because of the properties of GHFs, it can be made about a variety of functions. One can make a scaling hypothesis about three different classes of functions: thermodynamic functions (TF), static correlation functions (SCF), and dynamic correlation functions (DCF).

TF hypothesis: Close to the critical point $\tau = H = 0$, the singular part of the Gibbs potential per spin $G(\tau, H)$ is "asymptotically" a GHF.

SCF hypothesis: Close to the critical point and for large $|\underset{\sim}{r}|$, the static correlation function $C_2(\tau, H, \underset{\sim}{r})$ is a GHF.

DCF hypothesis: Close to the critical point and for large $|\underset{\sim}{r}|$ and t, the dynamic correlation function $C_2(\tau, H, \underset{\sim}{r}, t)$ is a GHF.

One can show that these statements are not entirely independent of one another and that in fact:

DCF hypothesis ⇒ SCF hypothesis

⇒ TF hypothesis.

The TF hypothesis predicts that Eq. (9) holds as an equality, and thus is consistent with the numbers shown in Table 1. However, it also makes other predictions, not anticipated before. For example, it predicts that all data taken near the critical point can be made to "collapse" onto a single curve providing the data are plotted in the correct units. The single curve is called a "scaling function," and examples of scaling functions are shown in Fig. 5 and defined in Table 2. The scaling function has just

TABLE 2. SUMMARY OF SCALING FUNCTIONS PREDICTED BY THE SCALING HYPOTHESIS FOR THE M-H-T EQUATION OF STATE. HERE δ IS DEFINED BY $H \sim M^\delta$. SKETCHES OF THE THREE FUNCTIONS ARE SHOWN IN FIG. 5

Function	Dependent Variable	Independent Variable
$H_\tau = \mathfrak{F}_{\mathrm{sgn}\,\tau}{}^{(1)}\,(M_\tau)$	$H_\tau \equiv H/\lvert\tau\rvert^{\beta\delta}$	$M_\tau \equiv M/\lvert\tau\rvert^{\beta}$
$H_M = \mathfrak{F}_{\mathrm{sgn}\,M}{}^{(2)}(\tau_M)$	$H_M \equiv H/\lvert M\rvert^{\delta}$	$\tau_M \equiv \tau/\lvert M\rvert^{1/\beta}$
$M_H = \mathfrak{F}_{\mathrm{sgn}\,H}{}^{(3)}\,(\tau_H)$	$M_H \equiv M/\lvert H\rvert^{1/\delta}$	$\tau_H \equiv \tau/\lvert H\rvert^{1/\beta\delta}$

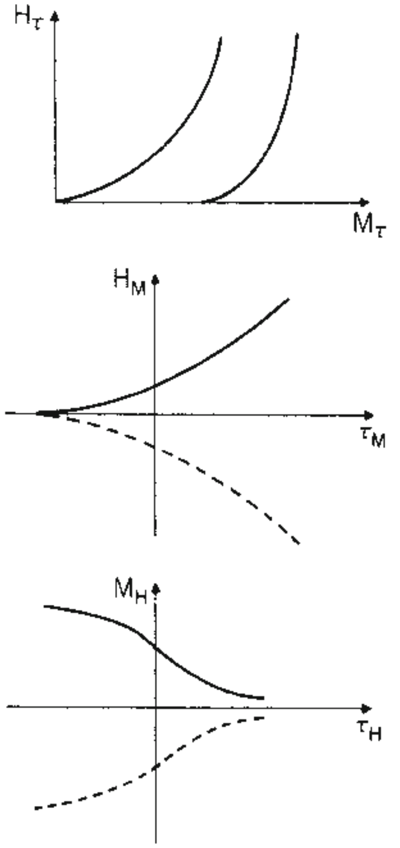

FIG. 5. Sketches of the three possible "scaling functions" for interpretation of MHT equation of state data near the critical point. A dashed line indicates that data are not taken for this "branch" of the scaling function due to MH symmetry.

recently been calculated directly for the Heisenberg model, and agreement with experimental data on magnetic systems is striking.[4]

Universality Hypothesis The universality hypothesis has arisen from attempts to answer the question "On what features of a model do critical properties (exponents, scaling functions, etc.) depend?" Universality states that the only properties are the dimensionality d and the "symmetry" n, where n actually denotes that dimensionality of the "order parameter" or spin space.

To make this concept more precise, let us introduce a general Hamiltonian which encompasses, as special cases, a very large proportion of the models that exhibit critical phenomena. This Hamiltonian utilizes the concept of classical spin vectors, situated on sites $\underset{\sim}{r}$ and $\underset{\sim}{r}'$ in a d-dimensional lattice, and interacting with energy parameters $J_{\underset{\sim}{r}-\underset{\sim}{r}'}{}^{\alpha}$ that depend upon the vector $(\underset{\sim}{r} - \underset{\sim}{r}')$. The important thing is that the spin vectors are taken to be unit vectors spanning a n dimensional space, i.e.,

$$\underset{\sim}{S} \equiv (S^1, S^2, \cdots, S^n), \qquad (12a)$$

with

$$(S^1)^2 + (S^2)^2 + \cdots (S^n)^2 = 1. \qquad (12b)$$

Thus the Hamiltonian under consideration is[5]

$$\mathcal{H} = - \sum_{\underset{\sim}{r},\underset{\sim}{r}'} \sum_{\alpha=1}^{n} J_{\underset{\sim}{r}-\underset{\sim}{r}'}{}^{(\alpha)} S_{\underset{\sim}{r}}{}^{\alpha} S_{\underset{\sim}{r}'}{}^{\alpha} \qquad (13a)$$

Note that when $n = 1$, this Hamiltonian reduces to the Ising model, since the spins become simply one-dimensional "sticks" capable of assuming the two discrete orientations +1 (up) and − 1 (down).

For $n = 2$, the Hamiltonian (13a) describes a system of two-dimensional vectors, and is generally called the XY of "plane rotator" model. It has also been called the Vaks-Larkin model, because Vaks and Larkin have considered it a lattice model for the superfluid transition in a Bose fluid.

For $n = 3$, (13a) describes the general anisotropic Heisenberg model, which has proved particularly useful in describing a variety of magnetic materials near their critical points.

For $n \to \infty$, (13a) reduces to the spherical model.[6]

A study that has recently been done concerns which parameters in the general model Hamiltonian (13a) are important for determining the values of critical-point exponents, and which are "irrelevant." To this end, one considers

(1) the lattice dimensionality, d;

(2) the spin dimensionality, n,

(3) the "lattice anistropy" or "nonuniformity of the interaction"—i.e., the dependence of $J_{\underset{\sim}{r}-\underset{\sim}{r}'}{}^{\alpha}$ upon the direction of $\underset{\sim}{r} - \underset{\sim}{r}'$.[7] There are many important materials for which the interaction strength in one crystal direction is different than in another direction, so this is not "of merely academic interest."

(4) the "spin space anistropy," or dependence of $J_{\underset{\sim}{r}-\underset{\sim}{r}'}{}^{\alpha}$ upon α. Probably no material is *perfectly* isotropic and there are certainly some materials for which the anistropy is believed to play a very important role.[8]

(5) the range of interaction, or dependence of $J_{\underset{\sim}{r}-\underset{\sim}{r}'}{}^{\alpha}$ upon $\underset{\sim}{r} - \underset{\sim}{r}'$. Again, there are probably no materials for which the commonly made assumption that only nearest neighbors of one another interact, and that all other pairs of spins are completely coupled, is valid.[9]

(6) the spin quantum number, S.[10] The Hamiltonian (13a) was for classical spins, and corresponds to the $S = 1/2$ Ising model and the $S \to \infty$ limits of the other systems. Materials in nature have a wide range of spin quantum number S, and accordingly we must consider what happens to these models for general quantum number S.

The conclusion of this work is that the only features of Eq. (13a) that are important are lattice dimensionality d and the symmetry of the ground state (which can be measured by an "effective dimensionality" of the spin). This conclusion is sometimes called "*the universality hypothesis*," and it has the implication—if believed—that one need only consider *two* parameters, d and n.[11,12] Hence (13a) may be replaced by[5]

$$\mathcal{H}_U(d,D) \equiv -J \sum_{\underset{\sim}{r},\underset{\sim}{\delta}} \sum_{\alpha=1}^{n} S_{\underset{\sim}{r}}^{\alpha} S_{\underset{\sim}{r}+\underset{\sim}{\delta}}^{\alpha} \quad (13b)$$

where here $\underset{\sim}{\delta}$ denotes a vector between nearest-neighbor pairs of lattice sites.

Conclusion and Outlook In this all-too-brief introduction to the subject of critical phenomena we have perforce concentrated our discussion on a single type of system, namely a simple magnet. One principal attraction, as noted above, is that a great variety of physical systems appear to behave quite similarly near their critical points. Indeed, the role of cooperative phenomena (and the proposed role of phase transitions) in certain biological systems has long been a subject of fascination for many, and it may be that the concepts that are eventually uncovered in our attempts to understand physical systems near their critical points will prove useful in elucidating biological behavior.[13-16]

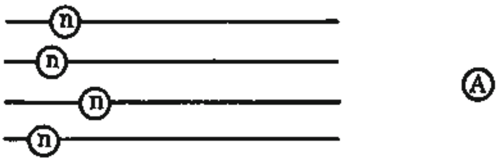
CROSS SECTION AND STOPPING POWER

Cross section, σ, is a conceptual quantity widely used in physics, particularly in nuclear physics, to represent the probability of collision between particles. For example, if a beam of neutrons ⓝ is incident from the left on a nucleus Ⓐ, a certain fraction of the neutrons will be removed from the beam by interaction with A.



By definition, σ is the fraction of neutrons, contained in 1 cm^2 of beam, that interact with A.

For a thin layer of material of thickness dx containing N nuclei/cm^3 the number of nuclei/cm^2 is $N\,dx$. If the flux of incident neutrons is ϕ/cm^2, the fractional decrease in traversing the thin layer will be:

$$-(d\phi/\phi) = N\sigma\, dx \quad (1)$$

or for a finite thickness x and incident flux ϕ_0:

$$\phi = \phi_0 e^{-N\sigma x} \quad (2)$$

For a given type of nucleus there are, in general, a number of possible interactions, $a, b, c, \cdots$. The total cross section σ_t is the sum of the cross sections for the individual interactions:

$$\sigma_t = \sigma_a + \sigma_b + \sigma_c \cdots \text{etc.} \quad (3)$$

A convenient unit for nuclear cross sections is the *barn*, an area of 10^{-24} cm^2, which is approximately equal to the cross-sectional area of medium weight nuclei.

The *stopping power*, *Sp*, of a material for an incident particle is the quantity $-dT/dx$, i.e., the energy loss per unit length of path, generally expressed in ergs per centimeter. This type of attenuation is used primarily in considerations of the passage of heavy charged particles, such as protons, deuterons and alpha particles, through matter. For example, for a particle of any spin having a rest mass $M(\gg m_0$, the rest mass of an electron), charge ze, and velocity $V(=\beta c)$, the energy loss (as excitation and ionization) per element of path $-dT/dx$ to a homogeneous medium containing N atoms/cm^3, each of atomic number Z, is given by:

$$-\frac{dT}{dx}=\frac{4\pi e^4 z^2}{m_0 V^2} NZ \left[\ln \frac{2m_0 V^2}{I} - \ln (1-\beta^2) - \beta^2\right] \tag{4}$$

where I is the mean atomic excitation potential calculable from the Thomas-Fermi electron distribution function to be $I = kZ \approx 11.5\ Z$ electron volts.

The *relative stopping power S* is the inverse ratio of the length of a material to the length of a standard substance having equivalent stopping power (usually referred to aluminum as $S_0 = 1$) at 15°C and 76 cm pressure:

$$S=\frac{(dT/dx)_1}{(dT/dx)_0}=\frac{N_1 B_1}{N_0 B_0}=\frac{\rho_1 B_1 A_0}{\rho_0 B_0 A_1} \tag{5}$$

where ρ is the density, A the atomic weight, and $B = Z \ln 2m_0 V^2/I$ from Eq. (4).

CRYOGENICS

Cryogenics is the science of very low temperature refrigeration and the study of phenomena which occur at these temperatures. In a general sense, cryogenics can be divided into two parts: the methods used to obtain and maintain very low temperatures, and the special techniques associated with measuring physical properties, particularly temperature, in the low temperature environment. Cryogenic temperatures are usually defined as those below about 90 K, (90 Kelvin) the liquification point of oxygen, although in the laboratory temperatures as low as 0.005 K (5 mK) are becoming commonplace.

Applications Industrial cryogenic applications include the shipment and storage of liquified gases such as nitrogen, oxygen, and natural gas fuel, and the use of these fluids through evaporation, particularly liquid nitrogen, as refrigerants. Liquid oxygen at 90 K is used extensively in the steel industry and in providing hospitals with oxygen gas for breathing. In addition, liquid oxygen and liquid hydrogen are used as rocket fuels in the space program. Liquid nitrogen, which is relatively inert, quite inexpensive (≈$0.15/liquid liter), and has a large latent heat at 77 K of 1.6×10^5 joules/liter, is used as a powerful refrigerant in a variety of applications including the frozen foods industry, the biological storage of tissue and live cells, the refrigeration of sensitive detectors of electromagnetic radiation, and in the production and storage of colder liquid cryogens such as hydrogen at 20.3 K and helium at 4.2 K. Perhaps the largest use for liquid nitrogen, however, is in the storage and transfer of nitrogen to provide clean and relatively inert atmospheres in the chemical and semiconductor industries.

Liquid ^{4}He at 4.2 K is at present used almost exclusively in laboratory applications, but may soon find its way into hospitals and even into the business world thanks to new technologies being developed based on superconductivity in metals. Superconductivity is a phenomena in certain metals where below a transition temperature T_c the electrical resistance of the metal vanishes completely, and electrical currents can flow with no dissipation of energy. For most elemental superconductors, T_c lies in the range of 1 K to about 20 K. If a magnetic solenoid wound of superconducting wire is energized and its leads are then joined together, the current source can be removed and the magnetic field will remain as the current continues to flow through the solenoid. Magnetic fields as high as 120,000 Gauss can be produced with such solenoids, which decay no more than one part in 10^8 per day. Less stable superconducting magnets have produced fields as high as 165,000 Oe. A conventional room temperature magnet able to produce such a high field would dissipate many millions of watts of electrical energy in maintaining the field, and this energy as heat would then have to be removed or the magnet would melt. Applications for superconducting magnets include uses in nuclear magnetic resonance (NMR) studies and in some large electric motors. NMR spectrometers capable of observing resonances in a whole human body are being built utilizing superconducting magnets which can produce three-dimensional images of the subject. Such devices may soon replace x-ray machines as diagnostic medical tools.

In addition to the absence of electrical resistivity, superconductors possess a variety of other exotic properties. For example, the current flowing in a closed superconducting loop is quantized in units of $h/2e$, where h is Planck's constant and e is the absolute value of the charge on an electron. *Superconducting quantum interference devices* (SQUIDs) are able to use this fact and the tunneling properties of electrons in superconducting weak links to measure minute magnetic fields. For example, the fields produced by electrical activity in the human brain, at the level of 10^{-12} Gauss are being studied with SQUID devices in a number of low temperature laboratories. Other applications of superconducting quantum tunneling have resulted in computer logic elements smaller and faster than conventional semiconductor devices. Such elements may ultimately be utilized to produce super powerful computers operating at 4.2 K.

Cryogenics serves three major purposes in the physics laboratory. First, many physical properties are temperature dependent, and can be more easily understood if studied as functions of temperature rather than at a single temperature. Second, thermal energies often mask important features which, when discovered and understood, allow a far deeper understanding of physical behavior to be obtained. One example, of such a feature was the discovery by de Haas and Van Alphen in 1930 of oscillations in the magnetic susceptibility of bismuth at low temperatures in a high magnetic field. This observation later provided the key to understanding complicated electronic properties of many metals. Thirdly, phenomena such as superconductivity can only exist at low temperatures. Superfluidity in liquid ^{4}He below 2.17 K and ^{3}He below .0027 K are other examples of ordered states which can only exist at very low temperatures. In these states the viscosity of the fluids vanish and they are able to flow without dissipating energy: a true case of the frictionless pulley. In the case of liquid ^{3}He the fluid becomes anisotropic, exhibiting liquid-crystal-like textures and many unique magnetic properties. In all superfluids heat can propagate as a wave, as opposed to the usual diffusive heat flow, and in the case of one of the superfluid phases of ^{3}He, this heat wave carries magnetization with it.

In other low temperature studies, physicists have been able to form crystalline lattices of free electrons on the surface of superfluid ^{4}He and measure their mechanical properties. In additional low temperature studies of two-dimensional electron gases, such as those found in MOS-FET devices, a quantized Hall effect is observed when the samples are placed in a very intense magnetic field. This unusual quantum effect is providing a new and better standard for the unit of electrical resistance.

Refrigeration Most refrigeration processes used to obtain very low temperatures involve the change of state of some fluid refrigerant. The most simple refrigerators involve the liquification of a gas under elevated pressure with the latent heat of condensation being removed to the outside world, followed by evaporation at a much lower pressure and temperature. Such processes will operate only between their critical temperatures and their triple point temperatures. Oxygen, for example, has a critical point at 50 atmospheres pressure and 154 K. Its triple point is at 54.4 K. To provide continuous cooling from room temperature such refrigerators must operate in series with other refrigerators using working fluids with higher temperature critical points, the hottest being above room temperature.

By far the most widely used refrigeration process involves the expansion of a gas under elevated pressure through a porous plug, the Joule-Thompson process. In such an expansion an ideal noninteracting gas will neither warm nor cool; however, with real gases the expansion alters the average potential energy between the gas particles, and as a consequence the temperature of the gas is changed. If the kinetic energy of the gas particles is sufficiently low (at low temperatures) so that the atoms or molecules feel mainly the attractive part of the interatomic (intermolecular) forces during collisions, the expansion will result in cooling; however, if the temperature is sufficiently high so that the gas particles feel mainly the repulsive short range interactions, the expansion will result in warming. In the limit of hard sphere gas particles with no attractive interactions and an infinite repulsive interaction, the volume excluded by the particles themselves causes the pressure to drop further during the expansion than it would for an ideal gas. As a result of this excess drop in pressure, more mechanical energy is expended in forcing the gas though the plug than can be recovered from the expanding gas on the low pressure side. This difference in energy results in heating of the gas. Not surprisingly, the maximum temperature at which cooling will occur, the inversion temperature, is related to the boiling temperatures of the liquified gases, since both temperatures depend on the interatomic forces. Helium (^{4}He), for instance, boils at atmospheric pressure at 4.2 K and has an inversion temperature of 51 K. Hydrogen boils at 20.4 K and has an inversion temperature of 205 K. Nitrogen and oxygen boil at 77.3 K and 90.2 K respectively, and have inversion temperatures of 621 K and 893 K. Since helium and hydrogen have inversion temperatures below room temperature, they cannot be used for this type of cooling process directly, but must be precooled by a prior refrigeration process to well below room temperature. Joule-Thompson expansion is the process most generally used in the liquification of oxygen and nitrogen, however, and it is the final refrigeration process used in the liquification of helium.

If rather than allowing a gas to expand through a porous plug as in the Joule-Thompson process, one allows the gas to expand against a piston or other moving wall (such as the vane of a gas turbine), any gas will cool at any starting temperature. This occurs because on the average when the gas particles recoil off the moving surface in an expanding volume they have lower kinetic energies than they had prior to their collisions with the moving wall. From a macroscopic viewpoint the gas is doing work against the moving piston, $P\delta V$. Expansion engines using either moving pistons or turbines are almost always employed in the liquification of helium, although a three-stage Joule-Thompson process to liquify helium using nitrogen, hydrogen and helium is possible. The disadvantage of expansion engines is that they involve closely fitting moving parts which require very high gas purity. Ice and frozen air are constant hazards in such machines.

Liquid ^{3}He and ^{4}He hold a special place in the field of cryogenics, largely because they are the only stable materials available to man which remain in a fluid state as their temperature is lowered arbitrarily close to absolute zero. (Both can be solidified near absolute zero, however, by applying pressures on the order of 30 atmospheres.) This fact not only makes ^{3}He and ^{4}He unique materials insofar as low temperature physics is concerned, it also allows them to be useful refrigerants to exceedingly low temperatures.

Liquid ^{3}He and ^{4}He have boiling temperatures at atmospheric pressure of 3.2 K and 4.2 K, respectively. By pumping away the vapor above the liquid phase, however, one can lower the boiling points to about 0.25 K for ^{3}He and 0.7 K for ^{4}He. Below these temperatures the vapor pressures above the liquids, which are decreasing exponentially with decreasing temperature, are insufficient to allow significant amounts of liquid to be evaporated, and the cooling capacities of ^{3}He and ^{4}He pumped cryostats drop rapidly to zero.

In the mid-1960s a novel refrigeration device called the ^{3}He-^{4}He dilution refrigerator was developed which overcame the problems of the vanishingly small vapor pressures of ^{3}He and ^{4}He at low temperatures. This device virtually revolutionized low temperature physics during the 1970s, and one can now purchase a dilution refrigerator capable of continuous refrigeration down to 0.004 K (4 mK) for about $100,000.

The key to the operation of the dilution refrigerator is the finite solubility of ^{3}He in superfluid ^{4}He. As ^{3}He is added to liquid ^{4}He at low temperatures (below about 0.2 K), the ^{3}He mixes with the ^{4}He to a maximum concentration of about 6%. In the mixing or *dilution* process the distance between the ^{3}He atoms increases and in the process the ^{3}He absorbs heat. The superfluid ^{4}He has very low specific heat and thermal conductivity at these temperatures, and in fact, the ^{3}He atoms do not scatter off the ^{4}He atoms in the superfluid. At these temperatures superfluid ^{4}He is often referred to as a *dense vacuum*. In a crude sense, one can therefore consider the mixing of ^{3}He in superfluid ^{4}He to be a form of evaporation. However, the density of ^{3}He in the ^{4}He is so high and the temperature is so low that this simple model breaks down. In fact, the heat absorbed by a quantity of ^{3}He mixing with superfluid ^{4}He is proportional to T^2. A moderately powerful dilution refrigerator has a cooling capacity at 10 mK of only a few micro-watts.

The ^{3}He which is diluted into the ^{4}He-rich fluid is withdrawn from it by connecting the region where the mixing occurs, the *mixing chamber*, to a *still* by a long capillary tube. The still temperature is regulated at about 0.8 K, where liquid ^{3}He has a much higher vapor pressure than liquid ^{4}He. Thus a pump which removes the vapor above the liquid in the still distills the ^{3}He out of the ^{4}He-rich phase. The ^{3}He removed from the still is pressurized to about 0.1 atmosphere and is reliquified in a pumped ^{4}He bath. It is then returned to the mixing chamber through a series of heat exchangers which transfer heat from the warm returning liquid to the cold dilute ^{3}He rising up to the still.

There is one additional refrigeration process involving ^{3}He called *Pomeranchuk* or *compressional cooling*. It relies on the unusual property that the liquid phase of He^3 below 0.3 K is more highly ordered than the solid phase. This is due to the random orientations of the ^{3}He nuclear spins in the solid, which give it a substantial disorder even at low temperatures. If one solidifies liquid ^{3}He below 0.3 K (about 34 atmospheres at 0.02 K), as solid ^{3}He forms it absorbs heat from the surrounding liquid and the system cools. A carefully designed Pomeranchuk cell precooled with a dilution refrigerator to about 25 mK can reach about 0.8 mK for short periods of time and can maintain 1.5 mK for several hours. Lower temperatures are not feasible because at 1.0 mK the nuclear spins in the solid order antiferromagnetically, and the difference in the degree of order between the liquid and solid drops rapidly to zero. Although not an important cooling process for external samples, this self-cooling of ^{3}He has been crucial in experiments designed to study the unusual superfluid phases of liquid ^{3}He below 2.7 mK and the nature of nuclear magnetic ordering in solid ^{3}He below 1.0 mK.

In many ways the most powerful and by far the most common technique now used to obtain temperatures below those available with dilution refrigerators is that of *adiabatic demagnetization*. In this technique a collection of spins, either electronic or nuclear, is partially ordered by the application of a large magnetic field. The magnetic moments associated with the spins tend to align along the direction of the magnetic field. The system is precooled, usually with a dilution refrigerator, until some significant fraction of the spins are aligned (the net polarization varies as $1/T$ for small polarizations). Then the magnetic refrigerant is thermally isolated from the precooling stage, and the magnetic field is lowered. As the field decreases, thermal excitations flip the aligned spins against the magnetic field and in the process thermal energy is absorbed. If the heat capacity of the magnetic coolant totally dominates the heat capacity of the sample being cooled, the ratio of the temperature to the sum of the external and effective internal magnetic fields stays constant. For nuclear coolants such as copper, the internal fields, which arise largely from the magnetic moments associated with the spins, are only a few Gauss. If the external field is lowered from 80,000 Gauss to 80 Gauss, the temperature of the copper nuclear spin system will drop by a factor of 1000. If the starting temperature is 10 mK, the final nuclear temperature will be 10 μK. Electronic moments and hyperfine enhanced nuclear moments may be polarized more easily at higher temperatures due to their larger magnetic dipole moments, but due to higher internal fields, they do not get as cold. The lowest temperature one can reach with even a very dilute paramagnetic salt such as cerium magnesium nitrate is about 2 mK.

Although one can achieve nuclear spin temperatures well below 1 μK in copper nuclear demagnetization cryostats, heat leaks have not allowed external samples to be cooled to this very low temperature. Thermal conductivities vanish as the temperature approaches absolute zero, and even heat leaks as small as 10^{-9} watts become important in determining sample temperatures. External metallic samples have not been cooled much below 50 μK with copper demagnetization refrigerators, and ^{3}He, which is harder to cool, has not been below about 120 μK.

Thermometry There are a wide variety of thermometry schemes for measuring cryogenic temperatures. Most are calibrated against certain easily reproducible fixed points whose absolute temperatures are established by some thermodynamic means such as the ideal gas law thermometer. Down to 90 K the accepted international thermometry scale is based on the electrical resistivity of platinum wire, which is nearly proportional to temperature in this range due to electron-phonon interactions. The vapor pressures of certain gases in equilibrium with their liquid phases provide highly reproducible thermometry scales over limited temperature intervals. In particular, the vapor pressures of ^{4}He from 5 K to 1 K and ^{3}He from about 3 K to 0.5 K are internationally accepted temperature scales. Thermocouple devices, particularly gold doped with iron vs chromel, can provide useful thermometry down to 1 K and below, although their use ,in the laboratory has waned in recent years.

By far the most convenient and prevalent secondary thermometry schemes are those based on the temperature dependent resistance of some stable device. Pure metal wires are commonly employed down to liquid nitrogen temperatures. Commercially available carbon resistors are the cheapest and most prevalent thermometers, being useful from close to room temperature down to temperatures as low as 10 mK. These thermometers do not tend to be very reproducible, however, and for high precision work doped germanium resistors are generally used down to about 50 mK. Virtually anything whose resistance is temperature dependent in a reproducible way can serve as a secondary resistance thermometer.

Below about 20 mK a variety of Curie law thermometers are generally used. These rely on the temperature dependence of the polarization of either electronic or nuclear magnetic moments in a magnetic field. Detection of the polarization can be either through a mutual inductance measurement, a static magnetization measurement, nuclear magnetic resonance, or a measurement of the anisotropy of gamma radiation emitted from polarized radioactive nuclei. Nuclear magnetic resonance of platinum wire or powder is the thermometer of choice below about 1 mK, and the lowest temperatures measured this way are somewhat below 50 μK.

Certain other thermometry schemes are also occasionally used at ultralow temperatures, such as those based on the temperature dependent dielectric constant of certain materials (a scheme virtually immune to even very large magnetic fields), the thermal noise power (Johnson noise) of a suitable resistor, and the ^{3}He melting pressure. In the range from about 100 mK to just above 1 mK a simple ^{3}He melting pressure thermometer can be produced with a resolution of somewhat better than .0001 mK or 100 nano Kelvin.

The major difficulty associated with thermometry schemes below 0.3 K is the absence of suitable calibration or fixed points whose temperatures have been established by thermodynamic means. A series of superconducting transition temperatures has been established by the U.S. National Bureau of Standards recently, but the lowest is at about 15 mK. Ultimately the superfluid ^{3}He transition temperatures at various sample pressures should provide a highly reproducible temperature scale from 1.0 mK to 2.7 mK, and almost all provisional temperature scales in this range are currently being referenced to superfluid ^{3}He transition temperatures.

The engineering aspect of cryogenics is itself a very challenging area. The properties of materials near absolute zero are generally quite different from those exhibited at room temperature. In particular, thermal contraction of materials being cooled to 4.2 K can amount to changes in length as large as 1% or as small as 0.1%. Materials which fit together well at room temperature may bind or leak badly at low temperatures. Some become too brittle to be of any use, while the mechanical properties of others improve dramatically. The problems of providing adequate thermal contact between the different parts of a cryostat and adequate heat exchange between warm and cold cryogenic fluids are enormous. Often the low temperature physicist or cryogenic engineer must exhibit considerable resourcefulness in utilizing the unusual properties of materials at low temperatures to overcome technical problems. Considerable progress is being made, however, and the facility with which one can now produce and maintain very low temperature environments is vastly expanding the applications of the cryogenic science.

CRYSTAL STRUCTURE ANALYSIS

Diffraction of radiation by the ordered, periodic arrangement of atoms in a crystal yields mainly information about: (1) the nature of the radiation (spectrum); (2) the geometry of the crystal (repeat unit and symmetry); and (3) the distribution of the scattering material in the repeat unit of the crystal. In the last category lies the powerful technique of *crystal structure analysis* as revealed primarily by x-ray diffraction, and also by neutron and electron diffraction. With x-rays the electron density distribution is determined, and from this rather precise information about atomic locations (±0.005 Å), as well as thermal motions, polarization effects, and disorder phenomena, is obtained. Neutrons yield information about positions and thermal motions of atomic nuclei, and also about distributions of magnetic and spin vectors in the crystal.

Experimental Aspects When atomic properties are of primary importance, the radiation used is monochromatic, usually generated as characteristic x-radiation from a specified target material in a Coolidge tube (typically CuKα, $\lambda = 1.5418$ Å, or MoKα, $\lambda = 0.7107$ Å). The diffraction effects are observed by various photographic methods, or by means of a goniometer or diffractometer fitted with a pulse counter.

The geometry of a crystal can be determined by routine methods, in which the diffraction effects observed are interpreted in terms of the reciprocal lattice (see CRYSTALLOGRAPHY). Various single-crystal film cameras are arranged to show separately the x-ray spectra produced by as many gratings in the crystal as possible (each spectrum corresponds to a node in the reciprocal lattice), and if the x-rays are monochromatic, each spectrum (or "reflection") appears as a spot-image of the crystal on the photographic film, or a sharp peak on the diffractometer trace. Within the limitations of Friedel's Law ($|F(hkl)|^2 = |F(\bar{h}\bar{k}\bar{l})|^2$, so that a center of symmetry is always present in the diffraction effects when the scattering is purely elastic), such observations show the crystal system, point symmetry, and dimensions of the unit cell of the crystal. Further information about glide and screw symmetries may lead to a unique assignment to one of the 230 space groups (such as the common $P2_1/c$, $Pcab$ or $P2_12_12_1$), but may leave a 2- to 4-fold ambiguity. The space group assignment and unit cell dimensions place severe, often crucial restrictions on the atomic arrangement in the crystal, and are a necessary prerequisite for any crystal analysis.

The *intensities* of the spectra, or reflections, form the basis of the determination of the atomic arrangement. The determination (using x-rays) is based on the development of the electron density distribution in the unit cell by means of the relationship:

$$\rho(x,y,z) = \frac{1}{V}\sum_h\sum_k\sum_l F(hkl)\,e^{-2\pi i(hx+ky+lz)} \qquad (1)$$

in which V is the volume of the unit cell. The structure amplitudes $F(hkl)$ are obtained experimentally from

$$|F(hkl)|^2 = \frac{K^2}{ALp} I(hkl) \qquad (2)$$

where A is an absorption factor, L is a geometric correction (Lorentz) factor and p is the polarization factor; $I(hkl)$ is the total intensity in the reflection peak (integrated intensity). The scale factor K is not usually determined, and so the observed data set consists of the relative structure amplitudes $|F(\text{obs})| = |F|/K$, each indexed and identified by the Miller indices h, k, and l.

Though the number of terms in (1) is theoretically infinite, the actual number is always limited by the wavelength and the angular range available. With x-rays (but not with neutrons) the average $|F|$ values decrease rapidly with Bragg angle, so that often no intensities can be measured at higher angles. Within these limitations, an effort is generally made to collect all of the independent relative amplitudes that can be produced by a crystal. Such a data set may contain about 1000 (for simple inorganic structures) or as many as 30 000 (for proteins) observations.

The Crystal Structure Problem A computation of the electron density distribution in the unit cell by Eq. (1) will clearly provide all the crystal structure information that can be extracted from the measured data. Unfortunately, there is one link missing between this desired result and the experimental observations, namely, the relative phases of the terms in Eq. (1). These phase angles cannot be determined experimentally and must be derived indirectly. This situation constitutes the notorious "phase problem" of crystal structure analysis, a major stumbling block in the procedure for the first 50 years following the discovery by Laue of x-ray diffraction in 1912, and one which strongly affected the character of crystal structure research during all that time. In the 1960s powerful theoretical arguments showed how the phase information was contained in and could be extracted from the intensity distributions within the data set itself. Thus, the chasm of the phase problem was finally bridged, so that there is no longer any limit on the complexity of structures that can be determined, and crystal structure analysis has become a standard and exceedingly powerful tool in the service of chemistry and physics.

Trial and Error Methods Formerly, an empirical trial structure model served as a starting point of an iterative procedure that was used to try to converge on a true set of phases for equation (1). From such a model, theoretical amplitudes and phases can be directly calculated by:

$$F(hkl) = \sum_n t_n f_n e^{2\pi i(hx_n+ky_n+lz_n)} \quad (3)$$

in which f_n is the form (scattering) factor of the atom n (a tabulated function of the Bragg angle), t_n is a thermal parameter of the form $\exp[-(2\pi\bar{u}_n \sin\theta)^2/\lambda^2]$ ($\bar{u}_n$ is the root-mean-square amplitude of vibration of atom n), and x_n, y_n, and z_n are the coordinates of the atom n. F is thus a complex quantity

$$F(hkl) = A(hkl) + iB(hkl) \quad (4)$$

where $A = F(hkl)\cos\alpha$ and $B = F(hkl)\sin\alpha$. In general, the phase angle α may have any value, but if the origin of coordinates is a center of symmetry, F must be an even function and therefore $B = 0$. In that case the phase problem reduces to a choice of sign for each term in the equation

$$\rho(x,y,z) = \frac{1}{V}\sum_h \sum_k \sum_l \pm|F(hkl)|\cos 2\pi(hx+ky+lz) \quad (5)$$

This condition enormously simplifies the phase problem.

The quality of a given model is judged by comparison of $|F(\text{obs})|$ with $|F(\text{calc})|$ obtained from equation (3). The traditional figure of merit commonly used in crystal structure analysis is a relative first moment coefficient

$$R = \frac{\sum ||F(\text{obs})| - |F(\text{calc})||}{\sum |F(\text{obs})|} \quad (6)$$

known as the "R factor," "reliability index," etc. For analytical purposes a so-called "weighted R factor" is also used:

$$R_w \text{ or } R_2 = \frac{\sum w(|F(\text{obs})| - |F(\text{calc})|)^2}{\sum w|F(\text{obs})|^2} \quad (7)$$

where $\sqrt{w}$ is the weight of the observation $|F(\text{obs})|$. In structure analysis where the observations often outnumber the parameters by more than 10 to 1, the two R indices follow each other closely.

If R for the initial model is < 0.50, the model may be at least partly correct, and is then tested by forming an electron density synthesis from Eq. (1) or (5), using only $F(\text{obs})$ terms whose phases are strongly indicated by Eq. (3). This map will show the starting partial model plus other features in the structure not included in that model (additional atoms, shifts in assumed atom positions, etc.), from which an improved model can be derived. This model is then used to calculate new values of $F(\text{calc})$, leading favorably to substantially reduced R, and thus initiating an iterative process of structure refinement.

Vector Maps Considerable information about the structure can be gained from another type of Fourier synthesis that does not depend on knowledge of phase angles, the so-called "Patterson function":

$$P(x,y,z) = \frac{1}{V}\sum_h \sum_k \sum_l |F(hkl)|^2 \cos 2\pi(hx+ky+lz) \quad (8)$$

It was shown by A. L. Patterson in 1935 that this function contains maxima at the points in crystal space which represent interatomic vectors in the crystal structure standing at the origin, and that the height of these maxima is proportional to the product of the electron densities of the two atoms forming these vectors. Thus, if there are n atoms in the unit cell, there will be $n(n-1)$ peaks in the Patterson map, the remaining n peaks being superposed at the origin representing self-vectors for each atom. The Patterson map is a convolution of the electron density over every point in space, or essentially every atom in the structure, and many highly ingenious techniques have been devised to effect a deconvolution. Nevertheless, when n becomes very large, interpretation becomes impossible. The Patterson map and its various convolutions are called generally "vector maps."

Obviously, the task of interpretation of a vector map is greatly simplified if there is one or a very few relatively heavy atoms in the structure (with large f in Eq. (3)), because these will be identified easily in the mapping, and will tend to dominate the distribution of phases in Eq. (1). This is the basis of the so-called "heavy-atom method." Where it is applicable, it can avoid much of the labor involved with more direct methods, and it is still of primary importance in protein structure analysis.

Statistical Methods of Phase Determination D. Sayre in 1952 first noted that when large F terms are concerned, there is a strong tendency for

$$S[F(h_1 \pm h_2, k_1 \pm k_2, l_1 \pm l_2)] \approx S[F(h_1 k_1 l_1)] \cdot S[F(h_2 k_2 l_2)] \quad (9)$$

where S signifies +1 or −1 according to the centrosymmetric phase of F. This relationship, which depends on the required positivity of the function (1), is the root of the most powerful phase-determining procedures in modern use, notably the "symbolic addition procedure" evolved by Karle and Karle (see ref. 6). These techniques, consisting of the analysis of vector combinations of the strongest F terms (usually normalized to emphasize the trigonometric part of equation (3)), have been extended to noncentrosymmetric cases with considerable general success, so that the phase problem may now confidently be said to be for the most part overcome.

Refinement of the Crystal Structure Once a satisfactory model structure has been evolved, defined by a given set of parameters (which may amount to hundreds or even thousands), the refinement of these parameters is carried out by differential methods. The least squares analysis of the F(obs) data set (in which a function based on Eq. (7) is minimized) is the most easily adapted to computers and is most widely used. Methods based on minimization of $\Delta\rho$ (using "difference maps" calculated by Eq. (1) with ΔF as coefficients instead of F) are also commonly used. Convergence when $R \sim 0.15$ is considered satisfactory (with standard error of bond lengths ~ 0.03 Å), but as the quality of data measurement and techniques of refinement have improved, R often nowadays reaches 0.05 or lower (standard error of bond lengths < 0.005 Å).

Crystal Structure Data The most important information yielded by crystal structure analysis, namely, the configuration of atoms in molecules and the solid state, and the distances between the atoms, forms a vast body of critical data on the properties of substances which is expanding at a rapid rate. Compilations of these and of unit cell geometry data are published with a lag usually of 10 years or more, so that reference to the journal literature is usually necessary to find reliable and recent data concerning a particular substance. Reference to original papers is also very desirable to answer the important question of the reliability and distribution of errors in a given structure determination.

Data compilations and treatments of techniques of crystal structure analysis are given in a list of selected references below.

CRYSTALLIZATION

The forms of natural crystals have been studied by mineralogists for many years and have been classified by symmetry, interfacial angles, perfection of shape, and more detailed criteria. These forms are often related to the molecular structure and growth of the crystals. The equilibrium shape of a crystal is that for which the surface energy is a minimum. Since atomic planes of densest packing usually have the lowest surface energy, these planes predominate in the surface facets of equilibrium crystals, resulting in a correspondence between the atomic structure and shape of the crystal. However, natural and even synthetic crystals rarely have the equilibrium shape, because for crystals larger than about 10 μ in dimension, the differences in surface energy between faces are too small to transport enough material over the distances required. Therefore the morphology of crystals is usually determined by the rate of crystal growth, rather than by the equilibrium shape.

A crystal is bounded by those faces whose rate of growth is slowest, since fast-growing faces grow out of existence. Close-packed planes frequently grow most slowly, so even when kinetic factors control the crystal shape there is usually a relation between the faces of a crystal and its molecular structure.

Unusual crystalline morphologies result from particular conditions. Dendritic (treelike) shapes result when crystals grow with high driving force, or with rapid transfer of heat.

Since crystallization proceeds by propagation of the nucleus into the parent phase, the surface separating these phases is the site of incorporation of molecules into the crystal. Thus the structure of this interface between phases is critical in determining the mechanism of growth. A crystal-vapor interface becomes molecularly "rough" above a critical temperature, so that molecules can be incorporated anywhere on it. For low-index faces this critical temperature is close to the melting temperature, and at lower temperatures the surface is molecularly smooth at equilibrium. If there is a monomolecular step on the surface, incorporation of molecules into the crystal will occur preferentially at the step. Such a step contains kinks or jogs, which are the final sites for incorporation. Thus the progress of a molecule from the vapor into the crystal is: (1) transport through the vapor to the crystal surface, (2) adsorption onto the crystal surface, (3) movement on the surface to a step (surface diffusion), (4) adsorption onto a step, (5) transport along the step to a kink, and (6) incorporation at the kink. Steps (2), (4), and (6) can involve reorientation and desolvation of the molecules. The rates at which crystals grow can be controlled by any one or several of these steps. In growth from the vapor it is usually step 3 involving surface diffusion that controls the rate of growth of the crystal.

If the crystal surface is molecularly perfect, a pillbox of material must be nucleated on it to create a step, which then grows to another perfect surface. Under these circumstances, continued surface nucleation is required, and growth occurs only below a certain undercooling. However, experimentally, crystals often grow at much smaller undercoolings than this calculated one, so that a continuous source of steps must exist. For this source F. C. Frank postulated a screw dislocation in the crystal that emerges at the crystal surface. This emergent dislocation provides a step pinned at one end, so that as it propagates it winds up into spiral and is always available for incorporation of molecules. Many spirals have been observed on crystal surfaces; one is shown in Fig. 1. The surface nucleation and screw dislocation mechanisms for crystal growth were definitely confirmed by the elegent experiments of G. W. Sears on the growth of perfect metallic filaments (whiskers), metallic platelets, and paratoluidine crystals.[10]

Impurity molecules can modify the morphology and growth rate of crystals by their effects on the relative surface energies and growth rates of different crystal faces. These molecules can poison growth on certain planes by adsorption at kinks in steps on these planes, slowing the growth of these steps. Impurities can also change the rate of adsorption and surface diffusion of incorporating molecules. The rate of pillbox nucleation can be increased by the lowering of surface tension by impurity adsorption. Therefore impurities can produce different crystal habits and either faster or slower growth rates.

Crystal growth from dilute solution is similar to growth from the vapor, but impurity effects are more marked and morphologies more varied. The growth rate is often controlled by the rate of diffusion of solute up to the crystal surface rather than interfacial processes, especially for crystals larger than a few microns in size. Convection in the liquid solution can change crystal morphologies and growth rates and make compositional and size control more difficult.[11]

The rate of crystallization from a pure liquid, often called *solidification* or *freezing*, is usually controlled by the rate at which the heat of fusion is removed from the interface. Only for slowly growing crystals in viscous melts do interface processes control the rate of crystallization. Nevertheless the structure of the liquid-solid interface can influence crystal morphologies. Many solid-liquid interfaces are "rough," but others appear to be similar to vapor-crystal and solution-crystal interfaces, as evidenced by growth facets in such materials as silicon, germanium, P_2O_5, and many organics. Growth in concentrated solutions (e.g., metallic alloys) is influenced by convective instabilities in the melt as well as instabilities of the interface (dendritic growth).

Crystal growth and liquid-crystal interfaces are being simulated in computers.[12]

To make crystals for laboratory and industrial use a great variety of techniques have been used. Growth by either condensation or chemical reaction from the vapor phase can give crystals with high purity and special structures and form. For large-scale industrial use, this method is too costly, although it is valuable for certain

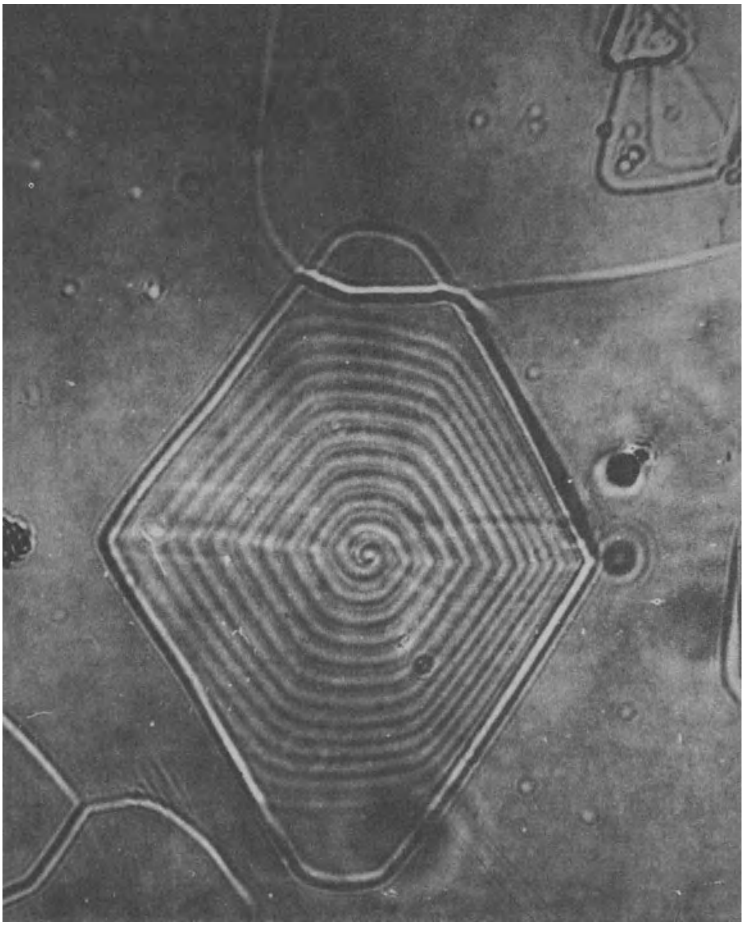

FIG. 1. Growth spiral on a paraffin crystal, observed by C. M. Heck. From Doremus, Roberts and Turnbull "Growth and Perfection of Crystals," by permission of John Wiley & Sons, Inc., New York.[4]

special applications. Luminescent crystals of zinc and cadmium sulfides are grown from vapor for industrial use. Metallic crystals with few impurities and defects, and in the special forms of thin films or whiskers, can readily be grown from vapor. Other crystals made in this way are silicon, germanium, iodine, selenium, phosphorus, and a variety of organic crystals. The study of the growth of ice crystals from water vapor has special importance in meteorology.[13]

The most common method of growing metallic and semiconducting crystals is by solidification of their melts. Special techniques have been developed to grow single crystals of these materials and many others. In the *Czochralski method*, a seed crystal is touched to the melt, and the crystal is "pulled" from it by slowly withdrawing the seed. In the *Bridgman technique*, the melt is slowly moved through a temperature gradient in a furnace, so that crystallization starts at one point in the melt and propagates through it relatively slowly. In the *Vernueil method*, powder is added to the molten surface of a crystal so that a crucible of other material is not needed. This method is used for materials with high melting temperatures, such as alumina, spinels, rutile, mullite, ferrites, and yttrium-iron garnet. A new method of growing sapphire crystals from the melt, called *edge-defined film-fed growth*, has been announced by Tyco Laboratories. The crystal is pulled rapidly from a die, to which molten alumina is transported as a film. Solid crystals are often purified by zone melting, in which a molten zone is moved through the crystal. Segregation of impurities into the melt purifies the crystal.

Precipitation from liquid solution is a common method of growing crystals. Ionic salts are grown from aqueous solutions both industrially and in the laboratory. Sugar is crystallized from water solution. Other organic crystals, including polymers, are grown from a variety of solvents. Quartz crystals are grown from aqueous solution at elevated temperatures and pressures (hydrothermal growth). Various crystals have been grown from more exotic solvents, for example: garnets, titanates, and ferrites from molten salts (fluxes); tin, iron, and phosphorus from mercury; and diamond from a molten metal under pressure.

Crystallization from the solid phase is also possible. Growth of grain size in a single-phase solid, called *recrystallization*, is often used to improve the properties of polycrystalline materials, particularly metals. Crystalline compounds can be made from high-melting-point materials by pressing together mixtures of their powders and diffusing them together at high temperature (sintering). Crystals can be grown from a solid solution. This type of precipitation is frequently used to improve the properties of metals, for example, to harden them.

CRYSTALLOGRAPHY

Crystallography is the science of the geometric properties of matter in the ordered solid state. When atoms or molecules condense into a solid phase from a liquid or gaseous phase, the lowest energy state is achieved if they become arranged in as regular a way as possible, usually by forming a small basic unit of structure which is repeated indefinitely in three dimensions throughout the solid to form a *crystal*. The geometric properties of this unit and its manner of regular repetition are highly characteristic of the substance in question, and constitute an exceedingly useful subject of study in connection with any field of science involving the solid state. Occasionally, no extended, regular repetition of structure is present in the solid phase, but this glassy state has many properties of a liquid and lies outside the realm of crystallography. In other cases, extended order may occur in one direction only (as in fibres) or in two directions (as in some clays), but by far the most common condition of the solid state is full three-dimensional order, and it is with this type of order that crystallography is primarily concerned.

The familiar outward manifestation of the three-dimensional order of the atomic structure of the solid is the polyhedral shape commonly exhibited by crystals. These remarkable shapes were admired for centuries (see, for example, Albrecht Dürer's engraving "Melancholia," 1514), but the underlying principle governing them was first discovered by Steno in 1669. This principle is expressed as the Law of the Constancy of Interfacial Angles, according to which the dihedral angles between the faces of all crystals of a given substance remain unchanged regardless of how the relative sizes and shapes of the faces may vary. René Just Haüy in the late eighteenth century was the first to present a systematic account of the characterization of substances by the measurement of interfacial angles, that is, crystallography, and thus establish it as a science. Haüy was a mineralogist, and through his influence crystallography was subsequently developed and applied by workers mainly in mineralogy, and to a small extent in chemistry. The link between external form and internal structure was dramatically completed by M. von Laue's discovery of x-ray diffraction in 1912, and from then on crystallography was rapidly developed and advanced in physics laboratories, and later more and more in chemistry.

A crystal may or may not exhibit external faces, but if it does, these may be studied in terms of their distribution and development, which constitutes the *morphology* of the crystal, by special techniques of *crystallometry*, usually making use of an instrument that reflects beams of light from the crystal faces into a telescope, the *two-circle goniometer*. If the crystal has no faces, its internal geometric properties may be studied by its interaction with radiation, by the methods of *optical crystallography* if refraction of infrared, visible or ultraviolet light is involved, or by *x-ray crystallography* if diffraction of x-rays (also neutrons or electrons) is studied.

The crystal can be defined completely (except for chance irregularities and defects) in terms of the arrangement of the atoms within a finite unit of volume called the *unit cell* (whose size is usually of the order of 10Å on an edge) and the way this unit is repeated in three dimensions to fill up the volume of the crystal. The shape and dimensions of the unit cell provide parameters characteristic of the substance and constitute the first primary geometrical property of crystals. The most general unit cell (triclinic case) is a parallelopiped which can be defined by six constants, three edge lengths (a, b and c) and three interedge angles (α, β and γ). This unit cell is repeated by *translation*, a shift along each of the cell edges by an integral number of edge lengths. If the unit cell and its contents are represented by a point in space, the crystal consists of a regular array of such points called a *lattice*, in which each point is related to every other by an integral number of vectorial translations corresponding to the unit cell edges. The lattice should be distinguished from the *crystal structure*, which refers to the arrangement of atoms within the unit cell, although the term "lattice" is sometimes loosely used in reference to the structure.

The atoms within the unit cell may be related to each other by a number of geometric operations called *symmetry*, and this phenomenon constitutes the second chief geometric property of crystals. The unit cell must embrace all of the different types of atoms related by symmetry that are not related by simple translation. On the other hand, the symmetry operations which apply to one unit cell are also operated on by the lattice translations, so that these symmetry operations must also apply to the entire crystal. Thus, the morphology of the crystal and all its other properties must obey this symmetry. The detection and definition of the symmetry also serve to characterize the substance and are equally as important in crystallography as the measurement of the lattice parameters.

The way in which symmetry operations can interact consistently with each other is strictly limited by the geometry of coincidence and can be rigorously analyzed by the mathematical methods of group theory, both as to what symmetry operations are possible and how they may be combined. The problem is usually approached by constraining all symmetry operations to pass through a single point in space, but special restrictions are introduced by the requirement that this point must be consistent with any point in the crystal lattice, that is, the symmetry groups must be consistent with the translational operations of the lattice. An important symmetry operation is the axis of rotation by which any motif is reproduced by a rotation around an axis of $360/n$ degrees, where n is the order of the axis; n successive operations then superimpose the object on itself. In crystals, because of the requirements of the lattice, n can only have the values 1, 2, 3, 4 and 6. A 5-fold axis is not possible, for example, for the same reason that it is not possible to fit regular pentagons into a regular two-dimensional pattern which will fill all space. Further, there are only 11 ways to combine the 5 axes together at a point; these are called the 11 axial point groups. These form a convenient basis for classifying all crystals into 6 *crystal systems*, which, while not strictly rational in their definition, provide a fundamental link between the symmetry of the crystal and its dimensional properties. Reference axes are generally chosen parallel to lattice translation directions, of course, but further, they are customarily taken parallel to prominent symmetry axes. Four of the axial point groups, for example, have a single 3-fold axis or 6-fold axis, with or without a number of 2-fold axes at right angles to them. In all these, the reference c axis is customarily set parallel to the unique 3- or 6-fold axis, and the other two axes a_1, and a_2, which are equivalent by symmetry, are taken normal to the c axis along lattice directions 120° apart, coincident with the 2-fold axes if present. These groups are all included in the hexagonal system.

The axial symmetry operations are operations of the first kind, that is, they reproduce left-hand motifs as left-hand motifs. Other symmetry elements of the second kind, that is, which reproduce left-hand motifs as right-hand motifs, are the center of symmetry and the mirror plane of symmetry. When these operations are added to the axial groups, 32 *point groups* are produced.

Referring to the lattice, the introduction of symmetry gives rise to a number of lattice groups in which various rational relationships

TABLE 1. THE SIX CRYSTAL SYSTEMS

			Number of Symmetry Groups			
System	Independent Lattice Parameters	Axial Relationships	Axial Point Groups	Point Groups	Bravais Lattices	Space Groups
Triclinic	$a, b, c, \alpha, \beta, \gamma$	none	1	2	1	2
Monoclinic	a, b, c, β	$\alpha = \gamma = 90°$	1	3	2	13
Orthorhombic	a, b, c	$\alpha = \beta = \gamma = 90°$	1	3	4	59
Tetragonal	a, c	$b = a$ $\alpha = \beta = \gamma = 90°$	2	7	2	68
Hexagonal	a, c	$b = a$ $\alpha = \beta = 90°$ $\gamma = 120°$	4	12	2	52
Cubic (isometric)	a	$b = c = a$ $\alpha = \beta = \gamma = 90°$	2	5	3	36

exist between the lattice parameters. One important result of this interaction is the appearance of *centered lattices*, in which the lattice unit cell chosen according to the rules used to set up the 6 crystal systems contains additional lattice points on body or face diagonals. There are 14 such "Bravais lattices." The symmetry groups so far mentioned can in favorable circumstances all be detected from the external morphology of the crystal.

When the combinations of lattice translations and symmetry operations, that is, the symmetry properties of the crystal structure, are analyzed, new symmetry operations are evolved (screw axes and glide planes) and each of the point groups contains many such combinations, adding up to a total of 230 *space groups*. These are detected by diffraction methods. Table 1 summarizes the relations between the crystal systems and the symmetry groups.

A fundamental concept of great importance to all aspects of crystallography is that of the *reciprocal lattice*. If the unit vectors of the direct lattice are **a**, **b**, and **c**, then a reciprocal lattice exists whose unit vectors are $\mathbf{a}^* = \mathbf{b} \times \mathbf{c}$, $\mathbf{b}^* = \mathbf{c} \times \mathbf{a}$, $\mathbf{c}^* = \mathbf{a} \times \mathbf{b}$, with lengths given by $a^* = (1/V)\ bc \sin \alpha$, $b^* = (1/V)\ ca \sin \beta$, $c^* = (1/V)\ ab \sin \lambda$; the reciprocal unit cell volume $V^* = 1/V$. Because the Bragg diffraction angle 2θ is a function of the reciprocal of spacings in the direct lattice ($2 \sin \theta = \lambda/d$), the various orders of diffraction are associated with nodes in the reciprocal lattice. These nodes are designated by their integral coordinates in the lattice h, k, and l, known as *Miller indices*. Each node in the reciprocal lattice corresponds to a set of net planes in the direct lattice, and vice versa; the duality is complete. Crystal faces, which are parallel to the direct lattice net planes are therefore designated by Miller indices. This duality of direct and reciprocal space is exactly parallel to that represented by the Fourier transform:

$$f(x,y,z) = \iiint g(h,k,l) e^{-2\pi i(hx+ky+lz)}\ dxdydz$$

where h, k, and l may now be continuously variable (nonintegral). The potential $f(x, y, z)$ at any point x, y, z in direct space (e.g., electron density) is thus a synthesis of all the reciprocal potential $g(h, k, l)$ (e.g., x-ray scattering) in reciprocal space (and vice versa). In a crystal, the reciprocal potential is sampled at the reciprocal lattice points (vanishing for nonintegral h, k, l) and the above integral becomes a triple summation. The concept is used also in the interpretation of electron momentum space in a crystal, in which the Brillouin zones are defined by the reciprocal lattice (see FERMI SURFACE).

CURRENT ALGEBRA

Current algebra is a study of hadronic matter, (i.e., strongly interacting particles like protons, neutrons, and π mesons), through their electromagnetic and weak interaction properties. This study leads to a degree of unification of the three different forms of elementary particle interactions: strong, weak, and electromagnetic. The electromagnetic four current density $J_{\text{e.m.}}{}^{\mu}(x) \equiv (\rho(x), \vec{J}(x))$, with $\vec{J}$ and ρ respectively the densities of electric current and charge, is long familiar from Maxwell's equations. The conservation of this current, of course, leads to charge conservation in nuclear reactions. Mathematically this is expressed by saying $Q = \int d^3x\rho(x)$ is a time-independent constant. In 1958 it was established that the weak decays of hadrons are also described by currents. This led to the highly successful (V-A) theory of weak interactions, proposed by Marshak and Sudarshan and independently by Feynman and Gell-Mann. (Here V is a vector current and A is an axial vector current.) Soon after the successful proposal of SU(3) symmetry for classification of hadrons (suggested by Gell-Mann and Ne'eman in 1961) Gell-Mann laid down the foundations of current algebra. In attempting to interpret in precise terms the notion of symmetry violated by the strong interactions, Gell-Mann suggested that SU(3) symmetry operators be identified with charges associated with the weak and electromagnetic currents. In particular he emphasized the equal time commutation rules of these charges, and suggested that they may remain unchanged even in the presence of SU(3) breaking interactions, showing how this leads to a precise notion of universality of weak and electromagnetic interactions.

In the SU(3) scheme, one can define eight vector currents, with the charges corresponding to these operators being the generators of the group. These charges obey the equal time commutator algebra.

$$[F_i, F_j] = if_{ijk}F_k \qquad i, j, k = 1 \cdots 8 \qquad (1)$$

where f_{ijk} are antisymmetric structure constants of the group SU(3). One may also define an octet of axial currents, and the charges associated with these currents, $F_i{}^5$, obey the algebra

$$[F_i, F_j{}^5] = if_{ijk}F_k{}^5 \qquad i, j, k = 1 \cdots 8. \qquad (2)$$

Gell-Mann further postulated that axial generators among themselves obey a similar algebra,

$$[F_i{}^5, F_j{}^5] = if_{ijk}F_k \qquad i, j, k = 1 \cdots 8. \qquad (3)$$

Such an algebra leads to an abstract group SU(3) X SU(3). Although such a group is in fact not a symmetry group of particle states, nevertheless the generators at equal time are assumed to obey the commutator algebra. Thus the axial charges are not constants of motion, nor are all the vector charges constants of motion. The charges that play a role in electromagnetic and weak interactions are respectively

$$Q = F_3 + F_8/\sqrt{3} \qquad (4)$$

and

$$J^{\pm} = \cos\theta\,(F_1 \pm i\,F_2) + \sin\theta\,(F_4 \pm i\,F_5)$$
$$-\cos\theta\,(F_1{}^5 \pm i\,F_2{}^5) - \sin\theta\,(F_4{}^5 \pm i\,F_5{}^5). \qquad (5)$$

Here θ is a parameter called the Cabibbo angle, and experimentally $\theta \cong 15^\circ$.

Gell-Mann suggested that the current algebra be used in the same way as the familiar quantum condition, i.e., $[q, p] = i\hbar$, to derive sum rules as in atomic physics. His proposal remained dormant until use was made of another concept called the partial conservation of axial current hypothesis (PCAC). This postulate connects the pseudoscalar pion field to the divergence of the axial current. This hypothesis was used to obtain a value for the weak decay of the π meson from the known strong interaction pion-nucleon coupling constant (Goldberger-Treiman relation) and is known to be accurate to about 10 percent.

Among the successful applications of current algebra are prediction of weak decay rates of hyperons [e.g., $\Sigma^- \rightarrow n + e^- + \bar{\nu}$]. Such decays involve vector and axial parts; the vector parts are predicted to be just Clebsch-Gordon coefficients of the group SU(3), while the axial parts are also predicted in terms of two unknowns (f and d type couplings). As for the meson decay rates, the $K \rightarrow \pi\ e\ \nu$ decay is predicted accurately, although in meson systems symmetry-breaking corrections have to be made in general before predictions can be compared.

Application of current algebra leads to *sum rules* between different observables, as was the case in atomic physics. To illustrate the use of commutators in atomic physics, we give a derivation of the Thomas-Reiche-Kuhn sum rule. One starts with the fundamental quantum-mechanical assumption

$$[\vec{\epsilon}\cdot\vec{q}_i,\ \ \vec{\epsilon}\cdot\vec{p}_j] = i\hbar\delta_{ij} \qquad (6)$$

where i and j label different electrons and $\vec{\epsilon}$ is an arbitrary unit vector. Assuming that forces are velocity-independent, we may write

$$p_i = im\ [H, q_i]\ \hbar \qquad (7)$$

Using Eqs. (1) and (2) we may take the expectation value between the ground state $|0\rangle$ of an atom with Z electrons.

$$\sum_{ij}\langle 0|\,[\vec{\epsilon}\cdot\vec{q}_i, [H, \vec{\epsilon}\cdot\vec{q}_j]]\,|0\rangle = \frac{Z}{m}\hbar^2 \qquad (8)$$

Now inserting a complete set of intermediate states one gets

$$\sum_n |\langle 0|\sum_{i=1}^{Z}\vec{\epsilon}\cdot\vec{q}_i\ |n\rangle|^2(E_n - E_o) = \frac{Z\hbar^2}{2m} \qquad (9)$$

The usefulness of the sum rule arises from the fact that the left-hand side of the equation involves matrix elements of dipole operators that are observable in the transition spectrum of an atom. Very similar methods can be used with current algebra to obtain sum rules.

A sum rule obtained by Adler and Weisberger for the axial vector coupling in β-decay is among the triumphs of the axial-charge algebra. Use was made of the commutation relation

$$[F_1^5 + iF_2^5, F_1^5 - iF_2^5] = 2\,F_3 \qquad (10)$$

to derive

$$1 = \left[\frac{G_A}{G_V}\right]^2 + \frac{F_\pi}{\pi}\int_\mu^\infty \frac{d\nu\sqrt{\nu^2 - \mu^2}}{\nu^2}\,[\sigma_{\pi^- p}(\nu) - \sigma_{\pi^+ p}(\nu)] \qquad (11)$$

Here G_A is the axial vector coupling, G_V is the vector coupling, F_π is the pion decay constant, ν is the laboratory pion energy, and σ is the pion-nucleon total cross-section. G_A calculated from this relation is in good agreement with experiment. Other results include: *Adler's neutrino sum rule*, which relates neutrino to antineutrino scattering on protons at high energy; *Cabibbo-Radicati sum rule*, which relates anomalous magnetic moments of nucleons to cross-sections for absorption of isovector photons on nucleons; and *photoproduction sum rules*. These sum rules, wherever tested, are in good agreement with experiment.

Another class of applications leads to derivation of *low-energy theorems*. These theorems especially relate to processes where pions are emitted. It was shown that the Adler-Weisberger sum rule could be obtained as a low-energy theorem relating (G_A/G_V) to s-wave pion-nucleon scattering lengths. Other theorems deal with leptonic decays of K-mesons. A theorem due to Callan and Treiman for the decay $K \to \pi\, e\, \nu$ states that the two form factors that enter this decay are related to the K and π decay constants.

$$f_+(m_K{}^2) + f_-(m_K{}^2) = F_K/F_\pi \qquad (12)$$

Other theorems due to Weinberg relate form factors in the $K \to \pi\,\pi\, e\, \nu$ decay and obtain $\pi\,\pi \to \pi\,\pi$ scattering lengths. Low-energy theorems that combine PCAC and current algebra are not tested as well by experiment and some corrections may have to be made.

Other applications of the current algebra lead to a value of the electromagnetic mass difference of $\pi^+ - \pi^0$ mesons. Current algebra has been further extended by assuming that the currents are proportional to vector fields, like ρ, ω, K^* mesons. This hypothesis, called the current-field identity, has led to predictions for a large number of strong interaction decay rates of mesons. Such applications, however, involve a large number of free parameters. Nevertheless this enables calculations to be made where no method existed before.

In recent years tremendous progress has been made in understanding the strong interactions. Quarks have emerged as the basic constituents of hadrons, and their interactions are described by a gauge theory called *quantum chromodynamics*. In such a theory current algebra is exact. The great utility of current algebra arises from the smalleness of quark masses, especially the "up" and "down" quarks. The notion of PCAC can then be made very precise. Thus all the basic hypotheses of current algebra, which were arrived at mostly through intuition, are now on very firm ground. The problem of how quarks form hadrons has not yet been solved in quantitative detail. Current algebra continues to provide a strong tool for the study of hadronic properties.

CYBERNETICS

Cybernetics was defined by Norbert Wiener in 1948[1] as "control and communication in the animal and the machine." Communication clearly implies the communication of *information*; and purposeful control requires information about the current position and about the end being sought. Thus cybernetics has a strong "information" connotation and may be equated to "information handling." Note that it is information *handling*, rather than communication, for two reasons: first, the information may be used to modify the system (rather than merely passing through it), and second, it may be necessary to marshal information from various sources and process it (e.g., by a computer) before using it to effect control to a desired end. Wiener's definition can then be rewritten as "the handling of information in animals and machines in order to achieve desired effects." This includes the idea of "goal-seeking" systems which adapt themselves, to a greater or less extent, to the requirement of moving from the current situation to the desired goal. The least extent of this is found in the constant-parameter closed-loop system, the design of which may nonetheless involve considerable sophistication in order to achieve optimum performance (see FEEDBACK, SERVOMECHANISM). A further component in the idea of cybernetics is that the system in question should be stochastic, i.e., that it should show random fluctuations, usually about a defined average trend. Wiener was concerned with this aspect and contributed to the theories both of the frequency spectra of stochastic time series and of the filtering of stochastic signals in order to get the best estimate of the underlying trend. The three elements in cybernetics, information, spectra of stochastic processes, and filtering of stochastic signals, can be summarized as follows.

Information Control systems respond to signals which carry information. For example, when a call is made for an elevator car in a modern multiple installation, the computer-like controller takes account of all calls which have not yet been answered and the relative positions and directions of travel of all cars before deciding which car shall answer each call. This is an example of information *handling* rather than communication. Another example is that in the CAD/CAM (Computer-Aided Design and Computer-Aided Manufacture) organization of an engineering plant, information fed to a computer during design of components may be used to control the machine tools which make the components. An objective definition of information, independent of the observer and of the medium in which the information exists, was provided by Shannon in his mathematical theory of communication.[2] (Information is intimately related to communication, first because it is what is communicated and second because it can be observed only when it is communicated to the observer.) In human terms the information possessed by an individual may be thought of as a weighted sum of probabilities (many of which may be practical certainties). This accords with Shannon's measure of information in physical communication systems, although this measure was derived from entirely different and specific considerations. Shannon's measure of the information conveyed by each unit signal is numerically equal to the negative of the *entropy H*, where

$$H = -\sum_{i=1}^{n} p_i \log p_i.$$

Here, p_i is the probability of the ith state of the receiver after receiving the signal, e.g., the printing of the ith character out of a set of n in a teletype system. This assumes that there is a finite number n of possible states. See Shannon's paper for a derivation of the number of possible states of a communication channel of given signal-to-noise ratio and the theorem that any waveform can be represented by a number of discrete signals equal to two per cycle of the maximum Fourier frequency (the *sampling theorem**).

Spectrum of a Stochastic Process The frequency spectrum corresponding to a specified time function can be found by Fourier transform, but this is not applicable to a stochastic time function of which the amplitude at any given time can only be stated as a probability. In that case one proceeds via the autocorrelation function $R_{xx}(t_1, t_2)$ which is defined[4] as the expectation (in the statistical sense) that the variable x has the values x_1, x_2 at times t_1, t_2. If the stochastic function is stationary one can replace t_1 and t_2 by the difference $\tau = t_2 - t_1$ and average over all times:

$$R_{xx}(\tau) = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{T} f(t) f(t-\tau)\, dt.$$

Having determined the autocorrelation function for all values of τ one obtains the power (squared amplitude) spectrum of frequencies via the Wiener-Khintchine transform,

$$W(f) = \int_{-\infty}^{\infty} R_{xx}(\tau) \cos 2\pi f\tau \, d\tau$$

Wiener Filters The classic idea of filtering is to separate frequency components, but Wiener posed a more fundamental question: Given the past history of a stochastic time series, how can one make a least-squared-error estimate of its value at any time? An exact answer requires the solution of an integral equation, which is not always feasible. Moreover, if "any time" includes the future, this implies prediction of the future, which is not consistent with a physically realizable filter. One method of avoiding prediction is to introduce delay, leading to the *infinite-lag* filter. By shifting to the frequency domain it is possible to design a filter of characteristic

$$Y(f) = \frac{W(f)}{W(f) + N(f)}\, e^{-j\beta 2\pi f}$$

where $W(f)$ is the power spectrum of the signal (the underlying trend) and $N(f)$ that of the noise (the superimposed fluctuation). The exponential term represents a delay which tends to infinity as the filter is elaborated to make $Y(f)$ exact, and this form of filter is physically realizable. In order to obtain a physically realizable filter without delay (the *zero-lag* filter) one must return to the time domain and factor the

*Shannon assumed a low-pass frequency characteristic, but bandpass characteristics have subsequently been treated.[3]

filter function into two components, having zero value for $t < 0$ and $t > 0$, respectively. The former corresponds to a physically realizable filter since it has no output before its input. This factor can be translated into the frequency domain to combine with a function of the signal and noise spectra to specify the optimum zero-lag filter. This is inevitably less effective than the infinite-lag filter, but delay cannot be tolerated in closed-loop systems.*

Adaptive and optimizing control can be applied to chemical process plant to maintain specified conditions of temperature, pressure, flow etc., in spite of changes in external circumstances which may include changes in the characteristics of input materials. One can go further and, for example, make a fractional distillation plant optimize the output of any desired fraction.

The first generation of industrial robots were not adaptive but merely followed a fixed cycle of operations, which was programmed by "leading" the robot through the cycle which it could then repeat exactly as often as required. But present development is concerned with achieving adaptive behavior by adding sensors to the robot, e.g., tactile sensors[5] or solid-state television cameras to provide vision.[6] For example, an arc welder may be made to follow the joint to be welded, in spite of variations in positions of component parts; or a mobile robot can avoid obstacles.[7]

The application of cybernetics to robots is very close to *artificial intelligence*, i.e., making machines behave as though they were intelligent living creatures. This was first demonstrated in the form of "mechanical animals,"[8] but now includes such things as chess-playing computers.

The recent tendency is to apply the term "cybernetic" to more abstract systems which exhibit feedback plus adaptation and often some degree of stochastic behavior. There is then a relationship between "cybernetics" and "general systems theory" which is discussed in a group of papers.[9] One application of this type is to education,[10] where there may be various forms of feedback from taught to teachers, and a random element is introduced by the varied abilities and motivation of students. Other applications have been to government policy,[11] power systems,[12] chemical analysis,[13] and the development and manufacture of silicon chips.[14] The point in the last is that there are two coupled loops, for process and for product development, and only the use of an *adaptive* controller overall can ensure stability. Some of these topics are often grouped under the heading of *economic cybernetics* while others fall within *biocybernetics*.[15] The whole field of cybernetics is reviewed from time to time in a "progress" volume.[16]

CYCLOTRON*

The cyclotron is an accelerator of ions widely used to study the nucleus, to produce radioactive substances, and to study the interactions of ionizing radiation with living systems and with inert matter. It is equally important as the first of a class—*Magnetic Resonance Accelerators*—which includes the various kinds of synchrotron (see SYNCHROTRON) as well as synchrocyclotrons and sector focused cyclotrons. The essential feature of this type of accelerator is that acceleration of charged particles to high energies is achieved by a successive application of small accelerations in synchronization with the rotational period of the particles in a magnetic field. The condition for synchronization is simple and can be derived as follows: A charged particle moving perpendicularly to the lines of force in a magnetic field will describe a circle which is defined by the equilibrium between the Lorentz force $F_{\ell} = eBv$ and the centrifugal force $F_c = mv^2/r$. Equating these, one may solve for the rotational frequency of the particles which is set equal to the frequency of the accelerating field. This is the *Cyclotron Resonance Condition:*

$$f_a = f_0 = \frac{eB}{2\pi m} \qquad (1)$$

where

f_a = frequency of accelerating field
f_0 = rotational frequency
e = charge of ion
m = mass of ion
B = magnetic field strength.

The important fact is that the rotational frequency is independent of the energy of the particle and depends only on quantities which are (approximately) constant. In 1929 the possibility of using this relationship as the basis for an accelerator occurred to Ernest O. Lawrence, who like many other physicists at the time had been inspired by Rutherford's success in disintegrating atoms with alpha particles from natural sources to seek a means of producing a controlled beam of high energy particles. The practicability of the idea was demonstrated, and most of the essential features of the Cyclotron were developed by Lawrence, M. Stanley Livingston, N. E. Edlefsen, and others during the next few years.

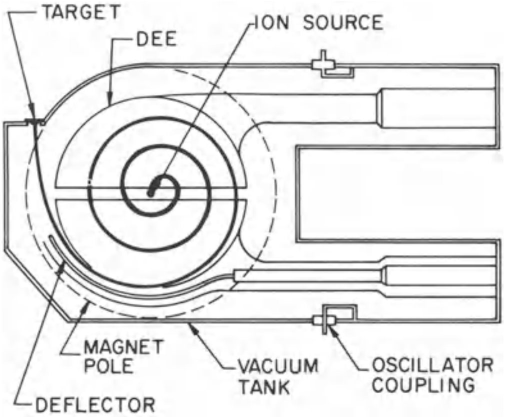

FIG. 1

Figure 1 is a schematic diagram showing the principle components of a cyclotron. The dees are two hollow semicircular electrodes in a vacuum tank located between the poles of an electromagnet which provides an approximately uniform magnetic field over the entire region. The dees are part of an electrical resonant circuit which may be excited by an oscillator whose frequency is adjusted to the rotational frequency given by Eq. (1). Ions are produced by an electric discharge in a source located at the center. They are drawn from the source and accelerated into a dee while it is negative, they follow a semicircular path in the (electrostatic) field free interior of the dee and again arrive at the gap between the dees where, by that time, the voltages are reversed in sign and they are accelerated again. The ions describe semicircles of increasing radius as their velocity and energy increase as a result of repeated accelerations. When they reach the maximum radius of the dee, they enter a channel between a septum in one of the dees and the deflector. The deflector is charged negatively and draws the particles out where they may strike a target in the target chamber or they may travel some distance as a beam outside the cyclotron before they are used.

The kinetic energy of the accelerated particles is given by:

$$T = \frac{1}{2}\frac{B^2R^2e^2}{m} \qquad (2)$$

where T is the kinetic energy and R is the radius of ion path at point of extraction. For protons, Eq. (1) reduces to $f = 1.52B$ MHz and Eq. (2) to $T = 0.484\,B^2R^2$ MeV with B in kilogauss and R in meters. The usual values of B are from 15 to 22 kilogauss.

In addition to the resonance condition, a successful cyclotron requires that the orbits be stable, i.e., they must remain in the median plane and at the appropriate radius. The first is achieved by introducing in the magnetic field a small negative gradient with respect to radius. The field lines are then bowed as shown in Fig. 2, and the Lorentz force on a particle off the median plane has a vertical focusing component. Radial stability results from the fact that the orbit of the particle is an equilibrium orbit with the inward Lorentz force predominating at radii larger than the equilibrium orbit and the centrifugal force predominating at smaller radii. Ions which are displaced either vertically or radially then execute oscillations about the equilibrium orbit. If the magnetic field is described by the index,

$$n = -\frac{r}{B}\frac{\partial B}{\partial r} \tag{3}$$

where r is the radius, then it can be shown that for $0 < n < 1$ stable oscillations occur with frequencies:

$$\begin{aligned} f_z &= f_0\sqrt{n} \\ f_r &= f_0\sqrt{1-n} \end{aligned} \tag{4}$$

where f_z is the frequency of vertical oscillations and f_r is the frequency of radial oscillations.

The negative gradient in the magnetic field results, however, in the situation where the rotational frequency, Eq. (1), is not exactly the same at all radii. In addition, it must be noted that the mass in Eq. (1) is the relativistic mass, $m = m_0 + T/c^2$ and increases with energy. The result of these two discrepancies is that the rotational frequency of the ion decreases as it is accelerated and there is an accumulated phase lag between the ion and the accelerating field which when it approaches π radians, results in no further acceleration. The energy limit of the conventional cyclotron imposed by this phase error can be shown to be proportional to the square root of the accelerating potential and to be about 30 MeV for protons with a dee-to-dee potential of 200 kV. It has not been possible to reach the theoretical maximum energy in practice, and for reasons made clear in the next sections, the incentive to do so has disappeared. The maximum energy which has been attained with protons is 22 MeV and that required about 500 kV on the dees. Currents in cyclotrons are usually of the order of 100 μA but up to 1 mA has been attained. The most commonly used ions are protons, deuterons, and alpha particles, although heavier ions such as carbon, nitrogen and oxygen ionized to +3 or +4 have also been accelerated.

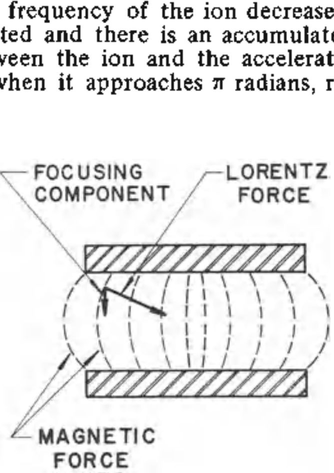

FIG. 2

A possibility of achieving higher energies with cyclotrons was opened up in 1945 when V. Veksler and E. M. McMillan independently pointed out the phase stable characteristic of the cyclotron resonance condition [Eq. (1)] which may be explained if the equation is rewritten in terms of particle energy:

$$f_0 = \frac{Be\,c^2}{2\pi(E_0 + T)} \tag{5}$$

where E_0 is the rest energy of the particle.

Consider a particle rotating in a cyclotron at the resonant frequency and crossing the accelerating gap at a phase such that it gains no energy and that a later arrival causes it to lose energy. If this particle is perturbed by an excess of energy, f_0 decreases and the particle loses energy. If the particle is perturbed in phase so that it arrives at the accelerating gap too early, it gains energy, f_0 decreases, and the phase slips back. Perturbations in energy or phase thus result in oscillations about the equilibrium phase. Under these conditions, if the accelerating frequency of a cyclotron is slowly decreased, the ions will execute stable oscillations about that phase which will give sufficient energy gain so that the radius and energy are matched as the orbits expand. This is the *Principle of Phase Stability* as applied to the Synchrocyclotron. It completely removes the energy limitation of the cyclotron previously discussed. This principle was immediately exploited and synchrocyclotrons (also sometimes called Frequency Modulated or FM Cyclotrons, and in the U.S.S.R., Phasotrons) have been built which give protons up to 1000 MeV. The only limit is the economic one due to the large size of the magnet.

The important structural difference between a synchrocyclotron and a conventional cyclotron is in the provision for a variable frequency. This is accomplished by placing a variable capacitor in the resonant dee circuit. Rotary blade capacitors have been in common use for this purpose, but in more recent designs, vibrating blade capacitors have been preferred. The required frequency swings are about two to one, and the usual modulation frequencies are about 60 to 100 Hz. The ions are accelerated in pulses as the accelerating frequency sweeps through its modulation cycle in contrast to the continuous acceleration in a conventional cyclotron. The result is that average currents in synchrocyclotrons are about 1 per cent of cyclotron currents, thus removal of the energy limit has been accomplished at the expense of a current limitation.

Another method of circumventing the energy limit of the cyclotron was proposed by L. H. Thomas in 1938, seven years before the principle of phase stability was enunciated. In the Thomas proposal, the average magnetic field increases with radius so that the resonance condition may be exactly matched by a constant accelerating frequency as the ion gains energy. The axial focusing force is supplied by an azimuthal variation of the magnetic field which may be obtained by using sectored magnet poles, Fig. 3a. The ion orbits are then no longer circular, and the radial component of velocity interacting with the azimuthal component of magnetic field produces an axial focusing force. This is the "edge focusing" which occurs when an ion crosses a fringe field obliquely, and it has long been used in mass spectrometers and other devices.

This idea was well in advance of the theory and practice of the cyclotron art at the time and was not immediately exploited. Development beginning in 1949 and extending to recent years has resulted in a whole subclass of cyclotrons characterized by a fixed rotational frequency and focusing forces derived from spatial variation in the magnetic field. For example, if the sectors are spiral shaped as in Fig. 3b, additional focusing forces of alternating gradient type are developed. These cyclotrons are variously called Sector Focused, Isochronous, and AVF (azimuthally varying field) cyclotrons. They have energies well beyond the energy limit of the conventional cyclotron and, at the same time, are capable of high average currents because they operate at a constant frequency. Provision of auxiliary magnet coils on the pole tips, to trim the field shape over a range of values of average field, and adjustable frequency oscillators, to provide for different ions and a variation in maximum energy, have made the modern cyclotron of this type very flexible.

In a further application of the Thomas principle, the magnet assembly is made up of individual sectors with field-free spaces between them. Fixed-frequency accelerating cavities are located between the sectors. This design variation of the sector-focused cyclotron makes it economically possible to go to higher energies, but at a sacrifice of some of the features permitting easy variation of energy and ion species. Cyclotrons may also be used two or even three in tandem. The extracted beam from a cyclotron designed for optimum acceleration of certain ions in a low energy range is used to provide an intense beam for injection into a larger cyclotron designed for a higher energy. Superconducting magnets have been used in some of the most recent cyclotron designs to produce magnetic fields more than twice that of conventional magnets, resulting in more compact installations and saving in magnet power.

The flexibility of cyclotron design, resulting from the application of the Thomas principle and concurrent technological developments, has rendered the classical cyclotron and synchrocyclotron obsolescent. A compilation of cyclotrons made in 1978 in connection with the Eighth International Conference on Cyclotrons and their Applications (see last reference) lists a total of 108 cyclotrons world-wide, in operation or under construction, of which 14 are synchrocyclotrons and only 4 classical. The remainder are variations of the sector-focused design. Two of these use superconducting magnets.

Source of data, "Eighth International Conference on Cyclotrons and Their Applications," *IEEE Transactions* NS-26, Number 2, 1979.

Table 1 gives a comparison of the salient design features and performance of typical examples of a classical cyclotron, a synchrocyclotron, a sector focused cyclotron designed for high intensity and variable ion and energy, and a sector focused cyclotron designed for high intensity and energy. The latter, giving copious secondary beams of pi mesons, are sometimes called meson factories.

The early and continuing impetus for cyclotron development has come from its use in research in nuclear physics and chemistry and particle physics. But applications in medicine where cyclotrons have provided radioisotopes for diagnosis and neutron and charged particle beams for therapy have been not far behind. Some of the other important applications have been trace elements analysis by activation of a sample and characterization of the resultant activity; solid state studies by creation of irradiation damage and by implantation of impurities; and production of many different radioisotopes for use as tracers in many fields of science and technology.

CYCLOTRON RESONANCE (DIAMAGNETIC RESONANCE)†

The term cyclotron resonance is used to designate the resonant coupling of electromagnetic power into a system of charged particles undergoing periodic orbital motion in a uniform static magnetic field. The frequency of the electric

†Support of U.S. Air Force is acknowledged.

field at resonance is simply related to the orbital frequency of the electron in the magnetic field. The effect has been observed and studied extensively in gases and in solids.

One important application of the cyclotron resonance principle is made in the acceleration of charged particles, as in a cyclotron. In a uniform magnetic field, H, a charged particle of mass, m_c, undergoes orbital motion with an angular velocity

$$\omega_c = \frac{eH}{m_c c}, \tag{1}$$

in which e is the charge and c the velocity of light. Energy from the electromagnetic fields, i.e., from the alternating electric and magnetic fields, is transferred into kinetic energy of the particle, and the radius of the particle orbit is increased with no change in angular velocity. Particle acceleration takes place *in vacuo* in order to prevent energy transfer to the gas by means of collisions.

In solids, cyclotron resonance has been successfully applied to studies of electronic energy band structure. The perfectly periodic array of atoms in an ideal solid scatters electrons coherently. An electron experiencing such coherent scattering can be described by the same equations of motion as the free electron, except that the free electron mass is replaced by an effective mass, m^*. Incoherent scattering from crystalline imperfections causes electronic collisions which limit the number of completed electron orbits, thus giving rise to a frequency bandwidth for the cyclotron resonance absorption. The observation of cyclotron resonance requires that the charged particle execute about one complete cyclotron orbit without collisions, or $\omega_c\tau \gtrsim 1$, in which the collision time, τ, is the mean time between incoherent scatterings. A long collision time is achieved by using samples of the highest possible purity and lattice perfection and by cooling to very low temperature (usually liquid He temperature, 4 K) to eliminate the thermal motion of the atoms. The condition for cyclotron resonance can also be satisfied by increasing ω_c through the use of high magnetic fields, e.g., 100-kilogauss static fields are currently available which for free electrons results in $\omega_c \approx 1.5 \times 10^{12}$ rad/sec or an electromagnetic wave length of about 1 mm.

Electrons moving in the periodic lattice of a solid occupy energy levels which are specified by the wave vector quantum number, **k**, or by the crystal momentum, $\hbar\mathbf{k}$. Since the number of electrons is very large, the wave vectors assume an almost continuous range of values. A knowledge of the functional form of the dependence of the energy on wave vector is necessary for a complete description of the behavior of electrons in solids. The simplest form of the relation between energy and wave vector valid for energy bands in cubic crystals is

$$E(\mathbf{k}) = \frac{\hbar^2 k^2}{2m^*}. \tag{2}$$

In this case, the constant energy surfaces in wave vector space are spheres, and the cyclotron mass of Eq. (1) is just the effective mass, m^*. For energy extrema located at general points in wave vector space, Eq. (2) becomes

$$E(\mathbf{k}) = \frac{\hbar^2}{2}\left(\frac{k_x{}^2}{m_x} + \frac{k_y{}^2}{m_y} + \frac{k_z{}^2}{m_z}\right) \tag{3}$$

in which the extremal point is taken as the origin, and m_x, m_y, and m_z are three components of an effective mass tensor. This generalization is also necessary in describing the energy bands for crystals with symmetry lower than cubic.

An expression for the cyclotron effective mass which is valid for an electron orbiting on a constant energy surface of energy E for an arbitrary $E(\mathbf{k})$ is

$$m_c(E, k_H) = 2\pi\hbar^2 \left(\frac{\partial A}{\partial E}\right)_{k_H} \tag{4}$$

in which k_H is the wave vector component parallel to the magnetic field, A is the area of the electron orbit in wave vector space, and $(\partial A/\partial E)_{k_H}$ is the derivative of this area with respect to energy evaluated at constant k_H. For spherical or ellipsoidal constant energy surfaces, the cyclotron mass is independent of both energy and k_H, and for these two simple cases, m_c is given, respectively, by $m_c = m^*$, and

$$\left(\frac{1}{m_c}\right)^2 = \frac{\alpha^2}{m_y m_z} + \frac{\beta^2}{m_x m_z} + \frac{\gamma^2}{m_x m_y} \tag{5}$$

in which α, β, γ are the direction cosines of the magnetic field with respect to the axes of the ellipsoidal constant energy surface.

For solids which have relatively low carrier density (e.g., insulators, semiconductors, and semimetals) the electronic states which are important in the transport properties are located near energy band extrema. For nondegenerate extremal points in wave vector space, $E(\mathbf{k})$ can be expanded in a Taylor's expansion. The leading term of such an expansion would be given by Eq. (3). For degenerate points (positions where two or more levels have the same energy), a simple generalization of a Taylor's expansion must be used. In solids with relatively high carrier density (e.g., metals), the transport properties are determined by electronic states which are far from the energy extrema and the $E(\mathbf{k})$ relation is not adequately described by a Taylor's expansion.

Cyclotron resonance experiments have been particularly successful in the quantitative determination of the band parameters of the semiconductors silicon and germanium. The successful application of this technique in these semiconductors is attributed to the high quality of the available material, and to the complete classification of the possible forms of the theoretical band structure model. Since in these materials the intrinsic carrier concentration is extremely small at low temperatures, electrons are optically excited out of filled valence levels in the crystal in order to produce sufficient carriers to obtain a measurable signal. Resonances are observed both for the excited electrons and for the holes left behind in the empty levels in the valence band.

In metals, the high carrier density requires modification of the conventional cyclotron resonance experiment. Two important consequences of this high carrier density are the nonuniform penetration of the electromagnetic field in the skin depth and the inapplicability of the simple effective mass theory to describe the electronic states. To overcome the problem of the small electromagnetic penetration depth, the geometrical arrangement suggested by Azbel and Kaner is used. The static magnetic field is applied in the plane of a flat sample, so that the electrons near the surface can be accelerated by the electromagnetic fields, and the orbits described by a cyclotron radius which is large compared with the skin depth. In this way, whenever the applied frequency is a multiple of the cyclotron frequency, a resonant condition is satisfied. This type of cyclotron resonance experiment yields an effective mass at the Fermi energy given by Eq. (4), which is, in general, dependent on the wave vector component parallel to the magnetic field. The interpretation of these experiments is not simple but when coupled with experiments which measure the shape of the Fermi surface, such as DE HAAS-VAN ALPHEN EXPERIMENTS, a fairly complete determination of the electronic band structure is possible. These techniques have been successfully applied in the study of copper.

Cyclotron resonance in ionic crystals allows the measurement of polaron effects. The POLARON denotes the charge carrier together with its local lattice distortion. Cyclotron resonance observed in AgBr has been interpreted as a polaron orbiting in the applied magnetic field.

D

DE HAAS-VAN ALPHEN EFFECT*

The de Haas-van Alphen effect is the periodic oscillation of the magnetization with inverse magnetic field. These oscillations were discovered in 1930 in Bi at very low temperature by W. J. de Haas and P. M. van Alphen. For some time the effect was thought to be unique to Bi but it was observed in zinc in 1947 and since then in a very large number of metals and intermetallic compounds. Related magneto-oscillatory behavior in the electrical resistance has even been observed recently in organic metals.

Peierls first explained the effect in 1933 as a consequence of the quantitization of the motion of the conduction electrons in a magnetic field. In zero field, electrons have a nearly continuous range of energies up to a maximum called the Fermi energy E_F. In momentum or wave number space, all states are occupied up to the Fermi surface. The Fermi surface is thus the boundary between filled and unfilled states in momentum space.

When a magnetic field H_z is applied, only discrete energy levels E_n are available for a given k_z, and the separation between these levels increases with field. If the energy surfaces are ellipsoidal so that E is proportional to k^2, E_n is exactly soluble from the Schrödinger equation. Typically the energy surfaces are much more complex but an approximate approach due to Onsager can be used. By application of the Bohr-Sommerfield quantization condition to orbits normal to the applied field direction, Onsager showed that the area A enclosed in an orbit satisfies

$$A = 2\pi(n + \gamma)\, eH/\hbar c \qquad (1)$$

where n is an integer, γ is a constant near $\frac{1}{2}$ (exactly $\frac{1}{2}$ for quadratic energy surfaces), $\hbar$ is Planck's constant divided by 2π, and c is the velocity of light. For a free-electron metal ($E \propto k^2$) at $T = 0$, the electrons are contained in a sphere in k-space of maximum energy E_F, while in a field H_z they are found in a series of cylinders with axes parallel to H_z as shown in Fig. 1. As the field magnitude increases the cylinders grow in size, and at a critical field given by

$$1/H = 2\pi(n + \gamma)e/\hbar cA_0 \qquad (2)$$

the nth cylinder becomes too large to be contained in the surface. Here A_0 is the maximum cross-sectional area of the sphere. This gives rise to oscillations in the free energy F periodic in $1/H$. This same result occurs for more irregular shaped Fermi surfaces, with the oscillations corresponding to *extremal* cross sections.

The effect is usually observable only below 4 K because the Fermi surface is blurred out over an energy range $\sim kT$ at finite temperatures T. If we define an effective carrier mass m^* by

$$m^* = \hbar^2/2\pi(dA/dE)_{k_z} \qquad (3)$$

then the oscillatory term in the free energy F is given[1] by

$$F \propto TH^{3/2} \exp\,[-2\pi^2\, k(T + X)\, m^*c/eH\hbar\,] \cdot \cos\,[c\hbar A_0/eH) + (\pi/4) - \delta\,] \qquad (4)$$

for the case when the argument of the exponential is much greater than unity. Here k is the Boltzmann constant, δ is a phase factor, and X is a term that takes into account the impurity collision broadening of the energy levels. By varying the temperature as the field is held constant m^* can be determined, and then by varying field at constant temperature the scattering factor X can be measured.

Historically the de Haas-van Alphen effect was measured using torsion balance techniques, usually at slowly varying fields considerably below 40 kG or using pulsed field techniques to a maximum of ~200 kG. In the former method the torque exerted on a sample as the field is changed is measured with the advantages of high sensitivity and accuracy. The disadvantages are insensitivity to spherical segments of the Fermi surface and practical limitation to moderate fields, which make large cross sections difficult or impossible to observe. The pulsed field technique employs 100-200 kG fields with rise times of the order of 10 msec. These high fields permit observation of very high de Haas-van Alphen frequencies but accuracy is limited by the necessity of making measurements of the susceptibility and field magnitude in a few msec.

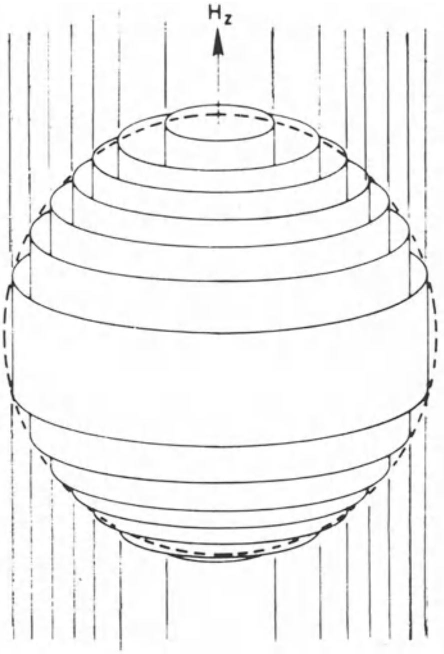

FIG. 1. Quantitized orbits for a free-electron metal in a magnetic field H_z. The dashed line is the boundary of the Fermi surface.

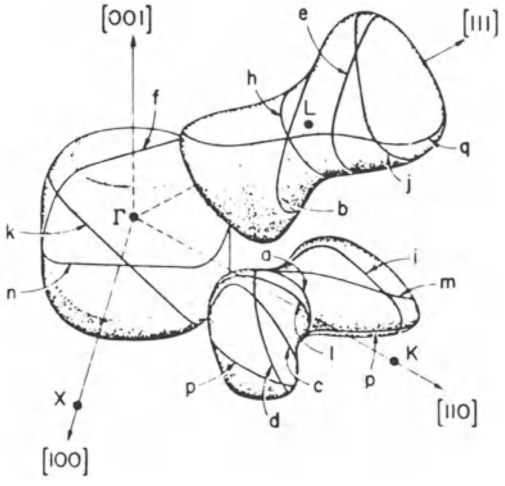

FIG. 2. Fermi surface of thorium as calculated by Gupta and Loucks.

In the past decade, the bulk of the detailed de Hass-van Alphen measurements have employed what is known as the *field modulation technique.*[2] Here a small balanced pickup coil detects the oscillations in the magnetization of the sample as the applied field is slowly varied

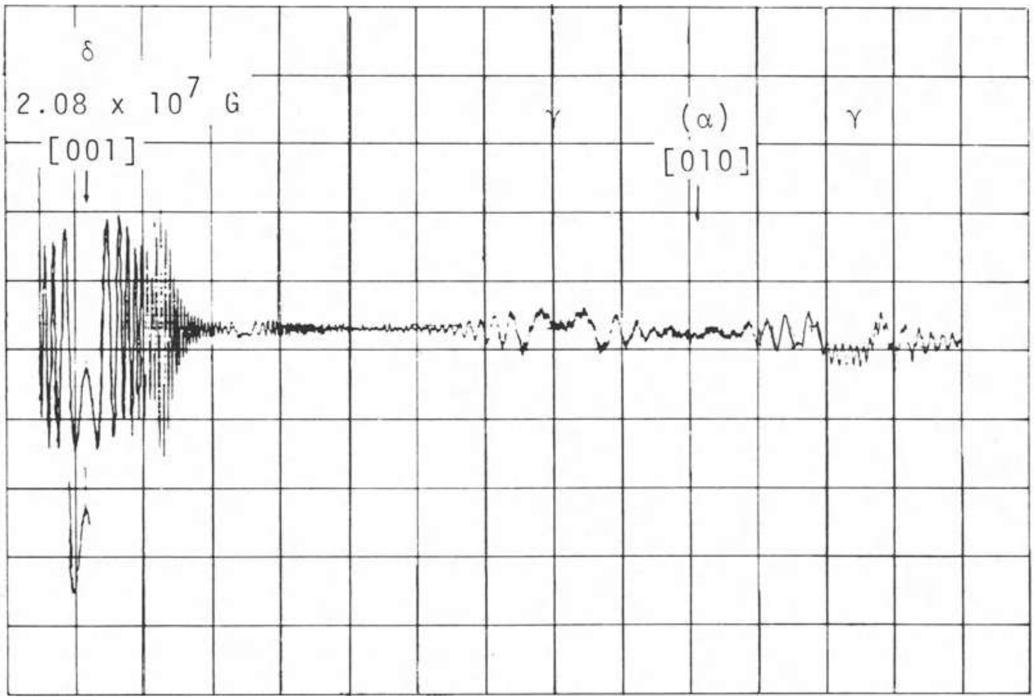

FIG. 3. De Haas-van Alphen oscillations obtained by rotation of the magnetic field about a single crystal of α-U at ~100 kG, 9 kbar and 1 K.

while being modulated sinusoidally. The technique lends itself to use with superconducting coils, which can now be obtained in the 100–150 kG range. The flexibility to vary the modulation amplitude and direction when coupled with detection of various harmonics of the modulation allows spectrometer action in sorting out complicated de Haas-van Alphen spectra. Fourier analysis of the spectra is also routinely employed. These techniques have resulted in an enormous amount of very accurate, and in many cases complete, experimental mappings of the Fermi surfaces of a great many metals. With high-quality, long-mean-free-path crystals, the limitation on the accuracy of the cross-sectional area data is reduced to the limitations in counting the oscillations and determining the absolute value of the magnetic field (which can be monitored by *in situ* nuclear magnetic resonance).

The calculated Fermi surface of thorium is shown in Fig. 2 and all of the extremal orbits shown on each of the three sheets have been observed. The detailed angular dependence of the sheets can be determined by rotation of the magnetic field (at constant magnitude) with respect to the crystallographic axes as shown in Fig. 3 for α-U. These data were taken at 1 K at 100 kG at a pressure of 9 kbar (~9000 atmospheres) in order to avoid low-temperature phase changes below 43 K. This is an indication of the versatility of present-day experimental de Haas-van Alphen techniques.

De Haas-van Alphen data have been important in the development of band calculations of electronic structure of metals. Because of its great sensitivity and the fact that it is nearly a dc experiment, the field modulation technique also lends itself to measurements of the pressure and strain dependence of the Fermi surface. This type of experiment provides critical and direct tests for the theoretical model descriptions which can be calculated easily at various interatomic spacings.

DENSITY AND SPECIFIC GRAVITY

Definitions The amount of a substance that occupies a given amount of space is an intrinsic property of the substance. This intrinsic property of substances is called *density*. Thus, density is a measure of the amount of matter that occupies a given amount of space. Precisely defined, density is the mass of a substance per unit volume. In the international system of units (Système International) the density of a substance is given in kilograms per cubic metre (kg/m^3). In the centimetre/gram/second (cgs) system the density of water is 1 g per cubic centimetre. It is possible to remove the system of units from the numerical value of density by defining a property called *specific gravity*. The specific gravity is the ratio of the density of the given substance to the density of a standard substance. It has been customary to define the specific gravity of a substance as the ratio of the density of the substance to the density of water. As a result, since the density of water in the cgs system is 1 g/cm^3, the specific gravity of an object has the same numerical value as its density in cgs units.

Density is the ratio of two independent extrinsic properties of a given amount of a substance, its mass divided by its volume. In common useage the concept of density is frequently confused with the weight of an object. In addition it is not uncommon to find weight and volume confused in common discussions of objects. The common confusion among weight, volume, and density is displayed in the child's trick question, "Which is heavier—a ton of bricks or a ton of feathers?" When trying to convey scientific information about the density of an object to the public, care must be taken to explain this intrinsic property of matter. It may be best to contrast density to the daily experiences of heft or heaviness.

Density is an intrinsic property of an object, i.e., it will not vary from one part of a homogeneous object to another, but it does depend upon the volume of the object. Hence, density is a function of those variables that can change the volume of an object. In general, the volume of an object is a function of both temperature and pressure. This functional dependence of volume on temperature and pressure is most striking for gaseous materials (see GAS LAWS) but temperature is also an important consideration for all three states of matter (see EXPANSION, THERMAL).

The concept of density as mass per unit volume seems to imply a continuous medium. According to the modern atomic theory of matter (see ATOMIC PHYSICS) all matter is made up of discrete entities called *atoms*. Hence, the density of a substance is a microscopic measure of how tightly the atoms of the substance are packed together. If a solid sphere model is adopted for an atom, then the density of individual atoms of various elements can be calculated and compared to the densities of normal materials (see the table at the end of this article). Similarly according to the nuclear model of atoms (see ATOMIC PHYSICS), an atom consists of a massive nucleus situated in the middle of an electronic cloud. Once again, if a solid spherical model is adopted for a nucleus, then one can take typical nuclear properties and calculate nuclear densities to compare with the densities of other kinds of matter (see the table at the end of this article).

Solids Since the compressibility of solids is very small, their density is essentially independent of pressure and only shows a small temperature dependence. The direct measurement method of density involves measurement of both mass and volume under the same conditions. For example the mass of 1 cubic meter of aluminum is 2700 kg. The hydrostatic method of measuring densities is based on the application of Archimedes' principle, which states that the buoyant force on an object immersed in a fluid is proportional to the mass of the volume of the displaced fluid. The hydrostatic method for measuring the density of a solid weighs the solid object in air and in water and uses the loss of weight in water as a way to determine the density of the object. If the solid has a weight in air W_a and a weight in water W_w then the density of the solid ρ_s, neglecting the buoyancy of air, is given by

$$\rho_s = W_a \rho_w/(W_a - W_w)\ (\text{kg/m}^3)$$

where ρ_w is the density of water.

The determination of the density of a solid by the hydrostatic method can be corrected for the buoyant force of the air. Then the density of the solid is given by

$$\rho_s = W_a(\rho_w - \rho_a)/(W_a - W_w) + \rho_a$$

where ρ_a is the density of air.

Sources of error in the hydrostatic method are largely due to surface tension effects and trapped air on the surface of the solid. As a rule of thumb a minimum volume of 5 cm^3 is required for an accuracy of one part in 10^4 in the corrected density.[1]

For solids less dense than water, a sinker (denser than water) is used. The sinker is weighed in air and in water as described above and then weighed with the unknown. The density of the unknown sample ρ_u is then found in terms of:

W_{ua} = weight of unknown in air;

W_{sa} = weight of sinker in air

W_{usw} = weight of unknown and sinker in water;

W_{sw} = weight of sinker in water

$$\rho_u = W_{ua}\rho_w/(W_{ua} + W_{sa} - W_{usw}) - (W_{sa} - W_{sw}))$$

$$\rho_u = W_{ua}\rho_w/((W_{ua} - (W_{usw} - W_{sw})) \cdot (\text{kg/m}^3)$$

where ρ_w is the density of water.

Liquids A standard object and the hydrostatic method can be used to find the density of a liquid. This process for determining the density of a liquid calls for measuring the weight of the object in air W_a and in water, W_w, and in the liquid, W_l, then the density of the liquid is given by

$$\rho_l = (W_a - W_l)\rho_w/(W_a - W_w)\ (\text{kg/m}^3).$$

Accurate density measurements must minimize temperature effects and are usually made at specified temperatures (e.g., 15°C).

A mechanical system for the rapid measurement of the density of liquids with extremely high accuracy has been developed.[2] This system measures the period of oscillation of a U-tube containing the liquid of unknown density. The period of oscillation is directly related to the density of the liquid in the U-tube.

The operation of this system is based on the physics of a damped harmonic oscillator. The instrument provides an external electromagnetic force to balance the damping forces on the oscillating U-tube. While this force balance is maintained the resonant oscillations of the system are established. The period of the resonance oscillations is then measured and related to the density of the liquid as follows:

The total mass of the vibrating objects is given by

$$M = M_t + V\rho$$

where M_t is the mass of the empty U-tube, V is the volume of the tube, and ρ is the density of the liquid in the tube.

The period at resonance is given by

$$T = 2\pi(M/k)^{1/2} = 2\pi((M_t + V\rho)/k)^{1/2}$$

where k is the restoring force constant of the oscillator.

The density of the liquid can be computed from the period of oscillation and the values of the instrument constants. In practice the instrument constants are determined by measuring the periods of oscillations of fluids of known density such as dry air and pure water.[3]

The commercially available instrument is designed to measure total time for a fixed number of oscillations in time ranges from 0.7 to 480 seconds.* During the time of measurement the temperature of the sample must be controlled to within $\pm 10^{-2}$°C for absolute errors in the density of the fluid less than 10^{-3} kg/m^3. In practice this temperature control is difficult and leads to the use of small sample volumes, i.e., seven milliliter volumes are the most common. The instrument specifications call for a maximum precision of 1.5×10^{-3} kg/m^3 for a measuring range of $0\text{–}3 \times 10^3$ kg/m^3 when density differences are measured. In comparing

*The commercial instrument is manufactured by the A. Paar Company of Graz, Austria and is marketed by the Mettler Instrument Corp. in the U.S.A.

the measurements using this mechanical oscillation instrument to other sources of density measurement of standard sodium chloride solutions, the precision of this instrument was found to be better than 5 parts in a million for all cases.

Gases The densities of a gas are strongly dependent on both temperature and pressure. It is the custom to give density values at the standard temperature and pressure (STP) values of 0°C and 1 atmosphere, respectively. Measurements under other conditions may be reduced to STP values by using the appropriate equation of state. In many cases, the ideal gas law can be used to give the STP density ρ from measurements at any pressure and temperature as follows:

$$\rho = M/V = MP_0(1 + 0.00366(T - T_0))/PV$$

where M is the mass of the gas, V is the volume of gas at a pressure P and temperature T(K), and P_0 and T_0 are the standard values of pressure and temperature. The experimental method used is the direct measurement of a known volume V of a gas at ambient temperature and pressure. A standard flask of air is evacuated, then filled with the gas to ambient pressure, and its mass is measured.

TABLE OF TYPICAL DENSITIES

Substance	Density (kg/m^3)
Smooth density of galactic material throughout the universe	2×10^{-28}
Mean density of interstellar gas	3×10^{-21}
Mean density of the moon	3.3×10^3
Mean planet densities	
Saturn	0.70×10^3
Jupiter	1.33×10^3
Mars	3.93×10^3
Venus	5.24×10^3
Earth	5.515×10^3
Typical densities of earth materials	
Air	1.293
Teak wood	0.58×10^3
Alcohol	0.80×10^3
Ice (0°C)	0.917×10^3
Water (0°C)	0.999841×10^3
Water (4°C)	0.999973×10^3
Water (20°C)	0.998203×10^3
Aluminum	2.70×10^3
Copper	8.96×10^3
Silver	10.5×10^3
Mercury	13.6×10^3
Gold	19.3×10^3
Platinum	21.5×10^3
Mean densities of atoms (using solid sphere model)	
Hydrogen	4.4×10^1
Oxygen	2.0×10^3
Uranium	1.7×10^5
Densities of stars	
The sun	1.41×10^3
White dwarf	1×10^9
Neutron star	2×10^{17}
Density of nuclear matter (using solid sphere model)	2×10^{17}

Applications Since density is an intrinsic property of a substance and is, in general, a unique value for each substance, density can be used as a way to distinguish one substance from another. In systems where the force on objects is proportional to mass, as in a gravitational field (See gravity) differences among the densities of fluids can be used to separate fluids from one another.

Typical Values of Densities The materials we commonly encounter have densities that vary only over a few orders of magnitude from air with a density of 1.3 kg/m^3 to gold with a density of 19×10^3. However, as shown in the Table of Typical Densities, in the whole universe the densities of matter vary over 45 orders of magnitude.

DIAMAGNETISM

Magnetic susceptibility is defined as $\chi_m = M/H$, where M is the magnetic moment per gram (gram susceptibility) or per mole (mole susceptibility) that is induced by an external magnetic field strength H. If $M > 0$, the susceptibility is *paramagnetic*; if $M < 0$, the susceptibility is *diamagnetic*. Whereas most magnetic phenomena, including PARAMAGNETISM, are manifestations of ELECTRON SPIN, diamagnetism reflects electron angular momentum.

If an external field strength H is applied to a conductor so as to change the number of lines of flux that thread through it, there is induced in the conductor an electric current whose associated magnetic field opposes the change (*Faraday's Law of Induction* and *Lenz's Law*). In most conductors the current I that is thus induced is rapidly dissipated as heat through the I^2R loss, where R is the electrical resistance. These currents are known as *eddy currents*, and they are of great practical interest in ac applications. However, such transients do not influence the dc measurement of χ_m. There are three other classes of electron-momentum change induced by H that are not dissipated: electron currents in SUPERCONDUCTORS, where the resistance is $R = 0$; currents of atomic dimension induced in atoms or molecules or the atomic "core" electrons of solids; and microscopic conduction-electron helical currents having quantized helical radii.

In a superconductor, switching on of an H induces eddy currents that permanently shield the inside of the conductor from penetration by the magnetic-field lines. Therefore the superconductor is an ideal diamagnet, except for a small skin depth at the surface. If a superconductor is cooled through the normal-conducting ⇌superconducting transition temperature in the presence of H and after the eddy currents induced in the normal-conducting state have been dissipated, the field lines are rapidly expelled from the superconductor (*Meissner effect*). This proves that the ideally diamagnetic state is thermodynamically stable.

An external field H superposes on the motion of atomic or molecular electrons (or the atomic core electrons in solids) a common circular motion about H of angular frequency $\omega_L = eH/2mc$, where e/m is the electronic charge-to-mass ratio (*Larmor's theorem*). This atomic current produces an atomic moment that is proportional to the square of the distance of a classical electron from the nucleus, $r_i \sim 1$Å. Therefore the diamagnetic contribution from electrons localized about an atomic nucleus is

$$\chi_m^{\text{core}} = -(Ne^2/6mc^2)\sum_i \overline{r_i^2},$$

where N is the number of atoms per gram (or mole).

In addition to macroscopic eddy currents, conduction electrons tend to move in microscopic helical paths in the presence of an H. The contribution to χ_m from this helical motion is a purely quantum mechanical effect. The radii of the H-induced helical paths are quantized, which leads to a "bunching" of the energy levels within an energy band of conducting states, and at large H these "bunches" can be resolved. They are known as *Landau levels* because Landau[1] first presented the quantum mechanical theory of conduction-electron diamagnetism, which for single parabolic energy bands gives

$$\chi_m^{\text{cond}} = -\frac{2}{3}\mu_B{}^2 N(E_F),$$

where μ_B is the *Bohr magneton* and $N(E_F)$ is the density of energy levels at the *Fermi energy* E_F. Since $N(E_F)$ oscillates with H as successive Landau levels pass through E_F, χ_m^{cond} shows oscillations in large H (DE HAAS-VAN ALPHEN EFFECT). Transitions between Landau levels, which are split by an energy $\hbar\omega_p = eH/m^*c$, may be induced by an electromagnetic field of angular frequency ω_p. This gives rise to resonance power absorption as ω passes through ω_p (*cyclotron or diamagnetic resonance*). These two effects are used to map out the contours in momentum space of the Fermi energies in metals.

DIELECTRIC THEORY

A dielectric is a material having electrical conductivity low in comparison to that of a metal. It is characterized by its dielectric constant and dielectric loss, both of which are functions of frequency and temperature. The dielectric constant is the ratio of the strength of an electric field in a vacuum to that in the dielectric for the same distribution of charge. It may also be defined and measured as the ratio of the capacitance C of an electrical condenser filled with the dielectric to the capacitance C_0 of the evacuated condenser:

$$\epsilon = C/C_0$$

The increase in the capacitance of the condenser is due to the polarization of the dielectric material by the applied electric field. Since the dielectric constant is not a constant, it is frequently called the "dielectric permittivity." The relative permittivity or dielectric constant is the ratio ϵ/ϵ_0, where ϵ_0 is the permittivity or dielectric constant of free space. In the mks system of units, the dielectric constant of free space is 8.854×10^{-12} farad/m, while in the esu system the relative and the absolute dielectric constants are the same. The relative dielectric constant, which is dimensionless, is the one commonly used. When variation of the dielectric constant with frequency may occur, the symbol is commonly primed. When a condenser is charged with an alternating current, loss may occur because of dissipation of part of the energy as heat. In vector notation, the angle δ between the vector for the amplitude of the charging current and that for the amplitude of the total current is the loss angle, and the loss tangent, or dissipation factor, is

$$\tan \delta = \frac{\text{Loss current}}{\text{Charging current}} = \frac{\epsilon''}{\epsilon'}$$

where ϵ'' is the loss factor, or dielectric loss, of the dielectric in the condenser and ϵ' is the measured dielectric constant of the material.

At low frequencies of the alternating field, the dielectric loss is normally zero and ϵ' is indistinguishable from the dielectric constant ϵ_{dc} measured with a static field. Debye has shown that

$$\frac{\epsilon_{dc} - 1}{\epsilon_{dc} + 2} = \frac{4\pi N_1}{3}\left(\alpha_0 + \frac{\mu^2}{3kT}\right) \qquad (1)$$

where N_1 is the number of molecules or ions per cubic centimeter; α_0 is the molecular or ionic polarizability, i.e., the dipole moment induced per molecule or ion by unit electric field (1 esu = 300 volts/cm); μ is the permanent dipole moment possessed by the molecule; k is the molecular gas constant, 1.38×10^{-16}, and T is the absolute temperature. An electric dipole is a pair of electric charges, equal in size, opposite in sign, and very close together. The dipole moment is the product of one of the two charges by the distance between them.

In Eq. (1) $\mu^2/3kT$ is the average component in the direction of the field of the permanent dipole moment of the molecule. In order that this average contribution should exist, the molecules must be able to rotate into equilibrium with the field. When the frequency of the alternating electric field used in the measurement is so high that dipolar molecules cannot respond to it, the second term on the right of the above equation decreases to zero and we have what may be termed the optical dielectric constant ϵ_∞, defined by the expression

$$\frac{\epsilon_\infty - 1}{\epsilon_\infty + 2} = \frac{4\pi N_1}{3}\alpha_0 \qquad (2)$$

ϵ_∞ differs from n^2, the square of the optical refractive index for visible light, only by the small amount due to infrared absorption and to the small dependence of n on frequency, as given by dispersion formulas. It is usually not a bad approximation to use $\epsilon_\infty = n^2$. The general Maxwell relation $\epsilon' = n^2$ holds when ϵ' and n are measured at the same frequency. The Debye equation may be written in the form

$$\frac{\epsilon_{dc} - 1}{\epsilon_{dc} + 2} - \frac{\epsilon_\infty - 1}{\epsilon_\infty + 2} = \frac{4\pi N_1}{9kT}\mu^2 \qquad (3)$$

A much better representation of the dielectric behavior of polar liquids is given by the Onsager equation

$$\frac{\epsilon_{dc} - 1}{\epsilon_{dc} + 2} - \frac{\epsilon_\infty - 1}{\epsilon_\infty + 2} = \frac{3\epsilon_{dc}(\epsilon_\infty + 2)}{(2\epsilon_{dc} + \epsilon_\infty)(\epsilon_{dc} + 2)}\,\frac{4\pi N_1 \mu^2}{9kT} \qquad (4)$$

Kirkwood developed an equation differing from that of Onsager (Eq. 4) in that μ^2 is multiplied by a correlation parameter g in an attempt to account for the hindrance of the rotational orientation of dipolar molecules by their neighbors. The departure of the value of g from unity is a measure of the hindrance to molecular rotation by short-range intermolecular forces. Positive deviations of g from unity occur when short-range hindering torques favor parallel orientation of neighboring dipolar molecules, while negative deviations occur when these torques favor antiparallel orientation. Empirically determined values of g are not far from unity for normal or unassociated liquids, but may depart considerably from unity for abnormal or associated liquids. When $g = 1$, the Kirkwood and the Onsager equations are identical. Both equations contain the approximation involved in treating the dipolar molecules as spheres. Johari has been successful in treating the water in certain clathrate hydrates, in which he finds the dipole moment of H_2O increased by nearly 30% over its vapor phase value.

An equation derived by Debye for the change of dielectric constant or permittivity $\Delta\epsilon$ produced by application of an electric field of intensity E to a liquid or gas

$$\Delta\epsilon = \frac{-4\pi N_1 \mu^4 E^2}{45(kT)^3}\;\frac{(\epsilon + 2)^4}{81} \qquad (5)$$

showed that any departure from linear dependence of polarization upon the intensity of the applied field was too small to be evident at the field intensities (<100 volts cm^{-1}) normally used in measurement of ϵ, but at higher applied fields in the kilowatt region and, especially with molecules of large dipole moments, departure from linearity was sufficient to give significant values of $\Delta\epsilon$. The important work of A. H. Piekara and his coworkers in this area has been reviewed and discussed by Davies (Hill, Vaughan, Price, and Davies, 1969) and more recently by Davies and by Piekara himself (Neel, L., Ed.). The Onsager treatment has also been introduced to change the factor $(\epsilon + 2)^4/81$ in Eq. (5). Several simple liquids, such as ethyl ether, chloroform, and chlorobenzene, the molecules of which have moderate-sized dipole moments, were found to show the predicted decreases in dielectric constant when a strong electric field was applied. However, in the case of the more polar nitrobenzene and 1,2- and 1,3-nitrotoluene, positive values of $\Delta\epsilon$ were observed, changing to negative on dilution with a nonpolar solvent, which presumably reduced or destroyed pairwise orientation of the dipolar molecules. These and more or less similar changes in dielectric constant or permittivity produced by application of a high electric field are called *nonlinear dielectric* or *saturation effects*, although the degree of saturation attainable before dielectric breakdown occurs is normally small. An exception cited by Davies is a dioxan solution of poly(γ-benzyl-L-glutamate), which has an enormous molecular dipole moment of about 2000 D. At a field intensity of about 40 kV cm^{-1}, the dielectric constant of the solution is reduced by an amount $\Delta\epsilon = -0.10$ to equal that of the pure solvent, which means that virtually complete dielectric saturation has occurred. Liszi, Mészáros, and Ruff have developed an equation for the field dependence of the dielectric constant or permittivity of liquids taking into account a field dependence of the Kirkwood correlation parameter g. This equation predicts both normal and anomalous dielectric saturation and the structure making and breaking effects of the field.

Anomalous dielectric dispersion occurs when the frequency of the field is so high that the molecules do not have time to attain equilibrium with it. One may then use a complex dielectric constant

$$\epsilon^* = \epsilon' - j\epsilon'' \tag{6}$$

where $j = \sqrt{-1}$. Debye's theory of dielectric behavior gives

$$\epsilon^* = \epsilon_\infty + \frac{\epsilon_{dc} - \epsilon_\infty}{1 + j\omega\tau} \tag{7}$$

where ω is the angular frequency (2π times the number of cycles per second) and τ is the dielectric relaxation time. Dielectric relaxation is the decay with time of the polarization when the applied field is removed. The relaxation time is the time in which the polarization is reduced to $1/e$ times its value at the instant the field is removed, e being the natural logarithmic base.

Combination of the two equations for the complex dielectric constant and separation of real and imaginary parts gives

$$\epsilon' = \epsilon_\infty + \frac{\epsilon_{dc} - \epsilon_\infty}{1 + \omega^2\tau^2} \tag{8}$$

$$\epsilon'' = \frac{(\epsilon_{dc} - \epsilon_\infty)\omega\tau}{1 + \omega^2\tau^2} \tag{9}$$

These equations require that the dielectric constant decrease from the static to the optical dielectric constant with increasing frequency, while the dielectric loss changes from zero to a maximum value ϵ''_m and back to zero. These changes are the phenomenon of anomalous dielectric dispersion. From the above equations, it follows that

$$\epsilon_m'' = (\epsilon_{dc} - \epsilon_\infty)/2 \tag{10}$$

and that the corresponding values of ω and ϵ' are

$$\omega_m = 1/\tau \tag{11}$$

and

$$\epsilon_m' = (\epsilon_{dc} + \epsilon_\infty)/2 \tag{12}$$

The symmetrical loss-frequency curve predicted by this simple theory is commonly observed for simple substances, but its maximum is usually lower and broader because of the existence of more than one relaxation time. Various functions have been proposed to represent the distribution of relaxation times. A convenient representation of dielectric behavior is obtained, according to the method of Cole and Cole, by writing the complex dielectric constant as

$$\epsilon^* = \epsilon_\infty + \frac{\epsilon_{dc} - \epsilon_\infty}{1 + (j\omega\tau_0)^{1-\alpha}} \tag{13}$$

where τ_0 is the most probable relaxation time and α is an empirical constant with a value between 0 and 1, usually less than 0.2. When the values of ϵ'' are plotted as ordinates against those of ϵ' as abscissas, a semicircular arc is obtained intersecting the abscissa axis at $\epsilon' = \epsilon_\infty$ and $\epsilon' = \epsilon_{dc}$. The center of the circle of which this arc is a part lies below the abscissa axis, and the diameter of the circle drawn through the center from the intersection at ϵ_∞ makes an angle $\alpha\pi/2$ with the abscissa axis. When α is zero, the diameter lies in the abscissa axis, there is but one relaxation time, and the behavior of the material conforms to the simple Debye theory. When, as may arise from intramolecular rotation, a substance has more than one relaxation mechanism, or, when the material is a mixture, the observed loss-frequency curve is the resultant of two or more different curves and, therefore, departs from the simple Debye or Cole-Cole curve.

The behavior of a good many materials which have been found, mostly at low temperatures, to depart from the symmetrical arc given by Eq. (12) has been well represented by the empirical equation of Cole and Davidson, in which the exponent $1 - \alpha$ in Eq. (13) is replaced by β. The corresponding curve is a skewed arc and the empirical parameter β, which has values between 0 and 1, measures the degree of skewness. Glarum has accounted for skewed-arc behavior in terms of the diffusion of lattice defects. Anderson and Ullman have treated the reorientation probability of a molecule as a function of the free volume, which fluctuates as the result of random thermal motion. If the rate of free-volume fluctuation is slow compared with that of molecular reorientation, the Cole-Cole plot is symmetrical, but flatter, the greater the dependence of the relaxation rate on the free volume. When the rate of change of free volume is much greater than that of reorientation, all of the molecules have the same environment and a single relaxation time should be observed. For an intermediate situation a skewed-arc plot is to be expected. These and other approaches to the problems of dielectric behavior have been described by Hill, Vaughan, Price, and Davies. Nee and Zwanzig have formulated a theory of dielectric relaxation involving dielectric friction on the rotating dipole, which leads to a frequency-dependent relaxation time. Frequency-dependent dynamic viscosity has been used by Johari and Smyth to explain an apparent wide distribution of the relaxation times of supercooled solutions of rigid polar molecules as well as the seemingly low dielectric relaxation times found for polar molecules at high frequencies or high viscosities. The complexity of molecular behavior in condensed matter is such that no molecular theory of dielectrics is completely satisfactory at the present time.

If the dielectric material is not a perfect dielectric, and has a specific dc conductance k' (ohms^{-1} cm^{-1}), there is an additional dielectric loss

$$\epsilon_{dc}'' = \frac{3.6 \times 10^{12} \pi k'}{\omega} \tag{14}$$

The effective specific conductance is given by

$$k' = \frac{1}{4\pi} \frac{(\epsilon_{dc} - \epsilon_\infty)\omega^2 \tau}{1 + \omega^2 \tau^2} \tag{15}$$

It is evident from this equation that k' increases with ω, approaching a limiting value, k_∞, the infinite-frequency conductivity, which is attained when 1 can be neglected in comparison with $\omega^2 \tau^2$, so that

$$k_\infty = \frac{\epsilon_{dc} - \epsilon_\infty}{4\pi\tau} \tag{16}$$

In a heterogeneous material, interfacial polarization may arise from the accumulation of charge at the interfaces between phases. This occurs only when two phases differ considerably from each other in dielectric constant and conductivity. It is usually observed only at very low frequencies, but, if one phase has a much higher conductivity than the other, the effect may increase the measured dielectric constant and loss at frequencies as high as those of the radio region. This so-called Maxwell-Wagner effect depends on the form and distribution of the phases as well as upon their real dielectric constants and conductances. Each type of form and distribution requires special treatment. For a commercial rubber, for example, the observed loss may be

$$\epsilon''(\text{observed}) = \epsilon_{dc}'' + \epsilon''(\text{Maxwell-Wagner}) + \epsilon''(\text{Debye}) \tag{17}$$

DIFFERENTIAL EQUATIONS IN PHYSICS

Because of their high frequency of occurrence and importance in the physical sciences it is fitting to introduce some of the more common differential equations that arise and to use these as a basis for discussion and development.

(i) When a given mass of a radioactive substance disintegrates it is well known that if at any time t the mass remaining is m, then the rate of decay of mass, $-dm/dt$, is proportional to the amount remaining. This implies that

$$-\frac{dm}{dt} = km \qquad (k = \text{positive constant}). \tag{1}$$

(ii) Suppose that an alternating voltage $E \cos \omega t$ is applied to an electrical circuit consisting of a resistance R, inductance L, and capacitance C in series connection, t specifying time. If i denotes the current flowing in the circuit at time t and q the charge on the capacitance plate into which it flows, then $i = dq/dt$ and so the potential differences across the three components are respectively Ri, $L\,di/dt$, q/C. Equating their sum to the applied voltage gives

$$R\frac{dq}{dt} + L\frac{d^2q}{dt^2} + \frac{q}{C} = E\cos\omega t. \tag{2}$$

(iii) When heat is conducted along a metal bar the temperature $u(x, t)$ at time t at a distance x from one end is known to satisfy

$$\frac{\partial u}{\partial t} = k\frac{\partial^2 u}{\partial x^2}, \tag{3}$$

in the case when there are no radiation losses. For homogeneous material and constant cross section, k is a positive constant.

(iv) If $y(x, t)$ denotes the lateral displacement at time t of a point distant x from one of the fixed ends of a string set in vibration, then it can be shown that

$$\frac{\partial^2 y}{\partial t^2} = c^2\frac{\partial^2 y}{\partial x^2}, \tag{4}$$

where c is a constant for a uniform string of constant cross section.

The equations (1) through (4) are examples of *differential equations*. In each case it is seen that a relation exists between a quantity or function whose value is sought, i.e., the *dependent variable*, one or more *independent variables*, and the derivatives of the dependent variables with respect to the independent ones. Equations (1), (2) are examples of *ordinary differential* equations and they involve only total derivatives as there is but one independent variable. Equations (3), (4), however, involve partial derivatives and are called *partial differential equations*. Partial differential equations involve two or more independent variables. In both cases the *order* of the differential equation is that of the highest-order derivative it contains. (1) is of first order, but (2), (3), (4) are all of second order.

In many physical problems which are formulated as differential equations auxiliary conditions are imposed upon the dependent variable and possibly also on certain of its derivatives. These conditions compounded with the partial differential equation constitute a *boundary value problem*. If, as often happens, such conditions are prescribed at $t = 0$, where t is an independent variable specifying time, the compound problem is called an *initial value problem*.

(1) Ordinary Differential Equations We now consider the ordinary differential equation of order n

$$a_n\frac{d^ny}{dx^n} + a_{n-1}\frac{d^{n-1}y}{dx^{n-1}} + \cdots + a_1\frac{dy}{dx} + a_0y = f(x)$$

or

$$L(D)y = f(x) \tag{5}$$

where $L(D) \equiv a_nD^n + a_{n-1}D^{n-1} + \cdots + a_1D + a_0$ and $D^r \equiv d^r/dx^r$. The coefficients $a_0, a_1, \cdots, a_n$ may be either constants or functions of x only. Note that y and all its derivatives in (5) occur only to the power unity and that there are no products of these quantities. Such an equation is said to be *linear*. Suppose that (5) is satisfied by the particular value $y = Y(x)$ so that $L(D)Y(x) = f(x)$. Then $Y(x)$ is called a *particular integral* of (5). Further suppose that the equation $L(D)y = 0$ has n linearly independent solutions $y_1(x), y_2(x), \cdots, y_n(x)$. Then it is easily seen that

$$L(D)(A_1y_1 + A_2y_2 + \cdots + A_ny_n) = 0,$$

where $A_1, \cdots, A_n$ are arbitrary constants, and so $y = A_1y_1 + \cdots + A_ny_n$ satisfies the homogeneous equation $L(D)y = 0$. This solution of the homogeneous equation is called the *complementary function* of the nonhomogeneous equation (5). The number of constants in it is equal to the order of the differential equation. Since

$$L(D)\{Y(x) + A_1y_1 + A_2y_2 + \cdots + A_ny_n\} = L(D)Y + 0 = f(x),$$

Eq. (5) is satisfied by

$$y = Y(x) + A_1y_1(x) + \cdots + A_ny_n(x). \tag{6}$$

This form can be shown to be the most general form of solution to (5) and it is called the *complete primitive*. Thus the task of finding the complete primitive to (5) consists of finding the complementary function, obtained by taking $f(x) = 0$, and adding to this a particular integral.

For the special case when the coefficients $a_0, a_1, \cdots, a_n$ in (5) are all constants—and this assumption will be made from now on—the general solution to the equation $L(D)y = 0$ is obtained by making the trial substitution $y = e^{mx}$, where m is an undetermined constant. We find

$$a_nm^n + \cdots + a_1m + a_0 = 0. \tag{7}$$

Let $m = m_1, m_2, \cdots, m_n$ be the n roots of the *auxiliary equation* (7). Then $L(D)y = 0$ has the n solutions $e^{m_1x}, e^{m_2x}, \cdots, e^{m_nx}$ and it can be shown that its most general solution is

$$y = A_1e^{m_1x} + A_2e^{m_2x} + \cdots + A_ne^{m_nx}, \tag{8}$$

where $A_1, \cdots, A_n$ are constants and the m's are all distinct. As an example the differential equation (1) is a first-order homogeneous equation, and by putting $m = e^{\lambda t}$ we find $\lambda = -k$. Thus the general solution is $m = Ae^{-kt}$, involving but one arbitrary constant. If it is given that $m = m_0$ when $t = 0$, we find $A = m_0$ and so the solution of this initial value problem is $m = m_0e^{-kt}$.

By way of further example, consider the second-order homogeneous equation

$$\frac{d^2y}{dx^2} + (a+b)\frac{dy}{dx} + ab\,y = 0$$

$(a, b$ unequal constants).

Putting $y = e^{mx}$ gives the auxiliary equation $m^2 + (a+b)m + ab = 0$ having roots $m = -a, -b$. Hence the general solution is

$$y = Ae^{-ax} + Be^{-bx} \qquad (a \neq b).$$

This form is suggested immediately if the differential equation is written in the operator form

$$(D+a)(D+b)y = 0 \qquad (a \neq b),$$

since $y = Ae^{-ax}$ and $y = Be^{-bx}$ satisfy $(D+a)y = 0$ and $(D+b)y = 0$ respectively. In the case when $a = b$, it can easily be verified that xe^{-ax} is a second solution to $(D+a)^2y = 0$ and so its general solution is

$$y = Ae^{-ax} + Bxe^{-ax}.$$

For the general solution of (5), it follows that the main task is the finding of a particular integral. Various techniques are available. Here we describe two methods using suitable examples.

The first is called the method of *variation of parameters*. Suppose it is required to solve for $y(t)$ the differential equation

$$\frac{d^2y}{dt^2} + \omega^2 y = \cos \omega t. \tag{9}$$

This is the resonance equation and we observe that when $R = 0$ and $\omega^2 = 1/LC$, Eq. (2) is of this form. The complementary function, found from the auxiliary equation $m^2 + \omega^2 = 0$ is clearly $y = ae^{i\omega t} + be^{-i\omega t}$. This may be more simply expressed in the form $y = A\cos\omega t + B\sin\omega t$ using the relations $e^{\pm i\omega t} = \cos\omega t \pm i\sin\omega t$, the constants A, B being given by $A = a + b$, $B = i(a - b)$. To obtain a particular integral of (9) take

$$y(t) = A(t)\cos\omega t + B(t)\sin\omega t; \tag{10}$$

then

$$\dot{y}(t) = -\omega A(t)\sin\omega t + \omega B(t)\cos\omega t, \tag{11}$$

provided A and B are so chosen that

$$0 = \dot{A}(t)\cos\omega t + \dot{B}(t)\sin\omega t. \tag{12}$$

Differentiating $\dot{y}$ in (11),

$$\ddot{y}(t) = -\omega^2 A(t)\cos\omega t - \omega^2 B(t)\sin\omega t, \tag{13}$$

provided A and B are so chosen that

$$\cos\omega t = -\omega\dot{A}(t)\sin\omega t + \omega\dot{B}(t)\cos\omega t. \tag{14}$$

Solving equations (12), (14) for $\dot{A}$ and $\dot{B}$ we find

$$\dot{A}(t) = -\frac{1}{\omega}\sin\omega t\cos\omega t, \quad \dot{B}(t) = \frac{1}{\omega}\cos^2\omega t$$
$$= \frac{1}{2\omega}(1 + \cos 2\omega t)$$

and so integrating these,

$$A(t) = -\frac{1}{2\omega^2}\sin^2\omega t,$$

$$B(t) = \frac{1}{2\omega}\left(t + \frac{1}{2\omega}\sin 2\omega t\right).$$

Thus on substituting these into (10) and simplifying we obtain the particular integral $y = (t/2\omega)\sin\omega t$. Hence the complete primitive is

$$y = A\cos\omega t + B\sin\omega t + \frac{t}{2\omega}\sin\omega t$$

$(A, B$ constants).

As a second method we introduce the *Laplace transform*. This device is eminently suited to solving initial value problems and it is consequently favored by electrical and control engineers. The Laplace transform of $f(t)$ is denoted either by $\mathcal{L}\{f(t)\}$ or by $\bar{f}(s)$ and it is defined to be

$$\mathcal{L}\{f(t)\} = \bar{f}(s) = \int_0^\infty e^{-st} f(t)\,dt.$$

By elementary integration one can compile the following useful table of Laplace transforms for different forms of $f(t)$:

$f(t)$	1	e^{at}	$\cos at$	$\sin at$	t^n
$\bar{f}(s)$	$\frac{1}{s}$	$\frac{1}{s-a}$	$\frac{s}{s^2+a^2}$	$\frac{a}{s^2+a^2}$	$\frac{n!}{s^{n+1}}$

Here a is constant and $n = 1, 2, 3, \cdots$. Also it is easy to show by integration by parts that

$$\mathcal{L}\left\{\frac{df(t)}{dt}\right\} = s\bar{f}(s) - f(0),$$

$$\mathcal{L}\left\{\frac{d^2f(t)}{dt^2}\right\} = s^2\bar{f}(s) - s\,f(0) - \dot{f}(0).$$

Let us use this method to solve again equation (9), subject to the initial conditions $y(0) = 0$, $\dot{y}(0) = 0$. Let $\bar{y}(s) = \mathcal{L}\{y(t)\}$. Then, using the initial conditions, $\mathcal{L}\{dy/dt\} = s\bar{y}(s)$, $\mathcal{L}\{d^2y/dt^2\} = s^2\bar{y}(s)$. Also the table shows that $\mathcal{L}\{\cos\omega t\} = s/(s^2 + \omega^2)$. Hence on taking the Laplace transform of both sides of (9),

$$(s^2 + \omega^2)\bar{y}(s) = s/(s^2 + \omega^2)$$

and so

$$\bar{y}(s) = s/(s^2 + \omega^2)^2.$$

Now

$$\frac{s}{s^2 + \omega^2} = \int_0^\infty e^{-st}\cos\omega t\,dt,$$

and so differentiating both sides of this partially with respect to ω,

$$-\frac{2\omega s}{(s^2+\omega^2)^2} = \int_0^\infty \frac{\partial}{\partial\omega}(e^{-st}\cos\omega t)\,dt,$$

$$= \int_0^\infty (-t\,e^{-st}\sin\omega t)\,dt.$$

Dividing through by -2ω, we have

$$\frac{s}{(s^2+\omega^2)^2} = \int_0^\infty e^{-st}\left(\frac{t}{2\omega}\sin\omega t\right)dt.$$

Thus

$$\bar{y}(s) = \mathcal{L}\left\{\frac{t}{2\omega}\sin\omega t\right\},$$

and so

$$y(t) = \frac{t}{2\omega}\sin\omega t.$$

(2) Partial Differential Equations The simplest methods of solution are based on the technique of *separation of variables* and on the use of an *integral transform* such as the Laplace transform. These are illustrated by means of examples.

Suppose it is desired to solve the one-dimensional heat conduction equation (3) holding along a uniform rod of length ℓ, being given that when $t = 0$, $u = u_0x$ and, for all $t \geqslant 0$, $\partial u/\partial x = 0$ at $x = 0$ and $x = \ell$ (i.e., both ends are thermally lagged). Making the trial solution $u = X(x)\,T(t)$, we find

$$X''(x)/X(x) = T'(t)/kT(t).$$

As the left side of this equation is a function of x only and the right one of t only, each is constant. The physical nature of the problem implies that as t increases, u decreases for any particular value of x. Hence T decreases as t increases and so $T' < 0$. Thus we take the constant to be negative, say $-m^2$, and obtain the ordinary differential equations

$$\begin{cases} X''(x) + m^2X(x) = 0, \\ T'(t) + m^2kT(t) = 0. \end{cases}$$

These have the general solutions

$$\begin{cases} X(x) = A\cos mx + B\sin mx, \\ T(t) = C\exp(-m^2kt). \end{cases}$$

Thus, writing $E = AC$, $F = BC$, a solution for $u(x, t)$ is

$$u(x,t) = XT$$
$$= \exp(-m^2kt)(E\cos mx + F\sin mx).$$

Since, for all t, $\partial u/\partial x = 0$ when $x = 0$ and when $x = \ell$,

$$F\,m\exp(-m^2kt) = 0,$$
$$m\exp(-m^2kt)(-E\sin m\ell + F\cos m\ell) = 0.$$

The first of these equations implies that $F = 0$ and the second that $m\ell = n\pi$, where n is an integer. Thus a solution satisfying the end conditions is

$$u(x,t) = E\exp(-n^2\pi^2kt/\ell^2)\cos(n\pi x/\ell),$$

where n is an integer. A more general solution may be obtained by superposition (as (3) is linear) in the form

$$u(x,t) = \sum_{n=0}^{\infty} E_n\exp(-n^2\pi^2kt/\ell^2)\cos(n\pi x/\ell)$$

Using the initial condition $u(x, 0) = u_0x$, the last form leads to the half-range Fourier series representation

$$\sum_{n=0}^{\infty} E_n\cos(n\pi x/\ell) = u_0x \quad \text{for} \quad 0 < x < \ell.$$

Determining the coefficients by the usual method,

$$E_0 = \frac{1}{\ell}\int_0^\ell u_0x\,dx = \frac{1}{2}u_0\ell,$$

and for $n = 1, 2, 3, \cdots$,

$$E_n = \frac{2}{\ell}\int_0^\ell u_0x\cos\left(\frac{n\pi x}{\ell}\right)dx$$

$$= -\frac{2u_0\ell}{n^2\pi^2}[1-(-1)^n].$$

Thus the solution to the boundary value problem is

$$u(x,t) = \frac{1}{2}u_0\ell$$
$$-\frac{4u_0\ell}{\pi^2}\sum_{n=1}^{\infty}\frac{\exp\{-(2n-1)^2k\pi^2t/\ell^2\}}{(2n-1)^2}$$
$$\cdot\cos\frac{(2n-1)\pi x}{\ell},$$

where $t \geqslant 0$ and $0 \leqslant x \leqslant \ell$. It can be shown that the solution is unique.

To illustrate the Laplace transform technique, consider the boundary value problem of solving for $f(x, y)$ the partial differential equation

$$\frac{\partial^2 f}{\partial x\partial y} = f(x,y)$$

in the region $x \geqslant 0$, $y \geqslant 0$ and subject to the boundary conditions

$$\begin{cases} f(x, 0) = 0, \\ f(0, y) = a \ (= \text{const.}). \end{cases}$$

The first boundary condition suggests taking the Laplace transform with respect to y. To this end write

$$\bar{f}(x, s) = \int_0^\infty e^{-sy} f(x, y)\, dy.$$

Then

$$\mathcal{L}\{\partial f/\partial y\} = s\,\bar{f}(x, s) - f(x, 0) = s\,\bar{f}(x, s),$$

and

$$\mathcal{L}\left\{\frac{\partial^2 f}{\partial x \partial y}\right\} = \frac{\partial}{\partial x}\,\mathcal{L}\left\{\frac{\partial f}{\partial y}\right\} = s\,\frac{d\bar{f}(x, s)}{dx}.$$

Thus the partial differential equation transfor into

$$\frac{d\bar{f}(x, s)}{dx} = \frac{1}{s}\,\bar{f}(x, s)$$

and this ordinary differential equation has the general solution

$$\bar{f}(x, s) = \bar{f}(0, s) \exp{(x/s)}.$$

Since $f(0, y) = a$, $\bar{f}(0, s) = a/s$ and so

$$\begin{aligned} \bar{f}(x, s) &= \frac{a}{s} \exp\left(\frac{x}{s}\right) \\ &= a\left[\frac{1}{s} + \frac{x}{s^2} + \frac{x^2}{2!\,s^3} + \frac{x^3}{3!\,s^4} + \cdots\right]. \end{aligned}$$

From the table, $\mathcal{L}\{y^n\} = n!/s^{n+1}$ for positive i tegral n, and so

$$f(x, y) = a\left[1 + xy + \frac{x^2 y^2}{(2!)^2} + \frac{x^3 y^3}{(3!)^2} + \cdots\right].$$

In terms of the modified Bessel function this may also be written as $f(x, y) = aI_0(2\sqrt{xy})$.

DIFFRACTION BY MATTER AND DIFFRACTION GRATINGS

According to the principle of Huygens (1629–1695) each point in the space which is touched by a wave gives rise to a spherical secondary wave, which again produces tertiary waves, and so on. Every wave interferes with the next one and quite generally gives rise to diffraction phenomena (see OPTICS, PHYSICAL). Such phenomena in the case of visible light first were observed by F. M. Grimaldi (1618–1663) and mathematically explained by J. Fresnel (1788–1827). G. R. Kirchhoff (1824–1887) gave the first exact mathematical solution of the scalar wave differential equation in terms of a boundary integral. If both the primary and the diffracted rays are parallel (e.g., small source, large distances between diffracting sample and source and detector), we have the experimental conditions of Fraunhofer (1787–1826). With two lenses L_1 and L_2, a collimator pinhole P in the focal plane of L_1, and a photographic plate F in the focal plane of L_2, this condition is fulfilled even for short distances (Fig. 1). Monochromatic light is produced by a Hg lamp with a Schott filter S and an aqueous solution of $CuSO_4$. If $\mathbf{s}_0$ and $\mathbf{s}$ are unit vectors in the direction of the primary and the diffracted beam, and λ is the wavelength of the source, then the diffracted intensity I is proportional to

$$I(\mathbf{b}) \cong f_e{}^2 f_\theta{}^2 \, |R|^2 \,;\ R(\mathbf{b}) = F(\rho) \qquad (1)$$

where

$$\mathbf{b} = \frac{\mathbf{s} - \mathbf{s}_0}{\lambda} \qquad (2)$$

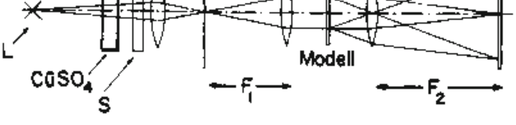

FIG. 1. Equipment for Fraunhofer diffraction.

and

$$F = \int e^{-2\pi i(\mathbf{bx})}\, dv_x \tag{3}$$

is the symbol of the Fourier transform, **x** is a vector in physical space, ρ^2 (**x**) is the transparency of the object M at the end point of the vector **x**, which lies in the plane of the object, dv_x is a surface element of the object, $f_\theta{}^2$ and $f_e{}^2$ are explained in Table 1 and **b** is given by Eq. (2). Figure 2(a) shows an object $\rho(\mathbf{x})$ in the form of a parallelogram with the edge vectors $\mathbf{L}_1$ and $\mathbf{L}_2$, and Fig. 2(b) give its Fraunhofer pattern:

$|R|^2 = |S|^2$;

$$S(\mathbf{b}) = |\mathbf{L}_1 \wedge \mathbf{L}_2| \frac{\sin \pi(\mathbf{bL}_1)}{\pi(\mathbf{bL}_1)} \cdot \frac{\sin \pi(\mathbf{bL}_2)}{\pi(\mathbf{bL}_2)} \tag{4}$$

Fraunhofer used assemblies of N parallel oriented metal wires with an intermediate distance d and the distance a (from center to center), in the direction s_1. Hence

$$\rho(x_1) = \begin{cases} 1 \text{ for } na - \frac{d}{2} \leqq x_1 \leqq na + \frac{d}{2} \\ 0 \text{ for all other } x_1 \end{cases} \tag{5}$$

and

$$I(b_1) = \frac{1}{a} f^2 \widehat{Z|S}|^2 \tag{6}$$

$$f = \frac{\sin \pi b_1 d}{\pi b_1}; \quad Z = \frac{1}{a} \sum_n^{\infty} P(b_1 - n/a);$$

$$S = \frac{\sin \pi b_1 Na}{\pi b_1} \tag{7}$$

TABLE 1. FACTORS $f_e{}^2$ AND $f_\theta{}^2$ FOR DIFFERENT RADIATIONS

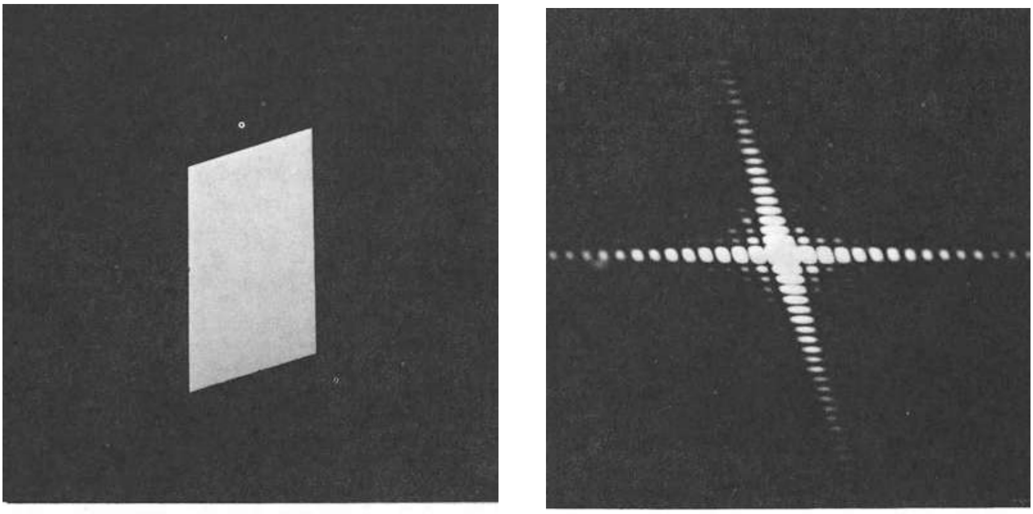
3	Electrons	$\dfrac{m_0 e^2 \lambda^2}{2h^2}$	$1/\sin^4 \theta$	c velocity of light h Planck's constant
4	Neutrons	Cross section	Polarization factor	λ (de Broglie) wavelength



(a) (b)

FIG. 2. (a) Parallelogram as diaphragm. (b) Fraunhofer pattern. Secondary maxima of the shape factor S^2 (Eq. (4)).

f is the Fourier transform of a single slit, S that of the shape of the whole lattice (length Na). Z is the "reciprocal" lattice point function (lattice factor) of the centers of the wire, since $P(b_1 - 0)$ is a normalized point function at $b_1 = 0$. The symbol of convolution $\frown$ is defined for both functions $G_1(\mathbf{b})$ and $G_2(\mathbf{b})$ in Fourier space, and $g_1(\mathbf{x})$ and $g_2(\mathbf{x})$ in physical space by

$$\widehat{G_1(\mathbf{b})G_2}(\mathbf{b}) = \int G_1(\mathbf{c})G_2(\mathbf{b} - \mathbf{c})dv_c \quad (8)$$

$$\widehat{g_1(\mathbf{x})g_2}(\mathbf{x}) = \int g_1(\mathbf{y})g_2(\mathbf{x} - \mathbf{y})dv_y \quad (9)$$

In the one-dimensional case of Eq. (8) $\mathbf{c}$ is to be replaced by the scalar quantity c_1 and dv_c by dc_1. Two-dimensional gratings are of high interest, since their Fraunhofer pattern gives all the information we need to understand the more complicated structural theories of three-dimensional matter. This will be shown below.

The technique of preparing such models is quite easy: in the examples of Figs. 4, 5, 6, 7, 8, 10 and 12, the objects were painted with india ink on paper 15 X 15 inches and then photographed on fine-grained films 0.5 X 0.5 inch with steep gradation characteristics (for instance Peruline film F 10). The black ink points now become transparent on a black background. In the models of Figs. 3, 9 and 11, steel balls of 2 to 3 mm diameter were placed into the focal plane of a lens system and photographed with a linear reduction 1 : 15 on the same film material mentioned above.

By defocusing the system, one obtains diaphragms, where the single balls do not touch each other (Figs. 3 and 9, but not Fig. 11). This is quite advantageous, since the width of the atom-factor f^2 [see Eq. (6)] is larger and more reflections are visible.

Fig. 3(a) shows a model of a two-dimensional ideal periodic "point lattice," and Fig. 3(b) represents its Fourier transform.

$$\rho(\mathbf{x}) = \sum_r^{\infty} P(\mathbf{x} - \mathbf{x}_r);\ \mathbf{x}_r = p_1\mathbf{a}_1 + p_2\mathbf{a}_2 \quad (10)$$

$$R^2 \sim Z(\mathbf{b}) = \frac{1}{|\mathbf{a}_1 \wedge \mathbf{a}_2|}\sum_h^{\infty} P(\mathbf{b} - \mathbf{b}_h);$$

$$\mathbf{b}_h = h_1\mathbf{A}_1 + h_2\mathbf{A}_2 \quad (11)$$

where $\mathbf{a}_1$ and $\mathbf{a}_2$ are the vectors of a lattice cell of the model, and $\mathbf{A}_1$ and $\mathbf{A}_2$ are those of the "reciprocal" lattice cell (in $\mathbf{b}$-space)

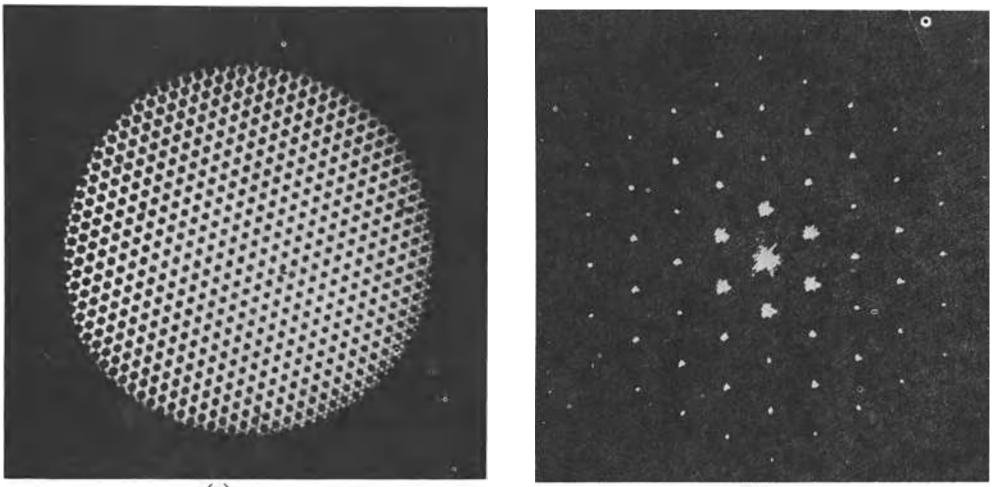
$$\mathbf{A}_1 = \frac{\mathbf{a}_2 \wedge \mathbf{a}_3}{\mathbf{a}_1(\mathbf{a}_2 \wedge \mathbf{a}_3)};\ \mathbf{A}_2 = \frac{\mathbf{a}_3 \wedge \mathbf{a}_1}{\mathbf{a}_2(\mathbf{a}_3 \wedge \mathbf{a}_1)} \quad (12)$$

$\mathbf{a}_3$ is an arbitrary vector orthogonal to $\mathbf{a}_1$ and $\mathbf{a}_2$, and p_1, p_2, h_1 and h_2 are integers. Since the lattice of Fig. 3(a) is bounded if one multiplies $\rho(\mathbf{x})$ by the shape function $s(\mathbf{x})$ of the lattice (which is 1 inside the lattice, and zero out of it) the p-summation can be extended to infinity. From the convolution theorem one obtains generally

$$Fg_1g_2 = \widehat{G_1G_2};\ F\widehat{g_1g_2} = G_1G_2 \quad (13)$$

Hence the Fourier transform of the bounded lattice $\rho(\mathbf{x}) \cdot s(\mathbf{x})$ is given again by the convolution product of Eq. (6), where $S(\mathbf{b})$ is the Fourier transform of $s(\mathbf{x})$ and $Z(\mathbf{b})$ is the Fourier transform of Eq. (11). $f^2 = 1$ applies only for "point-like" atoms, otherwise f is the Fourier transform of the shape of each "point."

M. v. Laue in 1911 prepared an article "Wellenoptik" for the "Encyclopedie der Math. Wissen-



(a)

(b)

FIG. 3. (a) Steel balls in a crystalline lattice. (b) Bragg reflections with shape factor S^2.

schaften" and found that Eq. (11) can be easily developed to the Fourier transform of three-dimensional point lattice, where $\mathbf{a}_3$ is a third lattice vector, non-coplanar to $\mathbf{a}_1$ and $\mathbf{a}_2$. Then $\mathbf{b}_h$ in Eq. (11) must be replaced by

$$\mathbf{b}_h = h_1\mathbf{A}_1 + h_2\mathbf{A}_2 + h_3\mathbf{A}_3;$$

$$\mathbf{A}_3 = \frac{\mathbf{a}_1 \wedge \mathbf{a}_2}{\mathbf{a}_3(\mathbf{a}_1 \wedge \mathbf{a}_2)} \quad (14)$$

Together with W. Friedrich and P. Knipping using x-rays of a wavelength of the same order of magnitude as that of the atomic distances, M. v. Laue (1912) found three-dimensional diffraction effects in single crystals. $f(\mathbf{b})$ then is the atom form amplitude

$$f(\mathbf{b}) = F(\rho_0) \quad (15)$$

where $\rho_0(\mathbf{x})$ is the electron density distribution of one atom, whose center lies at $\mathbf{x} = 0$.

C. J. Davisson and L. H. Germer (1927) observed the same diffraction phenomena using electron beams. $\rho(\mathbf{x})$ must then be understood as density distribution of both the electrons (negative) and protons (positive). If single diffraction processes occur, Eq. (6) remains unchanged.

D. P. Mitchell, P. N. Powers, H. v. Halban and P. Preiswerk (1936) found the same diffraction phenomena using thermal neutrons. In this case $\rho(\mathbf{x})$ is the density distribution of the nuclei, each one weighted by the mean of the square root of its respective cross section. The proportional factors $f_e{}^2$, $f_\theta{}^2$ of Eq. (1) for the different radiations are given in Table 1.

The vector $\mathbf{b}$ defined by the integral of Eq. (3) expands the three-dimensional Fourier space and is connected with the unit vectors $\mathbf{s}$, $\mathbf{s}_0$ of the diffracted and primary beam by Eq. (2). This is the construction of Ewald (1914). For a fixed λ and $\mathbf{s}_0$ all values $R(\mathbf{b})$ are in reflection positions, which lie on a sphere with radius $1/\lambda$ and the center at $\mathbf{b}_0 = \mathbf{s}_0/\lambda$.

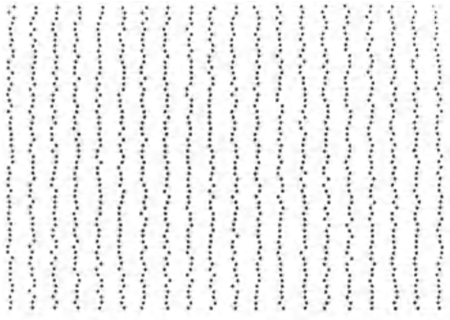
P. Debye (1915) found that the molecules in the gaseous state give rise to diffraction patterns depending on the structure of the single molecules, without any intermolecular interferences.

In 1927, F. Zernike and I. A. Prins discussed quantitatively diffraction phenomena of liquids and laid down the fundamentals of the structure analysis of amorphous matter. Moreover, P. Debye (1913) and I. Waller (1927) found that real crystals never have a periodic lattice similar to that of Fig. 3(a), since the atoms show thermal oscillations around their ideal positions. All these different phenomena can be studied quite easily with the help of two-dimensional statistical models and their Fraunhofer patterns, since Eq. (1) holds for all diffraction phenomena. In Fig. 4(a) we have the "frozen" structure of a point lattice with thermal oscillations. They are quite anisotropic and occur only in the horizontal direction. If $H(\mathbf{x})$ is the frequency of the center of an atom being at the distance x from its ideal position and if the atoms oscillate independently from each other, then R^2 is given by

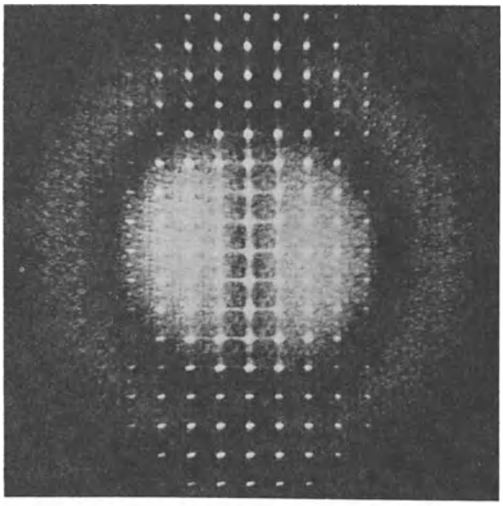
$$R^2(b) \doteq Nf^2(1 - D^2) + \frac{1}{v_r} f^2 D^2 \widehat{Z|S}|^2;$$

$$D(\mathbf{b}) \doteq F(H) \quad (16)$$

(v_r = volume of a lattice cell). In Fig. 4(b) can be clearly recognized the first term of Eq. (16) as a diffuse background. It has a structure in the horizontal direction. The "Bragg reflections" are weakened by the "Debye-Waller factor" D^2, the more, the stronger is the diffuse background $(1 - D^2)$. In nature there exist correlations between the different oscillations and "elastic waves" with an "acoustical" and "optical" frequency creep through the lattice.



(a)



(b)

FIG. 4. (a) Linear thermal oscillations without correlations. (b) Debye factor and thermodiffuse background.

Fig. 4(a) gives a single undamped longitudinal and sinusoidal wave with a horizontal wave vector $\mathbf{b}_t$ and a wavelength λ_t and amplitude $\mathbf{a}_t$

$$\lambda_t = \frac{1}{|b_t|} = 8a;\ |a_t| = \frac{1}{4}a \qquad (17)$$

According to the theories of M. v. Laue (1927) and Laval (1941) in Fig. 5(b) at the reciprocal lattice points

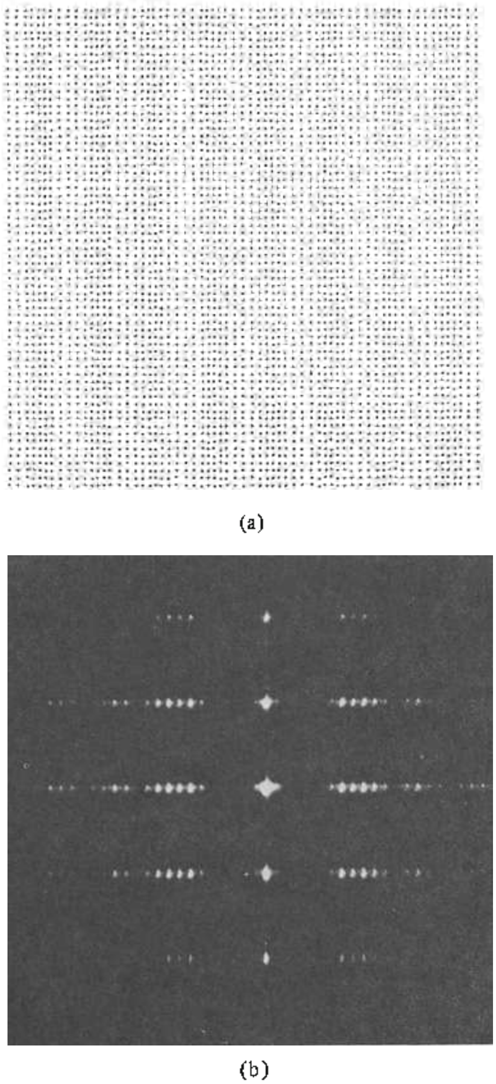
$$\mathbf{b} = \mathbf{b}_h + m\mathbf{b}_t \qquad (18)$$

"Extra Laue spots" ("Laval spots") occur. According to conventional theories, $m = 1$ is called one-phonon scattering, $m = 2$ is two-phonon scattering and so on; and it is said that the frequency ν_0 of the incident radiation is changed into $\nu_0 + m\nu_t$ ("inelastic scattering," ν_t-frequency of the phonons).

In Fig. 6(a) we have again a horizontal wave with the same wave vector [Eq. (17)], which now is transverse. From Laue's theory it follows, that the intensity of a Laue spot of the mth order is proportional to the square of the Bessel function

$$I_m(2\pi(\mathbf{ba}_t))$$

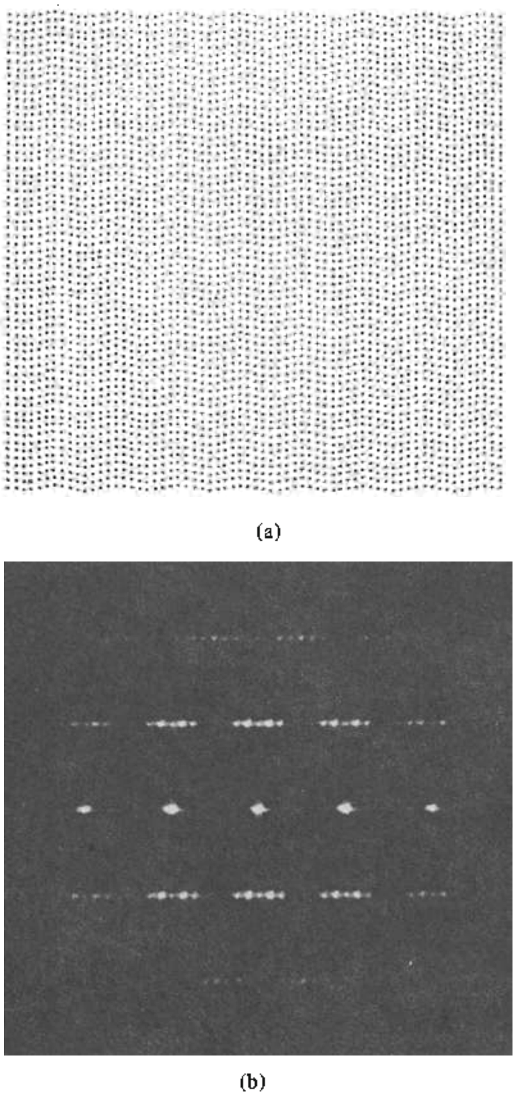
where m is the order of the Bessel function and $\mathbf{a}_t$ is the amplitude vector of the elastic wave. Hence in Fig. 6(b), strong Laval spots occur only in the vertical $\mathbf{b}_h$ direction; in Fig. 5(b), in the horizontal $\mathbf{b}_h$ direction. Since $I_1(I_2)$ has its maximum at $\mathbf{ba}_t = 0.25$ (0.5), in Figs. 5(b) and 6(b), the Laval spot $m = 1$ at the reflection h_1,



(a)

(b)

FIG. 5. (a) A single longitudinal wave. (b) Extra Laue spots.



(a)

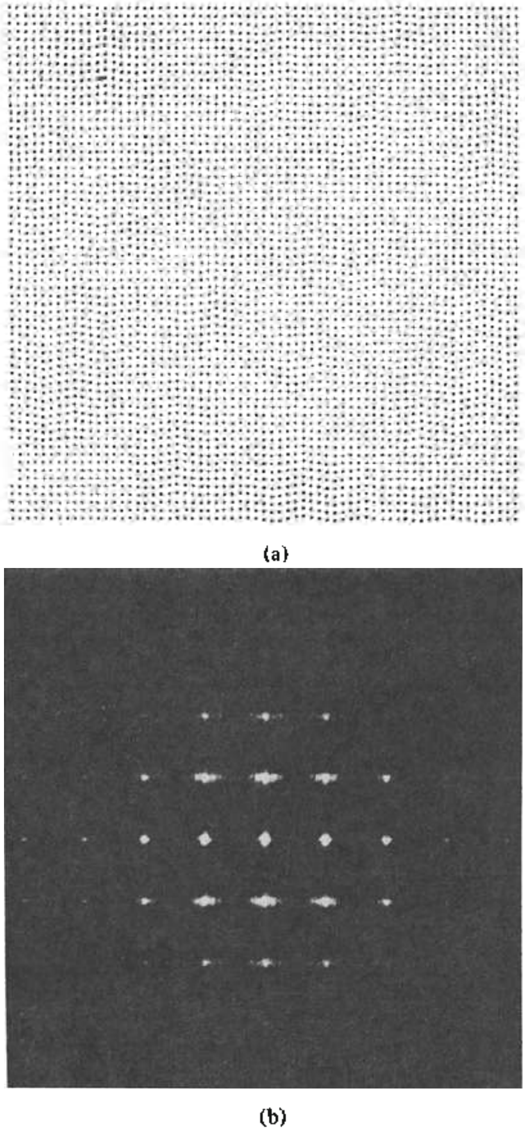
(b)

FIG. 6. (a) A single transversal wave. (b) Extra Laue spots.

$h_2 = 1.0$ (0.1) is much stronger and in the 2.0 (0.2) reflection, much weaker, than the Laval spot $m = 2$.

In nature, one never finds such sharp Laval spots, but a completely smooth "thermodiffuse" scattering, and it is said that a "white" spectrum of undamped elastic waves exists.

In Fig. 7(a) strongly damped transverse waves according to Eq. (17) consisting only of two maxima and minima are introduced. Now in Fig. 7(b) quite diffuse spots appear. Hence, in nature, such damped waves could also occur, and if they had a spectral distribution, they could give rise to the same observable thermodiffuse scattering. According to Debye's theory of heat capacity, every wave has a different amplitude $\mathbf{a}_r$, following a Boltzmann statistic. Then in certain regions of a single crystal, the atoms oscillate statistically with different amplitudes than in others. As a result, the lattice cells exhibit different sizes and paracrystalline distortions occur.



(a)

(b)

FIG. 7. (a) Twelve damped transversal waves. (b) Diffuse extra Laue spots.

Close to the melting point, the amplitudes a_t of the elastic waves become so large that the electron clouds of the atoms suffer large deformations, which damp these waves more and more.

Another physical reason for paracrystalline distortions below the melting point exists if the "motives" in the single lattice cells have different shapes. Such phenomena have been observed in the "macrolattices" of natural and synthetic high polymers.

Figure 8(a) shows a paracrystalline model, where both coordination statistics H_k are horizontal line functions. Figure 8(b) represents its Fraunhofer pattern and Fig. 8(c) the x-ray small-angle pattern of the β-keratin of the quill of a sea gull (Bear and Rugo (1951)). The cell edge $\mathbf{a}_2$ in the vertical direction parallel to the fiber axis has a constant length of 185Å but statistically changes its direction (with respect to the macroscopic fiber axis) within ±5°, while the orthogonal edge length $\mathbf{a}_1$ has an average value of 34Å and changes its length statistically within ±2.5Å. As a result of the van der Waals forces, which allow a variation of the length $\mathbf{a}_1$ orthogonal to the fiber axis, the homopolar forces along $\mathbf{a}_2$ have freedom to change their direction of the molecular chain, within one paracrystal. This paracrystal itself, therefore, shows a flexible character in atomic dimensions.

Equation (6) holds again, if one replaces the crystalline lattice factor Z of Eqs. (7) and (11) by the paracrystalline lattice factor

$$Z(\mathbf{b}) = \frac{1}{v_r} \prod_{k=1}^{3} Re \, \frac{1 + F_k(\mathbf{b})}{1 - F_k(\mathbf{b})} \qquad (19)$$

$$F_k(\mathbf{b}) = F(H_k) \qquad (20)$$

H_k is a so-called coordination statistic. $H_k(\mathbf{x})$ is the "a priori" probability of finding a cell edge vector $\mathbf{a}_k = \mathbf{x}$ in a certain paracrystalline lattice cell.

For the same reason, in mixed crystals consisting of atoms of different sizes, paracrystalline distortions can also occur.

Figure 3(a) showed a model of steel balls of the same size, building up a crystalline lattice. Figure 3(b) represents its Fourier transform. In Fig. 9(a) steel balls of different sizes built up a paracrystalline lattice, whose Fraunhofer pattern [Fig. 9(b)] exhibits characteristic features of a paracrystalline lattice [cf. Fig. 8(b)].

In Fig. 10(a) another model of a mixed crystal is given without paracrystalline lattice distor-

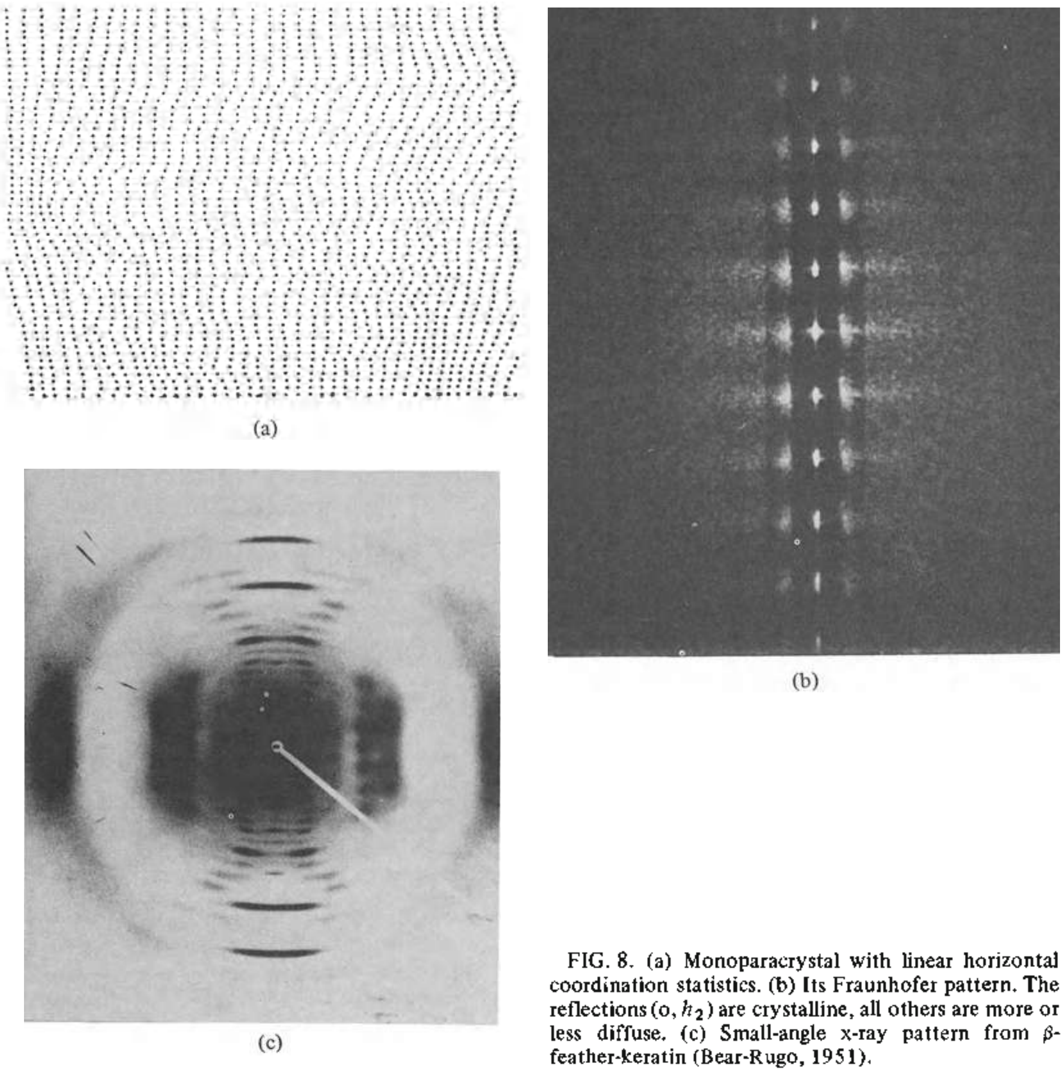


FIG. 8. (a) Monoparacrystal with linear horizontal coordination statistics. (b) Its Fraunhofer pattern. The reflections (o, h_2) are crystalline, all others are more or less diffuse. (c) Small-angle x-ray pattern from β-feather-keratin (Bear-Rugo, 1951).

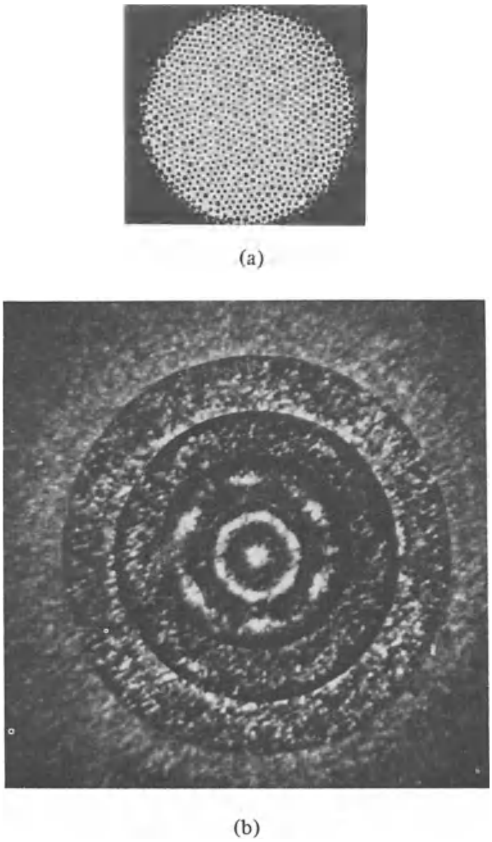
tions. Now the two kinds of atoms are not distributed totally randomly to the lattice points. Hence the Fraunhofer pattern of Fig. 10(b) shows a diffuse background, which is not given by

$$N(\overline{f^2} - \bar{f}^2) \qquad (21)$$

and which presents "diffuse walls" in the vertical direction at $h_1 = \pm\frac{1}{2}$ of a width $\delta b_1 \sim \frac{1}{8}A_1$. This means that in the horizontal direction, rows of about 8 atoms show a kind of "superstructure" (*Nahordnung*, "cooperative order"). This "superstructure" has a psychological background: The technician, painting the models row by row in the horizontal direction was anxious to choose thick and thin atoms quite arbitrarily. However, he did not use a Monte Carlo Method, but tried as arbitrarily as possible to draw statistical sequences. Unfortunately, after he painted a thick atom he tended to choose a thin one, etc. Unconsciously, he introduced "cooperative forces."

Similar diffuse walls are observed in ferroelectric $NaNO_2$ above the Curie point: In this case, rows of about six $NaNO_2$ molecules have parallel oriented polar axes, and have built up microferroelectric domains in a statistically paraelectric matrix (M. Canut and R. Hosemann, 1964).

In Fig. 11(a), similar to Fig. 9(a), steel balls of different sizes which now built up a structure of single small paracrystallites were used. The Fraunhofer pattern, Fig. 11(b), shows the typical features of a liquid or melt or "amorphous" solid. Hosemann and Lemm (1964) have proved, that in molten gold and lead such paracrystals can be found with average diameters of 12Å to 40Å.

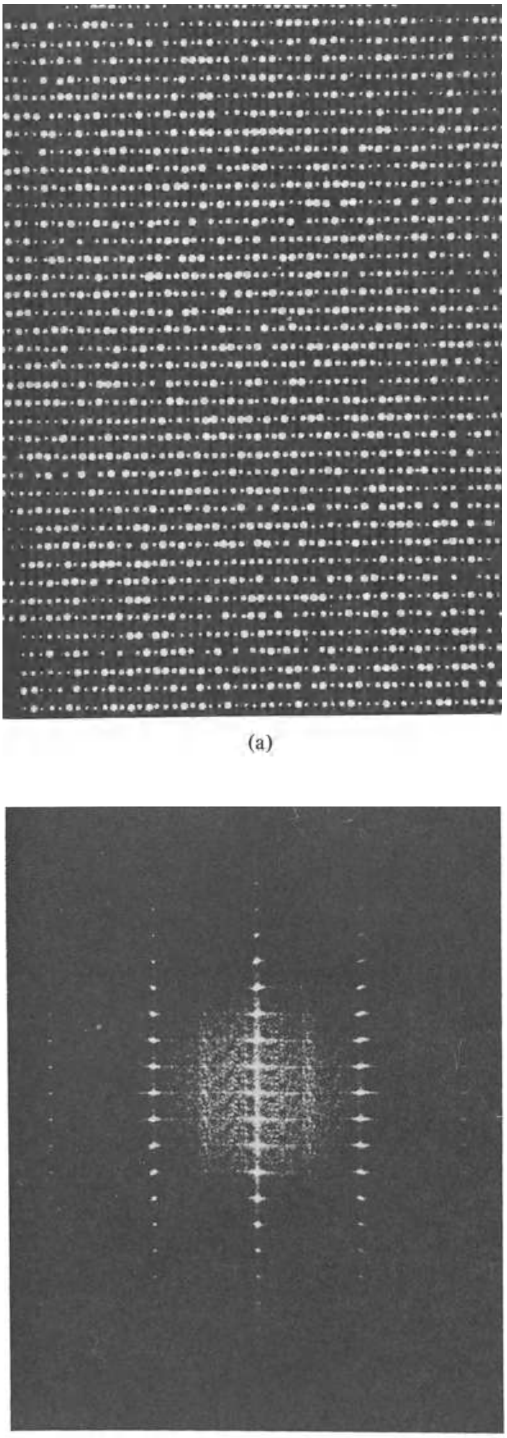


(a)

(b)

FIG. 9. (a) Mixed single paracrystal (steel balls). (b) Intensity function (Eq. (6) and (19)).

After having completed the step from crystals to amorphous matter, Fig. 12(a) gives an example of a special gas and Fig. 12(b) at larger b-values, the gas-interferences. Lord Rayleigh (1842–1919) proved that here phase relations between the single scattering centers are destroyed in the average as a consequence of their irregular positions. Since in Fig. 12 only 5200 centers were used, "ghosts" remain in the Fraunhofer pattern. Besides this fluctuation the intensity at large b-values is given by the shape of the single points. Moreover in Fig. 12(a) every 40 points cluster together. The clusters are arranged in a crystalline lattice. Hence, at small angles in Fig. 12(b), "Bragg-reflections" whose intensity is proportional to the squared transform Eq. (15) do occur. ρ_0 is now a forty-point function different for each cluster, and in Eq. (6), f must be replaced by the average $\overline{f}$. The diffuse background of Fig. 12(b), which now is the statistical fluctuation of the density distribution ρ_0 is given again by Eq. (21). If we replace the word "cluster" by zircon atom and



(a)

(b)

FIG. 10. (a) Mixed single crystal with "cooperative forces." (b) Background with diffuse walls (*Nahordnung*).

"point" by electron, Fig. 12(a) gives an instantaneous picture of the electron configuration in a zirconium crystal. The Bragg reflections give in this case information about Schrödinger's wave functions for electrons

$$\overline{\rho_0(x)} = \psi\psi^*$$

and the fluctuation term of Eq. (21) gives some information about the structure of a single electron. In reality, Compton processes disturb the

diffraction. There is some hope for further detailed studies.

DIFFUSION IN LIQUIDS

Diffusion, in a macroscopic sense, is a universal process that leads to the eliminating of concentration gradients in gases, solids, or liquids. At the molecular level, it arises because atoms or molecules undergo small, essentially random displacive movements as a result of their thermal energy. It is a property having great fundamental importance, because all useful theoretical efforts to understand the dynamical behavior of liquids at the molecular level must lead to agreement with accurate macroscopic measurements. It is one of four transport properties of matter: viscosity, diffusion, thermal conductivity, and (in electrically conducting media) electrical conductivity. Each of these transport properties measures the flux of some quantity in a gradient: *viscosity*, the flow of momentum in a velocity gradient; *diffusion*, the flow of mass in a concentration gradient; *thermal conductivity*, the flow of heat in a temperature gradient; *electrical conductivity*, the flow of electric charge in a gradient of electrical potential. Since their formal mathematical structures are the same, it is not surprising that there is often a quantitative correlation among them.

The diffusive motions of individual molecules may be likened to a kind of aimless three-dimensional *random walk*. If we limit our attention to the displacement of a single particle in a given direction from its position at some arbitrary zero time, the *probability* that it will be found at a distance, $\pm x$, from its origin after a time, t, is given by:

$$P(x, t) = \frac{1}{2(\pi Dt)^{1/2}} \exp(-x^2/4Dt) \qquad (1)$$

In this equation, the parameter D, called the *diffusion coefficient*, is a measure of the average rate with which the displacement of the particle occurs.

If, instead of attempting to follow the random motion of an individual particle, we introduce a large number of particles C_0 at a point within the system, their concentration $C(x, t)$ will vary with time and distance in a given direction according to:

$$C(x, t) = \frac{C_0}{2(\pi Dt)^{1/2}} \exp(-x^2/4Dt) \qquad (2)$$

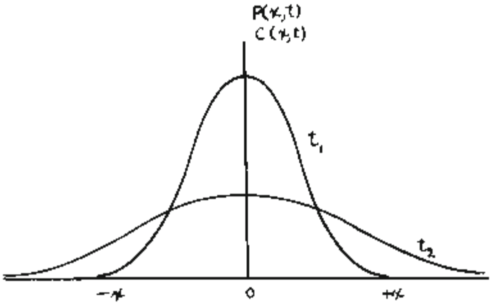

FIG. 1. Concentration or probability profiles for one-dimensional diffusion for times t_1 and t_2.

Both equations have the form of the well-known Gaussian error curve, which gives the distribution of random errors to be expected in a large set of measurements. Figure 1 illustrates these equations, showing the probability of finding a single particle at a distance from its origin (or the concentration distribution of a finite quantity of a substance) after times, t_1 and t_2.

Equation (2) is a particular solution of a pair of more general differential equations known as Fick's laws. Consider a plane of unit cross-sectional area in a system, across which a concentration gradient, $\partial C/\partial x$, exists. There will be a net flux of matter, J_x, through the plane from the region of higher to lower concentration given by Fick's first law:

$$J_x = -D\frac{\partial C}{\partial x} \qquad (3)$$

In principle, it is possible to determine the coefficient of diffusion on the basis of Eq. (3) by measuring the net quantity of matter that crosses through unit area of the plane in unit time. This proves to be difficult in liquids or solids, however, and an additional complication is that the concentration gradient $\partial C/\partial x$ is not constant but decreases with time.

For this reason, it is more feasible to measure the accumulation of matter in a small volume element after a measured period of time. We may consider such a volume element to be bounded by parallel planes of unit area, separated from one another by a distance dx, as shown in Fig. 2. The rate of change of concentration within the volume element is expressed by Fick's second law:

$$\frac{d}{dx}\left[J_x - \left(J_x + \frac{\partial J}{\partial x}\cdot dx\right)\right] = \frac{dC}{dt} = D\frac{\partial^2 C}{\partial x^2} \qquad (4)$$

This is the fundamental equation, upon which all experimental studies of diffusion depend.

One of the most widely used of the absolute

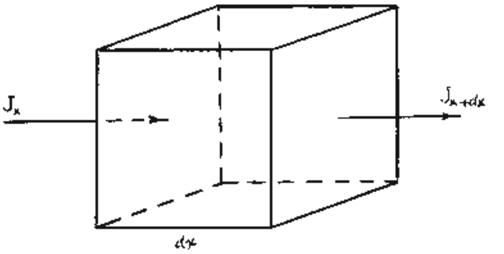

FIG. 2. Diffusive flux across parallel planes.

methods for measuring diffusion coefficients of liquids is the "open capillary" technique, devised by Anderson and Saddington.[1] A capillary tube, usually less than 1 mm in diameter and 2–3 cm in length, is filled with an isotopically labeled substance and immersed in a thermostatted bath of the unlabeled liquid. Interdiffusion of the labeled and unlabeled molecules occurs across the open end of the capillary, and at the end of the experiment, the average concentration of labeled substance remaining in the capillary is determined by suitable radiochemical or mass spectrometric techniques. The relation between the diffusion coefficient and the initial and final concentration of labeled substance in the capillary is given by a series solution of Fick's second law:

$$\frac{C_{av}}{C_0} = \frac{8}{(\pi)^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp\left(-(2n+1)^2\pi^2 Dt/4L^2\right) \quad (5)$$

In this equation, for which L and t are, respectively, the capillary length and time, the series converges rapidly and as a rule may be terminated after the first or second term with negligible error.

Other methods have been developed for the measurement of diffusion coefficients, usually limited to the liquids or solutions of a particular kind. One of the most accurate, limited to electrolytic solutions,[2] is based upon the measurement of the change in the electrical conductance as a function of time in a direction transverse to a concentration gradient in the solution. Such a method leads to the mean diffusion coefficient of ion pairs of a 1:1 salt, rather than the individual ionic diffusion coefficients if the concentration gradient is initially established between the electrolyte and pure water.

The diffusion coefficients of electroreducible or electrooxidizable ions in polar solvents may be determined by the method of polarography[3] or related techniques. Here the principle is the establishment of an ion-depleted zone of the solution next to the cathode or anode of a polarographic cell, and the measurement of the current carried by the appropriate ions as they diffuse through the depleted zone to the electrode. The Ilkovic equation gives the relation between the diffusion current and parameters of the system when the electrode is a flowing liquid metal, such as mercury:

$$i_t = 4\left(\frac{7\pi}{3}\right)^{1/2} nFD^{1/2}\, C\left(\frac{3m}{4\pi\rho}\right)^{2/3} t^{1/6} \quad (6)$$

where n is the number of equivalents involved in the electrode reaction,
F is the Faraday,
C is the concentration of reducible or oxidizable ions in the bulk solution,
m is the mass flow rate of metal (mercury),
ρ is the density of metal, and
D is the ionic diffusion coefficient.

Optical methods[4] are applicable to solutions that are transparent, and have been used extensively to measure the diffusion coefficients of polymers, proteins, and other biologically important compounds. They depend upon the variation of the index of refraction of a solution with the concentration of the dissolved substance. Schlieren images of a slit or interferometric fringes of a collimated beam of light that is deviated by refraction as it passes through a concentration gradient of the solution permit measurement of the time-dependent displacement of the solute.

A completely different method for the measurement of diffusion coefficients in the liquid state is based upon nuclear magnetic resonance (NMR). An assembly of atomic nuclei which have been excited to some nonequilibrium spin distribution will return to thermal equilibrium by a mechanism that involves the coupling of the nuclear spins with their local molecular environment. The rate of the return to equilibrium is characterized by a *relaxation time* (T_1, the spin-lattice relaxation time), and is governed by the variations in the local magnetic field at nuclei which are induced by the translational motions of neighboring molecules. In favorable circumstances the spin-lattice relaxation time may be obtained from the width of the NMR resonance line. Bloembergen, Purcell, and Pound[2] developed the basic theory which relates the spin-lattice relaxation time to the diffusion coefficient of molecules, and made the first measurements on water and a series of hydrocarbons to test its validity. A more direct determination of the self-diffusion coefficient of liquids is provided by NMR spin-echo experiments. These techniques employ rf pulses and either steady or pulsed magnetic field gradients to determine the rate of decay of the induced nuclear spin polarization. Spin echo measurements of the self-diffusion coefficients of liquid lithium and liquid sodium, as well as of H_2O and D_2O, are in excellent agreement with the results of isotope labeled diffusion experiments.[5]

A great deal of information[6] about the mechanisms of molecular motion is contained in the NMR signal and its time evolution. The processes of nuclear spin relaxation involve coupling to magnetic fields and electric field gradients (when $I \geqslant 1$) both internal and external to a molecule, and are modulated by their thermally driven fluctuations. Various theoretical models[7] have been devised to infer the details of translational and rotational motions of molecules from several characteristic correlation times that are observable by spin echo NMR methods. (A correlation time is the average time required for a molecule to lose the memory of its orientation in a prepared spin state.) It is often possible, for example, to deduce the rates with which molecules of low symmetry rotate about their axes, to ascertain whether the angular motion is through a small or large angle, and to characterize such motions by rotational diffusion coefficients or equivalently, correlation times.

Efforts to relate observable transport properties of a system of motions at the molecular level are based upon the so-called *fluctuation dissipation theorem*, which links the linear transport coefficients to time correlation functions of locally fluctuating dynamical variables (e.g., force, position, velocity, momentum). For translational self-diffusion, the self-diffusion coefficient is given[8] by the velocity autocorrelation function:

$$D = \tfrac{1}{3} \int_0^\infty dt \langle v(0) \cdot v(t) \rangle \qquad (7)$$

where $\langle v(0) \cdot v(t) \rangle$ is the average of the particle velocity over a short time Δt, which is nevertheless long compared with the period between "collisions." Similar time correlation functions are defined for other transport properties, such as viscosity and electrical conductivity, and for molecular rotation. The correlation times for molecular rotation are:

$$\tau_{1,2} = \int_0^\infty dt \langle Y_{lm}\,\Omega(0) \cdot Y_{lm}\,\Omega(t) \rangle \qquad (8)$$

and

$$\tau_J = \int_0^\infty dt \frac{\langle J(0) \cdot J(t) \rangle}{\langle J(J+1) \rangle} \qquad (9)$$

where, in Eq. (8), $l = 1$ for dielectric relaxation and $l = 2$ for nuclear spin relaxation by intramolecular dipolar or quadrupolar interactions, and in Eq. (9), $J(t)$ is the rotational angular momentum operator that governs nuclear relaxation by spin-rotation interactions. The relative magnitudes of τ_1 and τ_2 distinguish between small and large step angular motions, and τ_J depends upon the moments of inertia of the molecule.

A completely different approach to the study of the dynamics of atom motion in liquids is based upon slow neutron scattering. The angular and energy dependence of the cross section for inelastic scattering of neutrons by the nuclei of atoms in a liquid metal, for example, may be used to deduce the Van Hove space-time correlation function.[5] This function contains information about the diffusive motions of nuclei, and experiments on liquid metals indicate that a transition from the gas-like free motion of particles to solid-like diffusive displacements occurs on a time scale of 10^{-13} sec.

Studies of the temperature dependence of the diffusion coefficient of liquids generally lead to an empirical relationship of the form:

$$D = D_0 \exp(-(Q/RT) \qquad (10)$$

where D_0 and Q are experimental parameters that are essentially temperature-independent and characterize the diffusion process in the system at hand. Because of the exponential form of Eq. (10), the mechanism of diffusion in liquids is often assumed to be an activated process, by analogy with other kinetic processes to which the *absolute reaction rate theory* has been applied with much success. According to this theory, the rate-limiting step of a kinetic process is determined by the frequency with which atoms or molecules acquire sufficient energy through thermal fluctuations to surmount an energy barrier identified by the parameter Q. It has not yet proved possible to make accurate *a priori* calculations of D_0 and Q on the basis of the activated state theory, however, and the exponential form of Eq. (10) is no proof that the mechanism of atom transport in liquids is a thermally activated process in any simple sense.

In recent years high speed computers have made possible the simulation of self-diffusion experiments by molecular dynamics calculations. In such experiments the classical equations of the motion are solved by difference methods for a set of particles of given mass and assumed pair interaction potential at certain temperatures and particle densities. The time intervals are on the order of 10^{-14} seconds, and D is calculated from the Einstein equation with the mean square displacements $\langle R^2 \rangle$:

$$\langle R^2 \rangle_{av} = 6Dt. \qquad (11)$$

Calculations have been made for (noninteracting) hard spheres, liquid argon,[9] liquid sodium metal,[10] and molten sodium chloride,[11] and the agreement is generally very good. They show clearly that diffusion occurs by small steps of less than molecular diameter. This rules out the once favored "hole theory" of transport and corroborates other evidence that diffusion is a highly cooperative process, involving the participation of many particles. This, together with other evidence[12] based upon the small pressure-dependence of self-diffusion in liquid mercury, effectively disproves all models that appeal to the activated state theory of transport processes for the elementary diffusive step as a single particle jump over an intermolecular distance. The concept of an activated state also loses its meaning when the number of particles needed to define it becomes large and ill-defined. The characterization of the exponential temperature-dependence of self-diffusion by an "activation energy" should therefore be regarded as an experimental parameter, and not as a barrier that a single molecule must surmount. The same must be said of other pseudo-thermodynamic quantities (enthalpy, entropy, and free energy) that have been adduced to the transport properties of liquids.

DIFFUSION IN SOLIDS

The term "diffusion" refers to the random motion, generally activated by local fluctuations of thermal energy, of particles through a medium. The particles with which we shall be concerned are atoms and molecules; the medium can be various types of solids. Of special interest will be crystalline solids—these include all metals, most ionic substances, and many covalent ones—in which the atoms occupy periodic and well-defined sites.

The migrating particles may themselves be uniformly distributed constituents of the host solid; this is called self-diffusion. When the diffusing system contains chemical inhomogeneities or when a foreign substance diffuses in from the surface, we speak of chemical or of impurity diffusion. Diffusion processes are technologically important in the oxidation and tarnishing of metals, where one reactant must migrate through the layer of reaction product, and in the annealing of deformed or radiation-damaged materials. Self-diffusion is an essential step in the photographic process in silver halides, and impurity diffusion is widely used in the fabrication of semiconductor devices such as transistors. Many metals, such as steel and duralumin, are hardened by solid-state precipitation and reaction, in which diffusion plays a dominant role. It is also significant in the powder metallurgy technique of fabrication of parts from high-melting metals.

If, in the medium, there are variations in the concentration of the migrating atoms—perhaps chemically different atoms or, in the case of self-diffusion, radioactive tracer isotopes—then there occurs a net drift of the diffusing species from regions of high concentration to those of lower concentration. This flow takes place even though each individual atom may migrate completely at random. It is a statistical result of the fact that if there are more atoms per unit volume of, say, A to the left of a given plane than to the right, then even with random, nondirected motion, more A atoms will cross the plane from the left than from the right. We can define the flux of A as the net excess of A atoms crossing a plane of unit area in unit time. Experimentally, this flux is found to depend on the chemical natures of the medium and the diffusing species. If the medium is isotropic or is a crystal of cubic symmetry, the flux is along the direction of the concentration gradient. Moreover, if the system is not too thermodynamically nonideal, the flux is proportional to the concentration gradient; the constant of proportionality is called the diffusion coefficient, D. Thus, we write the flux $J = -D\, dc/dx$, where the negative sign indicates that the net flow is toward the region of lower concentration. This statement is known as Fick's law. If lengths are measured in centimeters and time in seconds, D is in units of square centimeters per second. It follows from

Fick's law that at any given point in the medium, the concentration of the diffusing entity A will change with time at a rate governed by the variation of the flux with distance [$\partial c/\partial t = \partial/\partial x(D\partial c/\partial x)$; for the particularly simple case where D is independent of distance, as in self-diffusion, then $\partial c/\partial t = D\partial^2 c/\partial x^2$]. Also, from the theory of random flights, it can be shown that the root-mean-square displacement of atoms resulting from diffusion for a time t increases as the square root of the product Dt; $R_{\text{rms}} = (6Dt)^{1/2}$.

It is observed that for any given system, D increases rapidly with increasing temperature, almost invariably following the Arrhenius relation $D = D_0 \exp(-H/RT)$. Here, D_0 and H are positive constants for a given system and R is the universal gas constant. The parameter H is called the activation energy and generally increases as the melting point of the host crystal increases. Typically, in crystals which melt at 400 to 500°C, H is about 20 000 to 25 000 cal/mole, or 1 eV/atom, for self-diffusion or diffusion of substitutionally dissolved impurities. In crystals which melt near 1000°C, such as the noble metals, the activation energy is approximately 2 eV/atom. The value of the parameter D_0 is usually in the range 0.01 to 100 cm^2/sec. It is interesting that for a large number of metals and simple ionic crystals, the diffusion coefficients for self-diffusion and for most impurities lie near to 10^{-8} cm^2/sec at temperatures approaching the melting point. Thus, after diffusing for one day at such a temperature, the value of R_{rms} is about 1 mm, rather a large distance when compared to the spacing between atoms in a crystal.

Because of the three-dimensional regularity of atomic positions in a crystalline solid, the unit step in diffusion must be the jump of an atom from one site to a neighboring, crystallographically equivalent site. Large-scale diffusion is the result of random superposition of many such jumps, all of the same length λ but distributed among the various jump directions allowed by the crystal. It is readily shown that the relation between the macroscopic diffusion coefficient D and the microscopic atomic jump frequency Γ is $D = 1/6\lambda^2\Gamma$. This equation may be compared with that given above for R_{rms} by noting that for random jumps $R_{\text{rms}} = \lambda(\Gamma t)^{1/2}$. Now λ will depend on the details of the mechanism of diffusion but it must be of the order of the interatomic spacing, about 3×10^{-8} cm. Then the typical high-temperature diffusion coefficient of 10^{-8} cm^2/sec requires each atom to make 10^7 to 10^8 jumps each second.

In most crystals the atoms are rather densely packed; thus the means whereby such a high frequency of jumps can be accomplished is not obvious. Conceptually, the simplest possibility is the simultaneous exchange of sites between two atoms, but this is ruled out because of the excessive activation energy that would be required to push aside the mutual neighbors of the pair. A dramatic demonstration that diffusion must proceed by a mechanism which allows independent motion of individual atoms is the Kirkendall effect. Two mutually soluble specimens of differing composition, say A and B, are welded together with inert markers imbedded at the interface. Subsequent interdiffusion of A and B results in a drift of the markers relative to the ends of the specimen, indicating that more atoms have left one side of the couple than have entered it from the other. Clearly a pair exchange mechanism cannot be operative here.

Extensive evidence is now available that in most cases of self-diffusion or of substitutionally dissolved impurities, migration proceeds as a result of the presence and mobility of vacant lattice sites. These vacancies exist in the crystal in thermodynamic equilibrium, at concentrations which increase with temperature as $\exp(-H_f/RT)$, where H_f is the energy required to form a vacancy (about 1 eV in the noble metals). At temperatures near the melting point, the fraction of sites vacant is typically 0.01 to 0.1 per cent. Vacancies move by the jumping of adjacent atoms, at a rate which varies as $\exp(-H_m/RT)$. H_m is the activation energy for the migration process. The average jump frequency of an atom must then be the product of the jump frequency of a vacancy and the fraction of atomic sites that are vacant. Comparing the temperature dependence of the diffusion coefficient with that of these two factors, it follows that H must equal the sum of H_m and H_f. Quantitative experimental verification of this equality in a number of substances has firmly established the vacancy mechanism for diffusion in such crystals.

Other mechanisms, however, are also known to operate. For example, linear or planar defects within the crystal can provide paths for easier and more rapid diffusion. Thus, along boundaries between crystal grains, on the external surfaces, and along the linear defects known as crystal dislocations, the atomic regularity is interrupted and binding energies are correspondingly decreased. As a result, the activation energy for diffusion is locally smaller and the diffusion coefficients are therefore larger; one speaks of a "short-circuiting" effect. Along dislocations and internal boundaries, the diffusion activation energy is typically only about half that for diffusion within the bulk crystal, and short-circuiting contributions become especially important at temperatures below about half of the melting point. Diffusion along external surfaces appears to depend strongly on the nature of the ambient atmosphere, and the details of the process are not well understood at present.

Another mechanism which is found in some systems involves the diffusing atom (or ion) migrating from one interstitial position (i.e., squeezed in between proper atom sites) to another. This process is not surprising in those cases in which a very small impurity ion is already dissolved interstitially, such as for carbon in iron; its occurrence is perhaps unexpected, however, in cases where the migrating ion is present primarily substitutionally (i.e., in normal atomic sites of the crystal). Thus, in the silver halides, self-diffusion of silver and the diffusion of several cationic solutes proceed primarily via the interstices of the lattice; perhaps the "softness" of the silver halides encourages such a mechanism. Also, in the loosely packed crystals of germanium and silicon, some solutes (such as copper or gold) diffuse interstitially, although they are dissolved mainly substitutionally. And more recently, it has come to be appreciated that in many polyvalent metals such as lead and tin, the noble metals and their divalent neighbors diffuse by some sort of interstitial process. In all such cases the diffusion coefficients at high temperatures are much larger, by several factors of ten, than would be expected for ordinary substitutional diffusion by means of vacancies.

Within the last decade, numerical procedures for calculating the energies of formation and migration of point defects have been developed to such a point that the interpretation of experimental data can often proceed with considerable confidence, especially in the case of diffusion and ionic conductivity in such relatively simple materials as halides and oxides. Thus, experimental deviations from the simple Arrhenius relation can be analyzed in terms of the dependence on temperature (through the thermal expansion of the lattice) of the parameters D_0 and H, and in terms of the operation of more than one mechanism of atom migration. In other cases, in which no unambiguous ion transport mechanism could otherwise be identified, the results of these calculations now serve as an invaluable guide. The most successful of these schemes has been the HADES code developed at AERE Harwell, in which point defect parameters are calculated from interatomic potentials which, in turn, are obtained by fitting the known dielectric and lattice mechanical properties of the substance. Examples of the use and versatility of this procedure may be found in the volume of *Journal de Physique* cited in the references.

Another recent development has been the rapid growth of interest in those ionic materials in which one component displays an unusually high mobility, giving rise to diffusivities and ionic conductivities in the crystalline solid that are comparable to those typically found only in liquids. These substances are referred to as fast ionic conductors, "superionic" conductors, or solid electrolytes—this last term reflecting their potential application in electrolytic cells.

Apart from the technological interest in these fast ion conductors, there is also a great scientific challenge in understanding the microscopic mechanisms and interactions involved. In such substances, one sublattice retains the normal crystalline order, but the other one invariably displays an extraordinarily high density of point defects—often in the range of several percent—which gives rise to the high mobility of the corresponding ionic component. For example, in α-AgI and $RbAg_4I_5$, the anion sublattice is relatively perfect, while the silver ion distribution is highly disordered. In many lead and alkaline earth halides, on the other hand, it is the anion sublattice which becomes disordered. In the several beta-alumina-type materials, blocks of perfectly ordered ions are separated by parallel planes containing a disordered distribution of mobile, monovalent cations.

One of the interesting questions posed by such materials is the origin, extent, configuration, and temperature-dependence of the disorder in just one of the sublattices. Another problem involves the very low activation energies of migration of the mobile ions and defects. Still a third point of interest hinges on the nature of cooperative interactions between the mobile ions. This is especially fascinating, since fast ion conductors are known in which the mobile ions can move either in all three dimensions (as in α-AgI), in only two dimensions (as in the conducting planes of the beta-aluminas), or along only one-dimensional channels (as in the mineral hollandite). It seems likely that these substances may well yield as rich a reward in scientific understanding as they promise to do in technical applications.

DIMENSIONS

When describing natural phenomena, certain physical attributes or characteristics, such as mass or length, are distinguished. To these are assigned numerical *magnitudes* by prescribed measuring procedures, in which selected *scales* are employed. The length of a Foucault pendulum might be measured with a meter stick and found to equal 64 *units* of measurement, namely 64 meters. The length is called a physical *quantity*.

Customarily, certain quantities, such as length and time, are chosen to be primary or fundamental. Other quantities, like velocity, can then be expressed in terms of these. They are termed secondary or derived quantities. When the meter and the second are taken as units of length and time, the magnitude of a velocity can be expressed in meters per second. The exponent of the power of any primary quantity is called the *dimension* of the secondary quantity in that primary quantity. The dimensions of a secondary quantity are then written in terms of the primary quantities from which they are constituted and the powers to which they are raised. Thus the dimensions of a velocity v, here written as $[v]$, with length L and time T as primary dimensions, are LT^{-1}.

Most physical statements, such as those relating to the conservation of energy or mass, or to equilibrium of forces, can be considered as accounting statements, certifying that there is to be neither a gain nor a loss of a certain quantity. The terms in the equations, in which such statements are expressed, then must all refer to the same quantity: The equations must be *dimensionally homogeneous*.

Consider Bernoulli's equation for steady, nonviscous, incompressible flow in a gravity field. It may be written as

$$p/\rho + v^2/2 + gz = \text{const.}$$

where p is the pressure, ρ the mass density, v the fluid velocity, g the acceleration of gravity, and z the vertical distance measured from some arbitrary level. When mass M, length L, and time T are selected as primary quantities, the dimensions of a force can be derived from Newton's second law as that of mass times acceleration: $[F] = MLT^{-2}$. Therefore the dimensions of pressure, being force per unit area, are $[p] = ML^{-1}T^{-2}$. Further

$$[\rho] = ML^{-3},\ [v] = LT^{-1},\ [g] = LT^{-2},\ [z] = L.$$

All terms in Bernoulli's equation have the dimensions L^2T^{-2}, which are those of the square of a velocity, but also of energy per unit mass. Dimensional homogeneity can be used as a check against errors.

Dimensional Analysis Mathematical relations, with which one attempts to describe nature's order, cannot depend on arbitrary units of measurement (meter, second, etc.). These relations must be expressible in dimensionless form by means of dimensionless parameters. Dimensional analysis, making it possible to find such parameters and to say something about the relation between them, is useful particularly in dealing with complex problems not amenable to direct analysis. It provides the rationale for all model experiments.

To perform dimensional analysis, one must have an insight into the quantities which are relevant to the problem in question. Typically, one lists these relevant quantities and selects the primary quantities in which their dimensions are to be expressed.

For example, assume that a homogeneous body of arbitrary shape and having a characteristic dimension ℓ, having been kept at uniform temperature, is suddenly subjected, over a portion of its surface, to a temperature which is greater by the amount θ_0. The remainder of the surface is to be insulated. What can be said about the temperature rise θ at any point, designated by some radius vector **r**, after a time t has elapsed?

Heat conduction being a geometric phenomenon, the heat-absorbing capacity per unit volume is judged to be relevant. With the specific heat c of the material being defined as the heat energy which raises the temperature of a unit mass by one degree, and designating the mass density by ρ, the heat capacity per unit volume is $c\rho$. Another relevant quantity must be the thermal conductivity k of the material, defined as the heat transmitted per unit time per unit cross section per unit temperature gradient.

For this problem heat energy $[E]$, length $[L]$, time $[T]$, and temperature $[\theta]$ are con-

TABLE 1.

Quantities	Exponents of Dimensions E	L	T	θ
ℓ		1		
$\mathbf{r}$		1		
θ_0				1
θ				1
$c\rho$	1	-3		-1
k	1	-1	-1	-1
t			1	

venient primary quantities. The quantities judged to be significant, with their exponents in terms of these primary dimensions are listed in Table 1. The number of dimensionless parameters to be obtained is determined by Buckingham's PI theorem. Formal ways to determine them are given in references 1 through 5. In this case, inspection shows that there are three dimensionless parameters, which can be written as:

$$\pi_1 = \theta/\theta_0, \quad \pi_2 = \mathbf{r}/\ell, \quad \pi_3 = kt/c\rho\ell^2$$

The result can be stated as: $\theta/\theta_0 = f(\mathbf{r}/\ell,\ kt/c\rho\ell^2)$. The temperature rise θ at any point and at any time is proportional to θ_0. The time t needed to attain a temperature rise which is a specified fraction of θ_0 is proportional to the square of the characteristic dimension ℓ (the size of the body). The material is fully described by the quantity $k/c\rho$, known as the thermal diffusivity.

Particularly in fluid mechanics and heat transfer, some dimensionless parameters have gained general significance. The Mach number is the ratio of local fluid velocity to local velocity of sound. The Reynolds number is $v\ell\rho/\mu$, where v is a characteristic velocity, ℓ a characteristic dimension, ρ the fluid density, and μ the viscosity of the fluid.

Dimensions and Physical Constants Physical constants appear when relations are established among quantities which are already dimensionally connected. For example, Newton's second law when written as $F = m d\mathbf{v}/dt$ fixes the dimensions of force as $[F] = MLT^{-2}$. But Newton's law of gravitation also relates a force (that of gravitation) with masses and their distance. With MLT dimensions taken to be independent, the gravitational law is written $F = Gm_1m_2/r^2$ where G is a dimensional gravitational constant. It is possible to write the gravitational law $F = m_1m_2/r^2$, but then M, L, T can no longer be independent. For example, the mass dimensions could be expressed in terms of L and T: $[M] = L^3T^{-2}$. Since physical constants are dimensional, they can be expected to be constant

TABLE 2. SOME QUANTITIES AND THEIR TYPICAL DIMENSIONS

Physical Quantity	MLT	Primary Quantities $MLT\theta$	$MLTQ$
Velocity	LT^{-1}		
Acceleration	LT^{-2}		
Force	MLT^{-2}		
Energy, Torque	ML^2T^{-2}		
Momentum	MLT^{-1}		
Density	ML^{-3}		
Viscosity	$ML^{-1}T^{-1}$		
Heat, Energy		ML^2T^{-2}	
Specific Heat		$L^2T^{-2}\theta^{-1}$	
Conductivity		$MLT^{-3}\theta^{-1}$	
Entropy		$ML^2T^{-2}\theta^{-1}$	
Electric Current			$T^{-1}Q$
Electric Potential			$ML^2T^{-2}Q^{-1}$
Impedance			$ML^2T^{-1}Q^{-2}$
Capacitance			$M^{-1}L^{-2}T^2Q^2$

only when the operational methods with which the fundamental units are defined are properly correlated. They then take on the character of conversion factors. The velocity of light, having the dimensions LT^{-1}, can be universally invariant only when the operational definitions of L and T make it so, as can be done by making use of radiation phenomena.

In thermal problems E, L, T, and θ can be selected as primary quantities. But, as $[E] = ML^2T^{-2}$, obviously M, L, T, θ can also be chosen where convenient. When physical constants are relevant to a particular problem with the dimensions selected, they must be listed among the relevant quantities. When the gas law $p = \rho R\theta$ applies to the problem, the gas constant R must thus be listed. Alternatively, R can be taken to be dimensionless, making $[\theta] = L^2T^{-2}$. Then θ would no longer appear as a primary quantity.

In electricity, a variety of primary quantities can be used, based on the manner in which the electrostatic and electromagnetic laws are stated. Often M, L, T, and Q (electric charge) are employed.

DIODE (SEMICONDUCTOR)

There exists a class of two-terminal devices which have the property of permitting current to flow with practically no resistance in one direction and offer nearly infinite resistance to current flowing in the opposite direction. These devices are called *diodes*. The applications of diodes to electronic circuits are numerous. To mention a few, they include rectification of alternating current to a unidirectional current, detection of radio waves, and gating circuits used in digital computers.

The basic materials utilized for making semiconductor diodes are germanium (Ge) and silicon (Si). These elements are included in column IV of the periodic table (see PERIODIC LAW AND PERIODIC TABLE). Both Ge and Si are *tetravalent* elements, i.e., they have 4 valence electrons. Elements in their pure state are said to be *intrinsic*.

Each element under column III of the periodic table has 3 valence electrons and is referred to as *trivalent*. Examples of trivalent elements include indium (In) and gallium (Ga). Elements in column V of the table have 5 valence electrons and are called *pentavalent*. Arsenic (As) and antimony (Sb) are examples of pentavalent elements.

The process of introducing one of the elements from column III or V into intrinsic Ge or Si is called *doping*. The doped material becomes impure or *extrinsic*. If a trivalent impurity is introduced in Ge or Si (trivalent elements have one less valence electron than Ge or Si) holes are created and the material is said to be *p*-type. Introduction of a pentavalent impurity (pentavalent elements have one more valence electron than Ge or Si) creates free electrons and the material is *n*-type.

Because of thermal effects, free electrons and holes are always being produced in Ge and Si (intrinsic generation of electron-hole pairs). Consequently, there will be some electrons in the *p*-type material and some holes in the *n*-type material. These carriers are referred to as *minority* carriers. Electrons in *n*-type material and holes in *p*-type material are termed *majority* carriers. The most widely used diode is the *p-n junction diode*. Imagine a single crystal of Ge (or Si) doped so half the material is *p*-type and the other half, *n*-type. The internal boundary between the two extrinsic regions is a *p-n* junction, and the resulting device is a junction diode (Fig. 1). The electrical symbol for the junction diode is illustrated in Fig. 2.

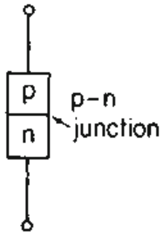

FIG. 1.

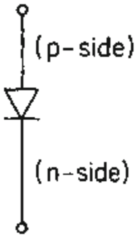

FIG. 2.

What are the characteristics of the *p-n* junction? To answer this question, three possible conditions are considered. Referring to Fig. 3, these are:

(1) *Unbiased: p-* and *n*-sides are connected by a wire.

(2) *Reverse biased:* the *p*-side is connected to the negative terminal of battery E, and the *n*-side connected to the positive terminal.

(3) *Forward biased:* the *p*-side goes to the positive terminal of E, and the *n*-side to the negative terminal.

Simple energy diagrams for the three conditions are shown in Fig. 3 for the electron. Similar diagrams can be generated for holes. When the diode is unbiased, no net flow of electrons takes place across the junction. Assuming that some electrons on the *n*-side have sufficient energy to overcome the potential hill, electrons on the *p*-side (minority carriers) "slide down" the hill making the net current flow zero. For the reverse biased case, the potential hill is raised and only the few minority carriers from the *p*-side "slide down." This results in a minute reverse saturation current. When the diode is forward biased, the potential hill is lowered. This enables electrons to climb over the hill and current flow occurs. The same considerations apply to holes. In fact, the total diode current is equal to the sum of the electrons and holes flowing across the junction.

The characteristic curve of a semiconductor diode is shown in Fig. 4. An equation for this curve, called the *rectifier equation*, is expressed as:

$$I = I_s(e^{-11600E/T} - 1)$$

where

I = diode current, amperes

I_s = reverse saturated current (which is temperature dependent), amperes

E = diode biasing voltage ($+E$ for forward bias;$-E$ for reverse bias), volts

T = absolute temperature ($°C + 273°$), degrees Kelvin.

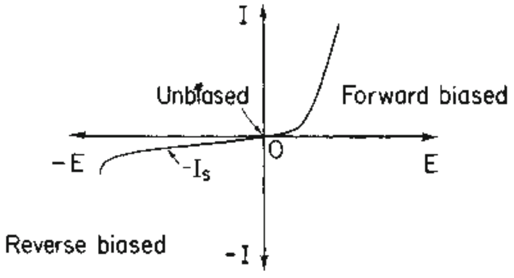

FIG. 4.

At room temperature (300 K) and $E > 0.1$ volt:

$$I \cong I_s e^{39E}$$

When E is more negative than 0.1 volt:

$$I \cong - I_s$$

An example of a simple rectifier employing a *p-n* junction diode is given in Fig. 5. During the positive half-cycle (0° to 180°) of the ac sinusoidal waveform v_s, the diode is forward-biased and conducts. The voltage v_L across load resistor R_L is therefore nearly identical to that of v_s for the positive half-cycle. For the negative half-cycle (180° to 360°) the diode is reverse-biased and does not conduct. No current flows in R_L, and $v_L = 0$ during the negative half-cycle. Because the diode conducts for only one-half cycle, the circuit of Fig. 5 is called a *half-wave rectifier*.

The waveform of v_L is only unidirectional. To obtain steady dc, like that from a battery, a filter is required. An example of an elementary filter is a large-valued capacitor placed across the load resistor.

The circuit of Fig. 5 can also be used as a detector of amplitude-modulated (AM) radio waves. Figure 6(a) illustrates the components of an AM wave. If this is applied to the input of Fig. 5, the wave is rectified and the output ap-

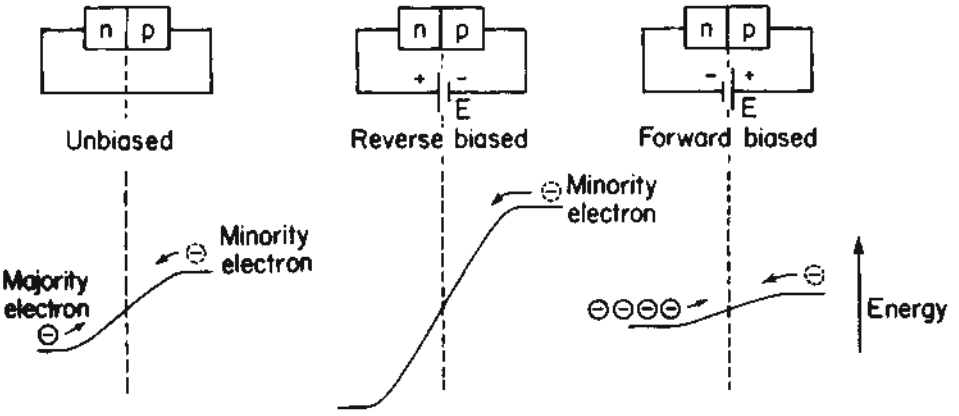

FIG. 3.

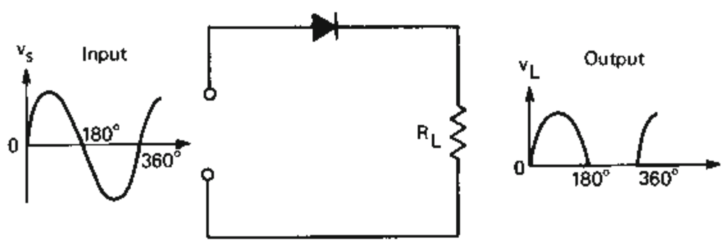

FIG. 5.

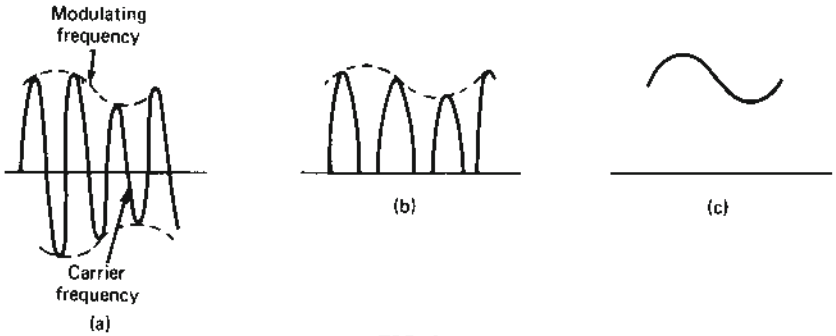

FIG. 6.

pears as shown in Fig. 6(b). Placing a small-valued capacitor across R_L filters out the carrier frequency and the desired modulating signal is obtained (Fig. 6(c).

Besides the *p-n* junction diode, there are a number of other diode types which find use in specialized applications. These include the following diodes:

Gunn: used for the generation of microwave power.
Hot carrier (*Schottky* barrier): used for fast switching of waveforms, such as found in computers.
IMPATT: used for the generation of microwave power.
Injection: used for the generation of laser frequencies.
Light-emitting (LED): used for alpha-numeric displays.
Varactor: a reverse-biased junction diode that behaves like a variable capacitor, as a function of the applied voltage across the device.
Zener (*avalanche*): a reverse-biased junction diode that exhibits a dc voltage which is nearly independent of a specified range of current flowing in the device. The *Zener* diode finds wide use as a voltage reference in regulated power supplies.

DIPOLE MOMENTS (ELECTRICAL AND MAGNETIC)

Uncharged molecules can be classified as nonpolar or polar dependently on whether, in the absence of an electric field, the centers of gravity of their constituent positive and negative charges are coincident or not. A body containing two opposite charges, $\pm Q$, separated by a distance d, is characterized by an electric dipole moment, $Qd = \mu$; μ is a vector quantity, expressed conveniently in debye (D) units: 1 debye = 10^{-18} esu = 3.33×10^{-30} [coul m].

In the presence of an applied field a normally nonpolar molecule becomes dipolar by induction, i.e., by deformation of its electronic and atomic arrangements: $\mathbf{m} = (\alpha_e + \alpha_a)\mathbf{E}$, where the coefficients of proportionality α_e and α_a are the electronic and atomic polarizabilities, respectively. In the general case of an anisotropically polarizable molecule, α_e and α_a are tensors, the components of which may be evaluated from observations of electric birefringence (Kerr effect), the depolarization of (Rayleigh) scattered light, refractive index dispersion, etc. An estimate of the mean of the three principal polarizabilities is given by $3R/4\pi N$, where R is a molecular refraction by the Lorenz-Lorentz formula; when R is extrapolated to infinite wavelength the mean polarizability obtained refers to the electronic deformations alone. Polarizabilities are expressed in volume units (cubic centimeters) (N = the Avogadro number).

A field **E** exercises a torque on an electric dipole μ, tending to align it in the field direction in opposition to the randomness caused by thermal agitation. In a large assembly of molecules, therefore, a statistical and temperature-dependent equilibrium is achieved which corresponds to a slight excess of molecules having their permanent dipoles oriented antiparallel to the field so that the average moment $\overline{m}$ of one molecule is apparently proportional to the field intensity, i.e., an orientation polarizability α_o is exhibited.

The electric dipole moment per unit volume of a dielectric material is the polarization vector **P**, understandable in magnitude as the charge density bound at the electrodes by a polarized dielectric. Based on the arguments of Mossotti (1850) and Clausius (1879), the polarization per mole is related to the dielectric constant ϵ by $M(\epsilon - 1)/d(\epsilon + 2) = 4\pi N\alpha/3$, where M/d is the molecular volume, N is the Avogadro number, and α is the over-all polarizability. Debye (1912) showed α_o to be $\mu^2/3kT$ (k = Boltzmann's constant, T = absolute temperature) so that $\alpha = \alpha_e + \alpha_a + \alpha_o$, and the total polarization per mole ${}_{\mathrm{T}}P$ is the sum of the electronic, atomic, and orientation polarizations: ${}_{\mathrm{T}}P = {}_{\mathrm{E}}P + {}_{\mathrm{A}}P + {}_{\mathrm{O}}P$. A possible fourth polarization mechanism, the blocking or trapping of migrating charge carriers in a dielectric, although ignored in the classical molecular theory, may also contribute to the apparent ϵ of solid or macromolecule-containing systems.

The commonest method for the determination of dipole moments involves the dispersion of ϵ: ${}_{\mathrm{T}}P$ is measured at radio and optical wavelengths (the second of these is a molecular refraction since the square of the index of refraction of a nonabsorbing, nonmagnetic material equals the dielectric constant at the same frequency), then approximately $R = {}_{\mathrm{E}}P + {}_{\mathrm{A}}P$, and $\mu^2 = 9kT({}_{\mathrm{T}}P - R)/4\pi N$. Although strictly valid only for gaseous dielectrics the Mossotti-Clausius-Debye equations have proved applicable also to solutes in nonpolar solvents, and by using alligation formulas, values of ${}_{\mathrm{T}}P$ for a dissolved species can be obtained at infinite dilution; such estimates are usually close to, but not identical with, the true ${}_{\mathrm{T}}P$'s directly observed on the vaporized solutes. Over the past thirty years, much effort has been devoted to theoretical or empirical treatments of "solvent effects." Since distortion polarizations are almost invariant with temperature, the temperature dependence of ${}_{\mathrm{T}}P$ follows as $({}_{\mathrm{T}}P)_{\mathrm{T}} = A + B/T$; the constants A and B, when fitted to experimental data by least squares, give $A = {}_{\mathrm{E}}P + {}_{\mathrm{A}}P$ and $B = 4\pi N\mu^2/9k$, whence $\mu = 0.012812B^{0.5}$ esu; results for about 350 gases are listed by Marryott and Buckley.

Practical details concerned with the measurement of dielectric constants, and other properties, necessary for the deduction of μ's of solutes or vapors, are described fully in the books (cited below) by Le Fèvre, Smith, and Smyth, wherein also references are made to other, but less simple, techniques by which dipole moments can be determined (e.g., Stark splitting in microwave spectra of gases at low pressures, the dielectric losses or power factors of dilute solutions, molecular beam studies, etc.); the first two of these are useful since they can detect very small moments which the ordinary dielectric constant methods cannot reveal accurately; the third technique—involving the deviation undergone by a thin ribbon of gaseous molecules in passing through an intense nonhomogeneous electric field—is applicable to substances, such as metal salts, which through insolubility or low volatility would be otherwise unexaminable.

By the end of 1961, some 7000 dipole moment values for more than 6000 substances had been recorded (see McClellan's Tables); they fall mostly in the range 0 to 5 debyes.

Chemical interest is largely due to the relationships between polarity and molecular structure. Monatomic molecules, diatomic molecules of the type AA, and centrosymmetric polyatomic molecules, are nonpolar; a linear triatomic molecule ABA is nonpolar, but if bent or constructed as AAB it is polar; pyramidal tetratomic molecules AB_3 are polar, etc. A more quantitative approach supposes that characteristic polarities are associated with covalent chemical bonds, e.g., that two bonds, having "bond moments" μ_1 and μ_2, mutually inclined at θ^0, produce a resultant of $(\mu_1{}^2 + \mu_2{}^2 + 2\mu_1\mu_2 \cos\theta)^{0.5}$. On this basis, bond moments deduced from the resultant moments of molecules with known structures, often permit the discovery or testing of stereo specifications of further molecules. However, caution is necessary since bond moments are not independent of bond environments, but may be modified by induced moments—determined by the fields of neighboring polar bonds or centers and the (anisotropic) polarizabilities of the bonds under consideration—or by other internal electronic effects (c.f. resonance, mesomerism, hybridization, etc.). Completely successful calculations of dipole moments from *a priori* theory have yet to be made.

Some concepts developed for electrostatic fields have magnetic counterparts; thus in place of polarization **P** there is magnetization **I**, the magnetic dipole moment per unit volume caused in a material by an externally applied field **H**; internally the magnetic flux density (the magnetic induction) is $\mathbf{B} = \mathbf{H} + 4\pi\mathbf{I}$; the ratio I/H is the volume susceptibility κ ordinarily measured. Individual magnetic monopoles are not known to exist in nature, but movements and spins of electrons in atoms and molecules—if viewed classically as direct currents flowing in closed circuits—can create fields identical with those expected from magnetic dipoles having moments dimensionally equivalent to products of pole strengths and distances. The elementary magnetic moment is the "Bohr magneton," 9.273×10^{-21} [erg gauss^{-1}], assumed to be the magnetic moment of an electron "spinning" on its own axis. Atoms may possess orbital moments (due to mechanical angular movements of electrons) and spin moments (one for each electron). Magnetic moments can be induced or permanent. A unit volume containing ν particles each of magnetizability α_m, subjected to a field H, displays a magnetization $\mathrm{I} = \nu\alpha_m\mathrm{H} = \nu\overline{m}$, where $\overline{m}$ is the average magnetic dipole moment per particle; thus $\kappa = \nu\alpha_m$, and the molar susceptibility $\chi = \kappa V = N\alpha_m$ (where V is the molar volume and N the Avogadro number); α_m can be split into $\alpha_i + \alpha_p$, to correspond with the contributions to **I** made by the induced and permanent moments respectively.

An electron in an orbit of radius r represents a current loop; application of a magnetic field H perpendicularly to the loop plane will induce a voltage tending to create a field opposing that applied; the effect will be manifest as an apparent induced moment antiparallel to H and—by classical calculations—of the value $-e^2r^2\mathbf{H}/6mc^2$ (here e is the electronic charge, m is the electronic mass, c is the velocity of light); hence $\alpha_i = -e^2r^2/6mc^2$, and for a monatomic substance with spherical atoms the molar diamagnetic susceptibility $\chi = -(Ne^2/6mc^2)\sum_n r_i^2$, where r_i^2 is the mean value of r^2 for the ith electron and the sum is taken over n electrons. The χ's observed for the inert gases, the C atoms in diamond, the Cl atoms in Cl_2, etc. have agreed with reasonable magnitudes of $\sum r^2$. Pascal (1910) showed diamagnetic susceptibility to be an "additive-constitutive" property, so that the χ's of polyatomic molecules can be approximately predicted by summing "atom" and "bond" susceptibilities in numbers and kinds appropriate to the molecular structure under consideration. The diamagnetic susceptibility of an individual molecule is a tensor quantity; χ/N by experiment is an average of three principal magnetic susceptibilities directed along three mutually perpendicular principal axes of magnetic susceptibility; these can be investigated through torsional movements of crystals in magnetic fields (Krishnan's method) or from magnetic birefringence measurements (Cotton-Mouton effects) in conjunction with data for χ_{mean} secured with a Gouy balance.

A permanent magnetic dipole will experience a torque in a magnetic field. Langevin (1905) showed that the mean moment $\overline{\mathbf{m}}$ of a gaseous molecule in the field direction (provided that H is not too large) is $\overline{\mathbf{m}} = (m_p^2/3kT)\mathbf{H}$, where m_p is the actual moment of each molecule; therefore the molar paramagnetic susceptibility χ_p is $N\overline{\mathbf{m}}/\mathrm{H} = N\alpha_p = Nm_p^2/3kT$. In practice χ_p is extracted from the observed χ by treating this as the algebraic sum of a negative diamagnetic susceptibility (estimated from Pascal's constants) and a positive paramagnetic susceptibility; thus m_p follows as $(3kT\chi_p/N)^{0.5}$ [erg gauss^{-1}] or as $2.84(T\chi_p)^{0.5}$ [Bohr magnetons]. Molar diamagnetic susceptibilities are independent of temperature, while molar paramagnetic susceptibilities in general vary as $1/T$ or $1/(T - T_c)$. The small paramagnetisms of alkali metals, Cu, Ag, etc., or of certain salts (e.g., $KMnO_4$ or $K_2Cr_2O_7$), attributable respectively to uncompensated spins of conduction electrons, or to uncompensated paramagnetisms of complex ions, are temperature invariant.

Normally any atom or molecule with unpaired electrons shows paramagnetism and possesses a magnetic moment. Magnetic properties can therefore provide important information on valency states in free radicals, molecules containing first period elements with unpaired p electrons, transition elements having unpaired d electrons, lanthanides with unpaired $4f$ and actinides with unpaired $5f$ electrons. Theoretical expressions exist to calculate paramagnetic moments in terms of atomic structures and spin and orbital angular momenta of unpaired electrons. Simple examples are the ions of transition metals where, if n is the number of unpaired electrons, m_p is approximately predicted as $[n(n + 2)]^{0.5}$ Bohr magnetons (for a full discussion of such relations see Nyholm's review). Determination of m_p thus gives n, which is often of value in deciding the three-dimensional arrangements and bond types involved in molecules, especially those built around a central metal atom.

For most substances χ is independent of field strength, but a few paramagnetic compounds can, below the characteristic temperature T_c (see above), show "ferromagnetism" due to spontaneous parallel alignments of spins of atomic magnets. Materials which are ferromagnetic at ordinary temperatures (e.g., soft iron) have nonlinear magnetization-field characteristics, develop large magnetizations in weak fields, rapidly approach saturation conditions, exhibit hysteresis, etc.; whole domains about 0.01 mm in diameter and magnetically saturated are thought to be undergoing orientation during such processes. Ferromagnetism—and related phenomena such as "antiferromagnetism" and "ferrimagnetism"—have at present few applications in chemistry; in electronics (e.g., ferrites in antennas and in magnetic tape), they are frequently important.

DOPPLER EFFECT

The wave effect by which astronomers measure the radial velocities of galaxies, and policemen determine the speeds of approaching automobiles, was in spite of its simplicity not discovered until the nineteenth century. In 1842, Christian Doppler predicted that the frequencies of received waves were dependent on the motion of the source or observer *relative to the propagating medium*. His predictions were promptly checked for sound waves by placing the source or observer on one of the newly developed railroad trains.

In his original article on the special theory of relativity (see RELATIVITY), Einstein[1] developed the expression for the Doppler shift of light waves which was dependent upon the velocity of the source *relative to the observer*. From the photon hypothesis for light, Schrödinger[2,3] obtained the same results. Thus, the Doppler effect provides one of the illustrations of the equivalence of the wave and particle descriptions of light.

Classroom demonstrations of the Doppler effect for water waves are made in shallow glass-bottom ripple tanks. Instead of giving the vibrating source a constant velocity, one lets the sheet of water as medium flow continuously by the source.

The circles of Fig. 1 are snapshots of the crests of a water wave or compressions in a sound wave observed when the source is moving at constant velocity v to the right relative to the medium. Points 1 and 2 are positions of the source one and two periods after passing O. The largest circular crest originated at O, the next at 1 and the smallest at 2. A crest is about to leave point 3 at the time the snapshot is taken. If the position P of the observer is a large distance from the source compared to the distance the source moves in one period, then with good approximation we may assume that two successive crests are moving in the same direction as they pass P. If v is the velocity of the source in the direction OA, the source moves a distance vT in one period T. In one period, the source comes closer to P by the amount $vT\cos\theta$, where θ is the angle between the direction of the velocity of the source and the line from the

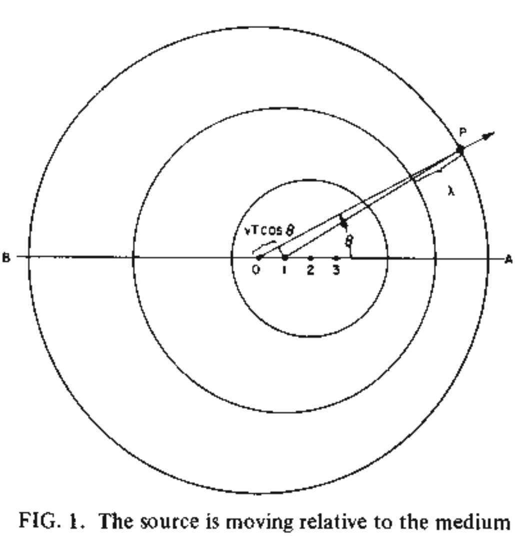

FIG. 1. The source is moving relative to the medium along the line BA. The circles represent crest of the wave at an instant. (Andrews, C. L., "Optics of the Electro-Magnetic Spectrum", Englewood Cliffs, N.J., Prentice-Hall, Inc., 1960).

source to the observer at P. Now λ_0 is the wavelength and ν_0 the frequency when the source is at rest; λ is the observed wavelength and ν the observed frequency when the source is in motion. Because of the motion of the source, the wavelength received at P is reduced by $vT\cos\theta$.

$$\lambda = \lambda_0 - vT\cos\theta$$

If c is the velocity of the wave, $T = \lambda_0/c$ and $\lambda = \lambda_0[1-(v/c)\cos\theta]$, but $\lambda = c/\nu$ and $\lambda_0 = c/\nu_0$. Therefore,

$$\frac{\nu}{\nu_0} = \frac{1}{1 - \dfrac{v}{c}\cos\theta} \qquad (1)$$

when the *source is in motion relative to the medium*.

In Fig. 2 the source is at rest, but the observer at P has a velocity v with respect to the medium. The velocity of the wave relative to the observer is equal to the vector sum of the velocity of the wave relative to the medium and the velocity of the medium relative to the observer. In Fig. 2, c is the velocity of the wave and v the velocity of the observer relative to the medium. Let λ_0 be the wavelength, ν_0 the frequency of the source, and ν the frequency received by the moving observer. The radial velocity of the wave relative to the observer is $c + v\cos\theta$ so that

$$\nu\lambda_0 = c + v\cos\theta$$

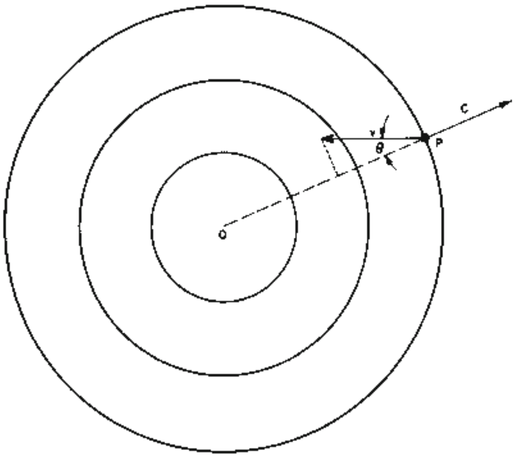

FIG. 2. The source is at rest at point O and the observer at point P is moving with velocity v relative to the medium. (Andrews, C. L., "Optics of the Electro-Magnetic Spectrum," Englewood Cliffs, N.J., Prentice-Hall, Inc., 1960).

For an observer at rest $\nu_0 = c/\lambda_0$. Substituting for λ_0, we obtain

$$\frac{\nu}{\nu_0} = 1 + \frac{v}{c}\cos\theta \qquad (2)$$

when the *observer is in motion relative to the medium*.

By a postulate of relativity, the velocity of light is the same relative to all observers. The theory of relativity yields the frequency

$$\frac{\nu}{\nu_0} = \frac{1 + \dfrac{v}{c}\cos\theta_0}{\sqrt{1 - \dfrac{v^2}{c^2}}} \qquad (3)$$

in which $v\cos\theta_0$ is the component of the velocity of the source toward the observer. The angle θ_0 is measured in the source system. If θ is the angle measured in the observer's system, then

$$\cos\theta_0 = \frac{\dfrac{v}{c} - \cos\theta}{\dfrac{v}{c}\cos\theta - 1} \qquad (4)$$

Figure 3 is a graphical plot of ν/ν_0 against v/c for the radial motion in the three cases we have treated. (1) The linear relation is that for the observer in motion relative to the medium that propagates sound or other mechanical waves.

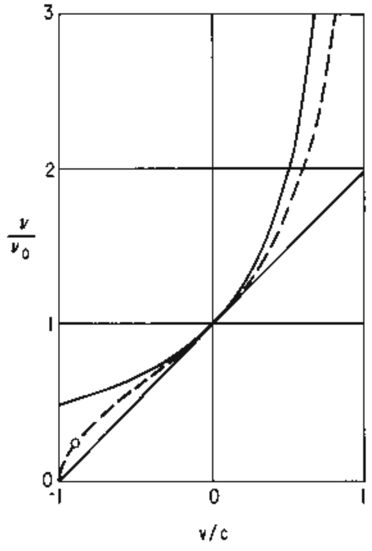

FIG. 3. Graphical plots of the ratio of the observed frequency to the frequency at the source against the ratio of radial velocity to the velocity of the wave for three cases: (1) sound waves from a moving source, (2) sound waves to a moving receiver, (3) electromagnetic waves. The circle represents the red shift of light received from the most distant galaxies observed.

(2) The other solid curve is for the source of sound in motion. (3) The broken curve represents the Doppler effect for electromagnetic waves such as x-rays, light, and radio waves.

By comparing several spectral lines of elements observed in a star with a laboratory spectrum of the same elements, astronomers use the Doppler effect to measure the radial components of velocity of astronomical bodies toward or away from the earth. Spectra of the edges of the sun's disk are measured to determine the velocities toward and away from the earth. The radial velocities of the principal stars of our galaxy have been recorded. The spectral lines of some of the stars are doublets which periodically come together and separate again indicating that the light comes from two stars revolving about a common center of gravity (see ASTROMETRY).

In the expanding universe, the radial velocities of other galaxies away from our galaxy are proportional to their distances from the observer. Thus, the Doppler red shift provides a means of determining the dimensions of the observed universe. In 1964, some of the most intense radio sources (see RADIO ASTRONOMY) were located with high precision by observing these sources when the moon passed in front of them. With this knowledge of position, the same sources were located with a light telescope.[4] The measured red shift was surprisingly high. The sources were not stars as previously thought but the most distant galaxies known. In a period of eighteen years the Doppler red shifts were measured for more than a thousand quasi-stellar objects. Quasar OQ172 in the Catalogue of Quasi-Stellar Objects[5] had the largest red shift. If this shift were due solely to the Doppler effect, the astronomers had to conclude that this quasar was moving away from us with 91% of the speed of light. The Doppler frequency and velocity of this source are indicated by a circle on the broken curve of Fig. 3.

If a microwave beam is reflected from a moving microwave mirror, such as a person, an automobile or a man-made satellite, the image of the primary source may be considered as another source moving with twice the velocity of the mirror. Since the speed is small compared with the speed of light, the squared terms of Eq. (3) may be neglected. Thus

$$\nu = \nu_0 \left(1 + \frac{2v}{c} \cos\theta\right)$$

Direct frequency measurements cannot be made to enough significant figures to distinguish ν from ν_0. However, if the two frequencies are combined they give beats or the difference frequency

$$\Delta\nu = \nu_0 \frac{2v}{c} \cos\theta$$

Since the beat frequency is porportional to the radial velocity, a frequency meter may be calibrated in miles per hour. The precision of such a speed detector depends upon the frequency of the source being so stable that it varies less than the Doppler frequency shift during the time that the wave travels from the source to the mirror and back. The same phenomena of beats between the direct wave from the source and the wave reflected from a moving mirror may be observed with light. If one of the mirrors of Michelson's interferometer is moved at constant speed, the frequency with which dark bands pass the cross hair is the difference in frequency of the two waves.

The numerator of Eq. (3) contains a term for the radial component of velocity. However, the second-order term in the denominator is independent of direction. Thus, as v/c approaches unity, one may expect to detect a *tangential Doppler effect.* Ives and Stilwell[6] have measured the predicted value of the Doppler shift in frequency due to a stream of radiating molecules for which v/c was 10^{-2}. This experiment was a direct proof of time dilatation (see RELATIVITY) for the transverse case. In order to separate the tangential from the radial effect, Ives and Stilwell produced a sharply collimated beam of molecules. In order that θ be precisely 90°, they set a mirror accurately normal to the line of observation and altered the line of observation until nearly the same wavelengths were given by direct and reflected light.

At relativistic speeds the transverse Doppler effect will be an important consideration in the final determination of the nature and positions of the quasars.[7]

DYNAMICS

Introduction *Dynamics*, a branch of mechanics, is often defined in two basic parts. First, *kinematics* is the study of the motion of bodies with no consideration of what has caused the motion, and second, *kinetics* is the study which relates the action of forces on the bodies to the resulting motion.

This order of presentation is often utilized in textbooks and other treatises on the subject. With various interpretations of the word *bodies*, the subject has also been divided into the areas of particle dynamics, rigid body dynamics, and fluid dynamics. As needs have developed, various specializations have been created and new theories have been formulated. These special areas include mechanical vibrations, flight dynamics, space dynamics, gas dynamics, magnetohydrodynamics, dynamic systems,[1] and relativistic dynamics, to mention a few.

The present state of knowledge recognizes all motion as relative, since no fixed reference is known for finding the absolute motion of any body. The earth, which is frequently used as a frame of reference is rotating about its own axis and is also revolving about the sun. The solar system, which consists of the sun and its planets, is a minute part of the Milky Way galaxy that is known to be revolving in space[2]. Beyond this, there is limited knowledge of the nature of motion that exists.

In the field of astronomy, measurements are evaluated in a coordinate system that is located relative to the *fixed* stars. These stars are located at such a vast distance from the earth that they appear as points of light that are almost motionless in space. In this frame of reference, the motions of celestial bodies are described with extremely great precision, and the motions of bodies within the solar system can be predicted accurately over periods of hundreds of years.

Some applied areas of dynamics, exemplified by the space exploration program, also require the degree of extreme accuracy that is possible with a celestial frame of reference. In many other areas, this extreme accuracy is not essential and measurements based upon this frame of reference would be tedious and impractical. In such cases, motion may often be adequately described in a coordinate system located relative to the earth.[3]

Kinematics A particle is a body having dimensions that are small, relative to other dimensions of the system, so that its motion may be considered equivalent to the motion of a point at its mass center with rotational effects neglected. Thus, particles may be either small or large. In the solar system, it would be possible to assume the earth to be a particle but, in a terrestrial system, this assumption could be totally unjustifiable.

A rigid body is a group of particles having unvarying external and internal configuration. The size of the rigid body would be appreciable in comparison to the other dimensions of the system, so that the rotational effect would have to be considered.

A fluid body is a group of particles with varying external and or internal configuration. The analysis of this type of system will not be considered in this article. (See FLUID DYNAMICS.)

The kinematic analysis of the motion of a particle may be approached through the establishment of a position VECTOR $\mathbf{r}$, directed from the origin of a specified fixed coordinate system to the point representing the position of the particle, to give

$$\mathbf{r} = x\,\mathbf{i} + y\,\mathbf{j} + z\,\mathbf{k} \tag{1}$$

where $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are unit vectors along the x, y, and z axes, respectively. Differentiating Eq. (1) with respect to time yields a velocity equation of the form

$$\mathbf{v} = \frac{d\mathbf{r}}{dt} = \frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} + \frac{dz}{dt}\mathbf{k} \tag{2}$$

where the instantaneous velocity, $\mathbf{v}$, of the particle at any position on its path is the instantaneous time rate of change of displacement. A second differentiation with respect to time yields the acceleration of the particle in the form

$$\mathbf{a} = \frac{d\mathbf{v}}{dt} = \frac{d^2\mathbf{r}}{dt^2} = \frac{d^2x}{dt^2}\mathbf{i} + \frac{d^2y}{dt^2}\mathbf{j} + \frac{d^2z}{dt^2}\mathbf{k} \tag{3}$$

where the instantaneous acceleration, $\mathbf{a}$, of the particle at any position on its path is the instantaneous time rate of change of velocity.

If x, y, and z are scalar functions of time, then Eqs. (1), (2), and (3) may be used to trace the path of the particle and determine the velocity and acceleration at any instant. These equations may be easily adapted to the cases of rectilinear translation and curvilinear translation of a particle in plane motion.

The kinematic analysis of a rigid body moving in a plane often involves the trace of two points, which may be called A and B, that are located on the body. These points move with the body and remain a fixed distance apart. Two coordinate systems may be used to define the position of the body in the plane. An X-Y coordinate system, with origin O, is a fixed reference, and an x-y coordinate system, with origin o located at A, is attached to the body so that it moves and rotates with the body. In the fixed reference system, a position vector $\mathbf{R}$ is directed from O to point A on the body and a second position vector $\boldsymbol{\rho}$ is directed from O to point B. In the moving coordinate system, a vector $\mathbf{r}$ is directed from A to B. An equation relating the position of the two points may be written as

$$\boldsymbol{\rho} = \mathbf{R} + \mathbf{r} \tag{4}$$

Using the $\mathbf{I}$, $\mathbf{J}$, $\mathbf{K}$ unit vectors for the X-Y-Z coordinate system and the $\mathbf{i}$, $\mathbf{j}$, $\mathbf{k}$ unit vectors for the x-y-z coordinate system, Eq. (4) may be rewritten as

$$\boldsymbol{\rho} = X\mathbf{I} + Y\mathbf{J} + x\mathbf{i} + y\mathbf{j} \tag{5}$$

Differentiating Eq. (5) with respect to time yields the velocity of B in the form

$$\mathbf{v}_B = \frac{d\rho}{dt} = \frac{dX}{dt}\mathbf{I} + \frac{dY}{dt}\mathbf{J} + \frac{dx}{dt}\mathbf{i} + x\frac{d\mathbf{i}}{dt} + \frac{dy}{dt}\mathbf{j} + y\frac{d\mathbf{j}}{dt} \quad (6)$$

Noting that $dx/dt = dy/dt = 0$, Eq. (6) simplifies to

$$\mathbf{v}_B = \mathbf{v}_A + \mathbf{v}_{B/A} \quad (7)$$

where $\mathbf{v}_B$ and $\mathbf{v}_A$ are the velocities of points B and A, respectively, and $\mathbf{v}_{B/A}$ is the velocity of point B relative to point A.

A second differentiation of Eq. (5) with respect to time yields the acceleration of B in the form

$$\mathbf{a}_B = \mathbf{a}_A + \mathbf{a}_{B/A} \quad (8)$$

where $\mathbf{a}_B$ and $\mathbf{a}_A$ are the accelerations of points B and A, respectively, and $\mathbf{a}_{B/A}$ is the acceleration of point B relative to point A.

A second important case of rigid body motion exists when point B is not attached to the same body as point A but is moving along a constrained path on this body. For the analysis of this motion, it is convenient to designate the fixed reference as body 1, the body to which point A is attached as body 2, and the body to which point B is attached as body 3. The same general arrangements of coordinate systems are used but in this case, the fixed X-Y coordinate system may be considered as attached to body 1 while the moving x-y coordinate system is attached to body 2. In the general case, vector $\mathbf{r}$ within the x-y coordinate system is varying in both magnitude and direction. Differentiating the position expression

$$\rho = \mathbf{R} + \mathbf{r} \quad (9)$$

once with respect to time and simplifying yields

$$\mathbf{v}_{B3} = \mathbf{v}_{A2} + \mathbf{v}_{B2/A2} + \mathbf{v}_{B3/2} \quad (10)$$

where $\mathbf{v}_{B3}$ is the velocity of point B on body 3, $\mathbf{v}_{A2}$ is the velocity of point A on body 2, $\mathbf{v}_{B2/A2}$ is the velocity of point B on body 2 relative to point A on body 2, and $\mathbf{v}_{B3/2}$ is the velocity of point B on body 3 relative to body 2.

A second differentiation with respect to time gives

$$\mathbf{a}_{B3} = \mathbf{a}_{A2} + \mathbf{a}_{B2/A2} + \mathbf{a}_{B3/2} + 2\omega_2 \times \mathbf{v}_{B3/2} \quad (11)$$

where $\mathbf{a}_{B3}$ is the acceleration of point B on body 3, $\mathbf{a}_{A2}$ is the acceleration of point A on body 2, $\mathbf{a}_{B2/A2}$ is the acceleration of point B on body 2 relative to point A on body 2, $\mathbf{a}_{B3/2}$ is the acceleration of point B on body 3 relative to body 2, ω_2 is the angular velocity of body 2, and $\mathbf{v}_{B3/2}$ is the velocity of point B on body 3 relative to body 2. The term $2\omega_2 \times \mathbf{v}_{B3/2}$ is often referred to as the CORIOLIS component of acceleration.

Equations 7 and 8 may be adapted to the case of rotation of a rigid body about a fixed axis at point A by considering point A to be fixed. Thus, $\mathbf{v}_A$ and $\mathbf{a}_A$ are both zero and

$$\mathbf{v}_B = \mathbf{v}_{B/A} \quad (12)$$

$$\mathbf{a}_B = \mathbf{a}_{B/A} \quad (13)$$

For a body rotating about a fixed axis, analysis of the rotational motion yields

$$\frac{d\theta}{dt} = \omega \quad (14)$$

$$\frac{d\omega}{dt} = \alpha \quad (15)$$

where θ is the angular displacement in radians, ω is the angular velocity in radians per second, and α is the angular acceleration in radians per second per second. It should be noted that time may be expressed in other units.

Kinetics *Newton's Laws of Motion* The laws of Newton are based upon the motion of a particle relative to a fixed frame of reference in which the particle can be made completely free of all outside influences. Under such a condition, the particle at rest will remain at rest and a particle in motion will continue to move at a constant velocity. This ideal frame of reference is often referred to as a Newtonian or as an inertial frame of reference.[4]

Since it is not possible to actually establish the Newtonian frame of reference, Newton's laws of motion are used in a celestial or a terrestrial frame of reference. The gyroscopic instruments and the stabilized platforms represent attempts to achieve a fixed or stabilized frame of reference for aircraft or space vehicles.

In modern terminology, Newton's laws of motion for a particle may be interpreted as

(1) A particle tends to remain at rest or continues to move at a constant velocity if there is no unbalanced force acting upon it.

(2) An unbalanced force acting on a particle will produce a time rate of change of momentum, $d(m\mathbf{v})/dt$, which, at any instant, will be proportional to the force and will be in the same direction as the force.

(3) The forces that exist between two contacting particles are equal in magnitude, are opposite in direction, and are collinear.[5]

The concept of the first law is the fundamental principle used for the analysis of forces acting on stationary particles and also for the analysis of forces acting on particles moving with a constant velocity. The concept has been expanded to include rigid bodies and fluid bodies.

The second law is the foundation of the analysis of forces acting on particles moving with accelerations and, again it has been extended to include rigid bodies which involve rotary motion and to include fluid bodies.

The third law is fundamental to the force analysis of interconnecting systems of particles under both static and dynamic conditions. It has also been extended to include simple contact between any pair of bodies and, with some modification, to include any type of interaction between bodies.

Force and Acceleration In general, Newton's second law is stated as

$$\sum \mathbf{F} = k \frac{d(m\mathbf{v})}{dt} \qquad (16)$$

where $\sum \mathbf{F}$ is the net unbalanced force on the particle; k is a constant of proportionality, consistent with the units used, that is determined experimentally; m is the mass of the particle; and $\mathbf{v}$ is the instantaneous velocity of the particle.

For a particle that is not shedding or accumulating mass, Newton's second law reduces to

$$\sum \mathbf{F} = km\mathbf{a} \qquad (17)$$

where $\sum \mathbf{F}$, k, and m are as previously defined and $\mathbf{a}$ is the instantaneous acceleration of the particle. By the proper choice of units in Eq. (16) and (17), the constants of proportionality can be made equal to unity.

For a rigid body in plane motion, both translational and rotational acceleration must be considered. By extending the concept of Newton's second law, it may be stated that

$$\sum \mathbf{F} = k_1 m\mathbf{a} \qquad (18)$$

$$\sum \mathbf{T} = k_2 \bar{I}\boldsymbol{\alpha} \qquad (19)$$

where $\sum \mathbf{F}$ and $\sum \mathbf{T}$ are the unbalanced force and unbalanced torque, respectively, acting on the body; k_1 and k_2 are constants of proportionally, consistent with the units used, that are determined experimentally; m is the mass of the body; $\bar{I}$ is the mass moment of inertia of the body about a centroidal axis that is perpendicular to the plane of the motion; $\mathbf{a}$ is the linear acceleration of the center of mass of the body; and $\boldsymbol{\alpha}$ is the angular acceleration of the body. Again, with proper choice of units, k_1 and k_2 can be made equal to unity.

The concepts and equations presented herein can be applied for the solution of a wide variety of problems which involve systems of particles, systems of bodies, or combinations thereof. The usefulness of this approach may be further broadened by the introduction of the closely related concepts of energy and impulse–momentum.

It should be noted that, in Newtonian mechanics, the fundamental property of the particle is an unvarying mass and time is absolute. It should also be noted that when the speed of the particle approaches the speed of light, this theory becomes inaccurate in compariosn to a theory based upon a more exact mathematical model attained through the application of the principles of RELATIVITY.[6]

E

ELASTICITY*

Elasticity is the part of mechanics dealing with deformations that vanish entirely once the forces that have caused them are removed. Most solid bodies behave elastically for sufficiently small deformations, and we will be concerned here with the infinitesimal theory of elasticity. Also we will consider only isotropic bodies, that is, bodies whose elastic properties are the same in all directions.

The fundamental quantities in elasticity are second-order tensors, or dyadics: the deformation is represented by the *strain dyadic*, and the internal forces are represented by the *stress dyadic*. The physical constitution of the deformable body determines the relation between the strain dyadic and the stress dyadic, which relation is, in the infinitesimal theory, assumed to be linear and homogeneous. While for anisotropic bodies this relation may involve as much as 21 independent constants, in the case of isotropic bodies, the number of elastic constants is reduced to two.

Let $\mathbf{s}(\mathbf{r})$ be the displacement vector, due to the deformation, of a particle that before the deformation was situated at point P having $\mathbf{r}$ as position vector with respect to some arbitrary origin. A neighboring point Q, whose position vector was $\mathbf{r} + d\mathbf{r}$ before the deformation, will suffer a displacement $\mathbf{s}(\mathbf{r} + d\mathbf{r})$ which will differ from $\mathbf{s}(\mathbf{r})$ by the quantity

$$d\mathbf{s} = d\mathbf{r} \cdot \nabla\mathbf{s}$$

The hypothesis of small deformations means that $d\mathbf{s}$, the change in the displacement vector when we go from P to the neighboring point Q, is very small compared to $d\mathbf{r}$, the position vector of Q relative to P. Consequently, the scalar components of the dyadic $\nabla\mathbf{s}$ are all very small compared to unity. The geometrical meaning of the dyadic $\nabla\mathbf{s}$ is obtained by separating it into its symmetric part $\mathbf{S} = \frac{1}{2}\ (\nabla\mathbf{s} + \mathbf{s}\nabla)$ and its antisymmetric part $\mathbf{R} = -\frac{1}{2}\ \mathbf{1} \times (\nabla \times \mathbf{s})$, where $\mathbf{1}$ is the unity dyadic. The antisymmetric part is interpreted as follows: if at some point M the symmetric part vanishes, then we have for the neighborhood of M the relation

$$d\mathbf{s} = d\mathbf{r} \cdot \mathbf{R}_\mathrm{M} = \boldsymbol{\omega}_\mathrm{M} \times d\mathbf{r}$$

where $\boldsymbol{\omega}_\mathrm{M} = \frac{1}{2}\ (\nabla \times \mathbf{s})_\mathrm{M}$ is an infinitesimal vector. This means that the neighborhood of point M undergoes an infinitesimal rigid rotation, without any change in shape or size. Consequently, the deformation is represented by the symmetric part $\mathbf{S}$, which is called the *strain dyadic*.

In a Cartesian orthonormal basis, in which we have $\mathbf{r} = \sum_{i=1}^{3} x_i\mathbf{a}_i$, we write $\mathbf{s} = \sum_{i=1}^{3} s_i\mathbf{a}_i$, and obtain

$$\mathbf{S} = \sum_{i,j=1} \mathbf{a}_i\mathbf{a}_j S_{ij}$$

where $S_{ij} = \dfrac{1}{2}\left[\dfrac{\partial}{\partial x_i}\ s_j + \dfrac{\partial}{\partial x_j}\ s_i\right]$. The diagonal components S_{11}, S_{22}, and S_{33} are the coefficients of linear extension in the directions $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$, respectively, while the non diagonal components $S_{12} = S_{21}$, $S_{13} = S_{31}$, and $S_{23} = S_{32}$ are called shear strains. For instance, $2S_{12}$ is the change in the angle of the dihedron formed by the planes that before the deformation were respectively normal to the directions $\mathbf{a}_1$ and $\mathbf{a}_2$. The shear strains are not essential for the complete representation of a deformation since they can be made to vanish by expressing $\mathbf{S}$ in the basis of its principal axes.

If an infinitesimal element of the body occupies the volume dV before the deformation and the volume dV' after, the relative increase of volume, or volumetric dilatation, is given by

$$\frac{dV' - dV}{dV} = S_{11} + S_{22} + S_{33} = |\mathbf{S}| = \nabla \cdot \mathbf{s}$$

The forces applied to a finite deformable body are either body forces acting on every volume element dV and represented by the notation $dV\mathbf{F} = dV\rho\mathbf{K}$, where $\mathbf{F}$ is the force per unit volume, $\mathbf{K}$ is the force per unit mass, and ρ is the density, or surface forces acting on every element dS of the bounding surface and represented by $dS\mathbf{T}$, where $\mathbf{T}$ is the surface stress, or surface force per unit area. The effect of these applied forces is transmitted throughout the body, so that through any surface element inside the body, there is a force exerted by the matter on one side of the element upon the matter on the other side. Such forces are called

*See MECHANICAL PROPERTIES OF SOLIDS for a less mathematical introduction to elasticity.

internal stresses and are defined as follows: let dS be a surface element completely inside the body, and let us choose arbitrarily the positive sense of the normal $\mathbf{n}$ to this surface element; this defines for dS a positive side, the one containing $\mathbf{n}$, and a negative side. Then $\mathbf{T_n}$, the stress vector on the positive side of dS is defined as a vector such that $dS\mathbf{T_n}$ is the surface force on the positive side of dS—i.e., the resultant of all the forces exerted through dS by the matter on the positive side of dS upon the matter on the negative side. In general there is a normal component $\mathbf{T_n} \cdot \mathbf{nn}$, which is a pressure or a traction depending upon whether the sign of $\mathbf{T_n} \cdot \mathbf{n}$ is negative or positive, and a tangent component $\mathbf{n} \times \mathbf{T_n} \times \mathbf{n}$ called the shear stress. The value of stress vector $\mathbf{T_n}$ depends upon the orientation of the normal $\mathbf{n}$, so that we can characterize the state of stress at a point by defining the *stress dyadic* $\mathbf{T}$ through the relation

$$\mathbf{T_n} = \mathbf{n} \cdot \mathbf{T}$$

The mechanical equilibrium conditions applied to an arbitrary volume V, bounded by the closed surface S, and completely inside the deformable body give

$$\int_V dV\mathbf{F} + \int_s dS\mathbf{n} \cdot \mathbf{T} = 0$$

and

$$\int_V dV\mathbf{r} \times \mathbf{F} + \int_s dS\mathbf{r} \times (\mathbf{n} \cdot \mathbf{T}) = 0$$

By the use of the divergence theorem, the first condition gives the equation

$$\nabla \cdot \mathbf{T} + \mathbf{F} = 0$$

at any point inside the body, and the second condition implies that $\mathbf{T}$ is a symmetric dyadic. On the external surface of the body, we have usually to fulfill the boundary condition

$$\mathbf{n} \cdot \mathbf{T} = \mathbf{T}$$

where $\mathbf{T}$ is the applied external force per unit area. Other boundary conditions can also be met, such that the value of the displacement be prescribed.

For infinitesimal deformations, we assume that the relation between strain and stress is expressed by Hooke's law: the deformation is proportional to the applied force. For isotropic bodies, this linear relation is

$$\mathbf{S} = \frac{1}{E}\left[(1 + \nu)\mathbf{T} - \nu\,|\mathbf{T}|\,\mathbf{1}\right]$$

where E is Young's modulus and ν is Poisson's ratio. These two elastic constants can be defined by considering the stretching of a cylindrical bar by normal traction forces uniformly distributed on the end sections; then we have

Young's modulus =

$$\frac{\text{Normal traction force/unit cross sectional area}}{\text{Relative longitudinal extension}}$$

and

$$\text{Poisson's ratio} = \frac{\text{Relative lateral contraction}}{\text{Relative longitudinal extension}}$$

We can also write

$$\mathbf{T} = 2\mu\mathbf{S} + \lambda\,|\mathbf{S}|\,\mathbf{1}$$

where $\mu = E/2(1 + \nu)$ and $\lambda = \nu E/(1 + \nu)(1 - 2\nu)$ are Lamé's constants. μ is the rigidity modulus, the only constant necessary when the volumetric dilatation vanishes everywhere.

Substituting the preceding relation into the equilibrium equations, we transform them into

$$2\mu\nabla \cdot \mathbf{S} + \lambda\nabla\,|\mathbf{S}| + \mathbf{F} = 0 \text{ inside the body}$$

and

$$2\mu\mathbf{n} \cdot \mathbf{S} + \lambda\mathbf{n}\,|\mathbf{S}| = \mathbf{T} \text{ on the bounding surface.}$$

These vector relations are not sufficient for the complete determination of the symmetric dyadic $\mathbf{S}$. To insure that a solution of the above equations corresponds to a possible displacement vector s, we must be able to integrate the relation

$$\mathbf{S} = \tfrac{1}{2}\,(\nabla\mathrm{s} + \mathrm{s}\nabla)$$

i.e., from a given expression for $\mathbf{S}$, obtain the value of s. From the vanishing of the curl of a gradient, it is easily seen that this integrability condition, also called the compatibility equation, is

$$\nabla \times \mathbf{S} \times \nabla = 0$$

By elimination of the vector products, we obtain the equivalent form

$$\nabla\nabla \cdot \mathbf{S} + \nabla \cdot \mathbf{S}\nabla - \nabla\nabla\,|\mathbf{S}| - \nabla \cdot \nabla\mathbf{S} = 0$$

Using the stress-strain relation and the equilibrium conditions, we obtain the Beltrami-Michell form of the compatibility equation:

$$\nabla \cdot \nabla\mathbf{T} + \frac{1}{1 + \nu}\nabla\nabla\,|\mathbf{T}| = -\frac{\nu}{1 - \nu}\nabla \cdot \mathbf{F1} - (\nabla\mathbf{F} + \mathbf{F}\nabla)$$

Finally, by expressing the strain dyadic in terms of the displacement vector, we obtain Navier's form of the equilibrium equations:

$$\mu\nabla \cdot \nabla\mathrm{s} + (\lambda + \mu)\nabla\nabla \cdot \mathrm{s} + \mathbf{F} = 0 \text{ inside the body}$$

and

$$\lambda n\nabla \cdot \mathrm{s} + 2\mu\mathrm{n} \cdot \nabla\mathrm{s} + \mu\mathrm{n} \times (\nabla \times \mathrm{s}) = \mathbf{T}$$

on the bounding surface.

Dealing here directly with the displacement vector, there is no need of considering the compatibility equation.

The propagation equation for elastic disturbances is obtained by adding the inertia force to the body force. We get then

$$\mu\nabla\cdot\nabla\mathbf{s}+(\lambda+\mu)\nabla\nabla\cdot\mathbf{s}+\rho\mathbf{K}=\rho\frac{\partial^2}{\partial t^2}\mathbf{s}$$

inside the body.

The stress-strain relation and the boundary conditions are not affected, but we generally have to take into account initial conditions.

The energy density u, or energy per unit volume, is given by

$$u=\frac{1}{2}\mathbf{S}:\mathbf{T}+\frac{1}{2}\rho\frac{\partial\mathbf{s}}{\partial t}\cdot\frac{\partial\mathbf{s}}{\partial t}$$

where the first term is potential, or strain energy, and the second term is kinetic energy. The energy flux density vector

$$\mathbf{S}=-\frac{\partial\mathbf{s}}{\partial t}\cdot\mathbf{T}$$

is a vector such that $dS\mathbf{n}\cdot\mathbf{S}$ gives the quantity of energy that flows per unit time through the surface element dS in the positive direction of $\mathbf{n}$, the normal to dS. At any point the energy continuity equation

$$\frac{\partial u}{\partial t}+\nabla\cdot\mathbf{S}-\rho\frac{\partial\mathbf{s}}{\partial t}\cdot\mathbf{K}=0$$

expresses the conservation of mechanical energy.

ELECTRICAL POWER GENERATION

About 98% of the electric power produced in this country is by three-phase generators. It is transmitted and distributed this way. Advantages of three-phase generators lie in economy of apparatus, lower transmission losses, inherent starting torque for polyphase motors, and constant running torque for balanced loading. A generator is built with axial slots for armature coils in a stationary hollow cylindrical iron core called the *stator*. The windings are placed in the slots so that when carrying current they produce a chosen even number of alternate magnetic poles. The coils over each magnetic pole are grouped in three equal bands to give a three-phase balanced system of terminal voltages.

An inner rotor has coils which carry direct current to give the same number of alternate magnetic poles as on the stator. Rotor current strength is controlled by a rheostat or voltage from a dc generator. Voltages are produced in the stator windings by flux cutting as the rotor magnetic flux sweeps by them, currents flow when the generator terminals are connected to a three-phase load impedance. The three-phase stator line voltages are equal in magnitude and 120 electrical degrees apart in time sequence. So also are the line currents for a balanced three-phase load. Generator voltages are of the order of 12,000 to 30,000 volts for large machines.

Generator frequency is the product of the pairs of magnetic poles and the speed in revolutions per second. At 60 Hz (cycles per sec), a two-pole generator runs at 3600 rpm and a six-pole generator at 1200 rpm. The maximum speed of 3600 rpm has been increasingly adopted even for very large machines because high speed means decreased size and weight for a given kilowatt rating and better steam-turbine performance. Waterwheels and water turbines show best characteristics at much lower speeds—roughly a range of 100 to 600 rpm. A frequency of 60 Hz prevails in this country for public utility power generation. Because of weight and space limitation, 400 Hz is found in the aircraft industry. Europe is basically on 50 Hz.

In the large central station steam power plants, single generators (*units*) reach, or go somewhat beyond, 1,250,000 kW in rating. Some units have ratings up to 1.5 million kilowatts.

Direct-current generators are built with their dc magnetic poles in the stator. Armature conductors in the rotor have ac voltages induced in them as they are rotated; the same principle of flux cutting holds as before. An automatic mechanical switching device, called a *commutator*, is placed on the shaft. It carries fixed brushes, and with its many insulated copper bars connected to the armature coils, it inverts every other alternation of the voltage at the two armature terminals. It is the commutator that requires the rotor to be the armature so that coils and their switching arrangement always move exactly together. Direct-current generators are generally limited to several thousand kilowatts and their application lies mainly in industrial plants.

The majority of central station generating plants in the USA are steam turbine generators. Coal, oil, or gas is used to heat water to around 1000°F at pressures of 2000–3500 psi. This superheated steam is successively expanded through high pressure, medium pressure, and low pressure turbines, all mounted on a common shaft with the generator. Steam is extracted at perhaps five to seven points through the turbines. This extracted steam is used to reheat the water from the condenser in the boiler feedwater heaters. The effect is to "square-off" the Rankine cycle and bring the system efficiency closer to Carnot efficiency. Actual generating plant efficiencies approach 40%.

Nuclear power plants utilize the same Rankine steam cycle as do fossil fuel plants, but, the heat is provided by nuclear fission. Temperatures and pressures are not as high as in fossil fuel plants, and therefore operating efficiencies are not quite as high. Nuclear power generation has suffered some growing pains that have served to increase the wariness of the populace. Such wariness has slowed the growth of nuclear power.

Other methods of generating electricity include gasoline- and diesel-driven generator sets, gas turbine-driven generator sets, fuel cells, solar cells, wind driven generators, magnetohydrodynamic (MHD), generators, and geothermal generators. The engine- and gas-driven generators are normally used as backup sytems or peaking systems for high demand periods. They are also used for prime power in remote, isolated installations. Fuel cells and solar cells are being used in very small power demand applications such as microwave relay sites and spacecraft. Both have yet to demonstrate the efficiencies necessary for economic feasibility. Wind driven generators up to a few hundred kw are being developed to relieve the burden on fossil fuels. Relability and economic feasibility have not yet been demonstrated. MHD generators received much attention during the 1970s, but many technological challenges have not yet been met. MHD units have had fair success in Britain when combined with conventional steam turbine-generator plants to raise the overall plant efficiency.

The limited efficiency of steam turbines imposed by the thermodynamic properties of steam has stimulated the development of methods to convert heat directly into electricity. The MHD generator is one in which a thermally ionized gas is forced at high temperature, pressure, and velocity through a duct situated in a transverse magnetic field. An induced voltage appears in the third mutually perpendicular direction (the Hall effect), and this voltage may be tapped by electrodes within the duct (see MAGNETOFLUID-MECHANICS).

When the exhaust gas from the MHD generator is used to heat steam for a conventional generator, a larger portion of the thermal spectrum is utilized and the system efficiency may be raised from the present 40% to possibly 50 or 55%. Heat for the system may come from the use of fossil fuel, nuclear reactors, or as expected in the future, fusion reactors.

Geothermal production of electric power uses natural steam obtained from the earth through steam wells and piped to turbines. Italy produces about one-third of a million kW in this manner and New Zealand has slightly less installed capacity of this kind. The only US installation is about 175,000 kW on the West Coast. Geothermal power is limited. Temperatures and pressures are low, but there is a lower capital investment and absence of fuel cost. A serious problem lies in elimination of contamination in the steam. These systems remain in prototype stages.

Probable Future Trends Considerable work is being done on boiler materials to increase the operating temperatures and pressures of steam plants. Ceramics look promising. Nuclear fusion research will provide the answers in clean nuclear power. Fluidized bed combustion techniques will reduce fossil fuel emissions.

ELECTRIC PROPULSION

Electric propulsion is a form of rocket propulsion in which electric power, generated on board the propelled vehicle, is used to eject propellant rearward at high velocity to produce thrust. Electric propulsion systems can be considered to be made up of two major components: (1) the *electric power generation system*, which converts power from a basic power source (such as a nuclear reactor or the sun) into electric power, and (2) *the thruster*, which uses this electric power to produce thrust by ejecting the propellant.

The primary potential advantage of electric rockets over chemical rockets (or hypothetical solid-core nuclear rockets) is that much higher propellant ejection velocities can be attained. Higher ejection velocities, in accordance with Newton's law, produce higher thrust per unit mass of propellant, so that the total mass of propellant needed for space missions can be greatly reduced. The mass of required electric power generation equipment is appreciable, however, so that some of the saving in propellant mass is offset by the mass of the power generation system. The net mass saving possible using electric propulsion therefore depends strongly on the performance parameters of the system.

One of the most important of these performance parameters is the propulsion-system specific mass α, which is defined as

$$\alpha = \frac{m_{\mathrm{ps}}}{P_{\mathrm{j}}} \quad \frac{\mathrm{kg}}{\mathrm{kW}} \tag{1}$$

where m_{ps} is the total propulsion system mass (in kilograms) and P_{j} is the jet power produced (in kilowatts). If this parameter is less than about 30 kg/kW, electric propulsion systems can be employed to advantage over nuclear or chemical rockets for many unmanned interplanetary exploration missions. For such missions, typical required power levels range from about 25 kilowatts to several hundred kilowatts, to propel vehicles having initial mass in earth orbit in the range of 1000 to 10 000 kg.

If α is less than about 5 kg/kW, mission studies indicate that electric propulsion is superior to nuclear rockets, with regard to required initial weight and trip time, for manned expeditions to the near planets.[1] For these missions, power levels of several megawatts would be needed for vehicle weights (in orbit) of the range of 100 000 to 1 000 000 kg.

In other possible applications, such as providing small amounts of thrust for attitude control or orbit control of satellites, the specific mass is less important, since the required electric power is small compared to that used by the other on-board equipment.

Most of the mass of an electric propulsion system resides in the electric power generation system; however, the performance of the other major component, the thruster, is of equal importance in determining the over-all specific mass. The most important parameter for the thruster is the efficiency η with which the electric power is converted into jet power. If this efficiency is low, the required electric power, and therefore the power-plant mass, is correspondingly high.

Another important parameter for the thruster (as for all rockets) is the specific impulse I. This parameter is defined as the thrust F produced per unit weight flow of propellant:

$$I = \frac{F}{\dot{m}_{\mathrm{p}} g_0} \quad \mathrm{sec} \tag{2}$$

where $\dot{m}_{\mathrm{p}}$ is the mass flow rate of propellant and g_0 is the acceleration of gravity at the earth's surface (9.8 m/sec^2) which relates mass to weight. The relation of thrust, specific impulse, and propellant ejection velocity is

$$F = \dot{m}_{\mathrm{p}} g_0 I = \dot{m}_{\mathrm{p}} v_{\mathrm{j}} \quad \text{newtons} \tag{3}$$

where v_{j} is the mean propellant ejection velocity (more commonly called *effective jet velocity*). The first and last terms in Eq. (3) express Newton's law that force is equal to the time rate of change of momentum. The last two terms show that specific impulse is directly proportional to effective jet velocity.

The *jet power* is the time rate of change of jet kinetic energy, or

$$P_{\mathrm{j}} = \tfrac{1}{2}\, \dot{m}_{\mathrm{p}} v_{\mathrm{j}}^2 = \tfrac{1}{2}\, F v_{\mathrm{j}} = \tfrac{1}{2}\, g_0 I F \quad \text{newton-m/sec}$$

or, in kilowatts,

$$P_j = \frac{g_0 I F}{2000} \quad \mathrm{kW} \tag{4}$$

For constant thrust and jet velocity, the total propellant mass m_{p} needed for a mission can be written [from Eq. (3)] as

$$m_{\mathrm{p}} = \frac{Ft}{g_0 I} \quad \mathrm{kg} \tag{5}$$

where t is the total propulsion time and Ft is the total impulse required for the mission. From Eq. (1) and (4), the propulsion system mass can be written:

$$m_{\mathrm{ps}} = \alpha P_{\mathrm{j}} = \frac{\alpha g_0 I F}{2000} \quad \mathrm{kg} \tag{6}$$

These equations show that, although propellant mass can be reduced indefinitely by increasing the specific impulse [Eq. (5)], the power required (and therefore the power-plant mass) is increased when this is done [Eq. (6)]. It is, therefore, desirable to use that value of specific impulse for which the *sum* of the masses of propellant and propulsion system is lowest. This optimum specific impulse will yield the least total mass for the mission, or the highest payload mass for a given total mass. For lunar and interplanetary missions and for specific mass likely to be obtained, calculations show that the optimum specific impulses range from about 1500 to 15 000 seconds (corresponding to jet velocities of about 15 to 150 km/sec). These specific impulses compare with values of about 450 seconds that are typical for high-energy chemical rockets and about 900 seconds that may be possible with solid-core nuclear rockets.

Another characteristic feature of electric propulsion systems is the very low thrust generated in comparison with chemical or nuclear rockets. This can be seen from Eq. (6) which can be written:

$$\frac{F}{m_{ps}g_0} = \frac{2000}{\alpha I g_0{}^2} \tag{7}$$

For a specific mass α of 10 kg/kW, and a specific impulse I of 5000 seconds, Eq. (7) yields a thrust-to-weight ratio of about 4×10^{-4}. This very low value results partly from the higher specific impulse typical of electric rockets, but mostly from the specific mass, which is of the order of 1000 or more times higher than that obtainable with solid-core nuclear rockets or chemical rockets. The low thrust-weight ratio means that electric propulsion systems cannot be used for launching from planetary surfaces. They are best suited for propelling vehicles between orbits about the planets or between orbits about the earth and the moon.

Because the thrust-weight ratio is so low, electric rockets must operate for much longer periods of time (of the order of 1000 times longer) than chemical or nuclear rockets to produce the same total impulse. Typically, for interplanetary missions to the near and far planets, these required operating times range from many months to several years. The removal of limitations on jet velocity, therefore, is obtained at the expense of greatly increased propulsion system mass and required operating lifetime.

Power Generation Systems The need for low specific mass dominates the selection of suitable methods for generating electric power for primary propulsion of space vehicles. The requirement that power be generated with very little consumption of mass dictates that either nuclear or solar energy must be used as the basic energy source.

Among the possible methods of converting this energy into electric power, the most direct are photovoltaic solar cells. Considerable progress has been made in reducing the thickness, and hence the weight of photovoltaic solar cells;[2] eventual achievement of a specific mass near 5 kg/kW appears possible. A lightweight radioisotope cell, in the range of 1 kg/kW, has been proposed and analyzed[3] but not yet demonstrated. This cell is basically a very high-voltage, low-current device, which converts a fraction of the kinetic energy of the isotope decay particles directly into electric power.

Somewhat less direct in energy conversion are systems that use thermionic cells

$$\left(\begin{matrix}\text{nuclear} \rightarrow \\ \text{solar} \quad \rightarrow\end{matrix}\ \text{heat} \rightarrow \text{electricity}\right)$$

A nuclear reactor or solar concentrator is used to heat a suitable material (such as tungsten) to temperatures high enough to produce thermal emission of electrons. These electrons traverse a gap to a cooled collector electrode, thereby producing electric power at a potential of the order of 1 volt. Many thousands of these thermionic cells must be connected in series-parallel combinations to achieve the required power levels and voltages. Also, to produce useful power densities, emitter temperatures must be in the range 1500 to 2000 K. Conversion efficiencies (heat into electric power) of 15 to 30 per cent are possible. The remaining 70 to 85 per cent of the thermal power must be radiated into space. The collector electrodes, where this waste heat appears, must be adequately cooled by a heat-transfer fluid that is pumped past the collector to pick up the waste heat and carry it to a radiator. In order that the radiator be of adequately low size and weight, it must operate at temperatures of about 900 K or higher. Analyses for a complete nuclear thermionic system yield specific masses of the order of 4 to 10 kg/kW, but numerous severe performance, design, and engineering problems remain to be solved before such systems can be developed to mission status [4]

Still more indirect, in the conversion of energy, are the turboelectric systems

$$\left(\begin{matrix}\text{solar} \quad \rightarrow \\ \text{nuclear} \rightarrow\end{matrix}\ \text{heat} \rightarrow \text{mechanical} \rightarrow \text{electric}\right)$$

For these, as well as the thermionic systems, the nuclear reactor appears to be a better basic energy source than the sun, because it provides a more compact and versatile system, suitable for operation in shaded regions and at any distance from the sun.

A nuclear turboelectric system for electric propulsion (as illustrated in Fig. 1) is basically a lightweight adaptation to space conditions of small ground-based nuclear power stations.[5] The chief differences result (as for the thermionic systems) from the lack of means other than radiation to eliminate the waste heat resulting from inescapable conversion inefficiencies. To produce specific mass below 10 kg/kW, the waste-heat radiator must operate at temperatures above 900 K, which in turn requires that the nuclear reactor operate at temperatures in excess of 1200 K.

The most suitable working fluid, at these temperatures, is potassium, if a liquid-vapor thermodynamic cycle (Rankine cycle) is used. In a single-loop version of this cycle, the liquid metal is vaporized in the nuclear reactor; the resulting vapor drives the turbine, which in turn drives the generator to produce electric power. The vapor passes from the turbine through the radiator, where it is recondensed, and the liquid is then recirculated through the reactor. A major problem is to develop materials with adequate corrosion resistance during long periods of high-temperature operation with alkali liquid metals. As illustrated in Fig. 1, the radiator is the largest and heaviest part of the system.

A possible alternative to the turboelectric system is an MHD (magnetohydrodynamic) generator, which replaces the turbogenerator with a duct through which a hot, electrically conducting fluid is passed. The duct is embedded in a

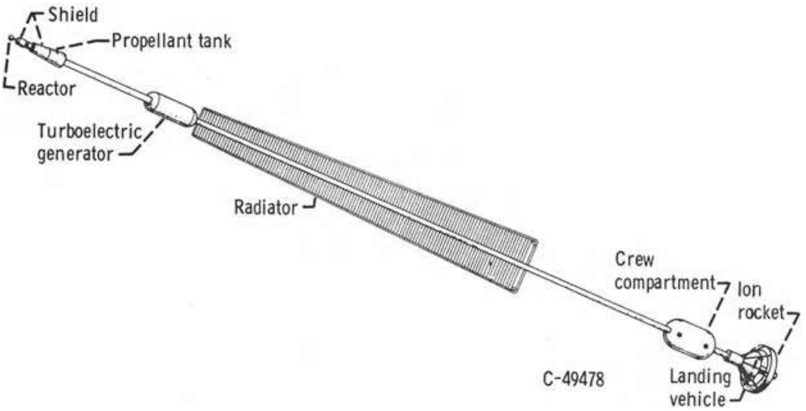

FIG. 1. Conceptual design of space vehicle for manned Mars mission. Nuclear turboelectric propulsion system.

strong magnetic field which must be produced by superconducting coils to minimize the power consumption. The most suitable fluid seems to be a noble gas seeded with cesium to make it electrically conducting.[6] When this fluid, heated by the nuclear reactor, is forced through the magnetic field, electric currents are induced, and power can be extracted by electrodes embedded in the duct. Such a system can tolerate higher temperatures than turbines, and should be particularly attractive for required power levels in the multi-megawatt range.

Thrusters A large number of methods are possible to eject propellant by use of electric power. These are generally divided into three categories: (1) *electrostatic thrusters*, in which atoms (or heavier particles) are electrically charged and then accelerated rearward by means of an electrostatic field; (2) plasma thrusters, in which the propellant is made into an electrically conducting gas and accelerated rearward by application of electromagnetic forces; (3) electrothermal thrusters, which use the electric power to heat the propellant, and then accelerate it rearward by thermal expansion through a nozzle.

Electrostatic thrusters that accelerate atomic ions (ion rockets) have received the most research and development attention, as a result of early demonstrations of good efficiencies in the range of specific impulses needed for major space missions. Typical of these ion rockets is an electron-bombardment thruster (such as that shown in Fig. 2) which uses mercury vapor as propellant.[7] The propellant atoms are ionized by collision with electrons emitted by the cathode and attracted toward the anode. A weak axial magnetic field is maintained in the ionization chamber to make the electrons spiral around on their way to the anode, thereby increasing their path length and their probability of colliding with propellant atoms. The resulting positive ions are extracted through a screen grid by means of an accelerating grid that is maintained at the proper voltage difference (usually several thousand volts) to produce the desired ejection velocity (specific impulse). A second electron emitter (not shown) is placed adjacent to the ion beam, downstream of the accelerator, to neutralize both the ion space charge and the net current leaving the thruster. Experimental efficiencies in converting electric power into jet power range from 60 to 80 per cent at specific impulses in the range 2500 to 9000 seconds. Thrusters in sizes up to 150 cm in diameter, with jet powers near 180 kW have been successfully operated.[7]

Other ion thrusters, using contact ionization of cesium atoms on hot tungsten to produce the ions (rather than electron bombardment), have achieved somewhat lower performance. In these thrusters, cesium vapor is passed through porous tungsten, which must be heated to about 1500 K to evaporate enough cesium ions from the ionizer surface. The high work function of tungsten and the low ionization potential of cesium make these two substances the most promising for contact ionization thrusters.

Atomic-ion thrusters tend to become less efficient at low ejection velocities (low specific impulse), because a certain fixed amount of energy is needed to ionize the propellant atoms. As the ejection velocity decreases, the jet power approaches the power required for ionization, and the efficiency decreases. A possible way to increase the efficiency is to increase the mass of each charged particle so that its kinetic energy, at a given jet velocity, is higher. This approach leads to use of colloidal particles in place of atomic ions. Because of the much higher mass per unit charge, voltages in the hundreds of kilovolts are needed to produce the desired jet velocities.

Although the efficiencies attainable with electrostatic thrusters are high, there remains a limitation which, although not crucial, is undesirable, namely, a low thrust (or power) per unit beam area, due to limitations on ion beam cur-

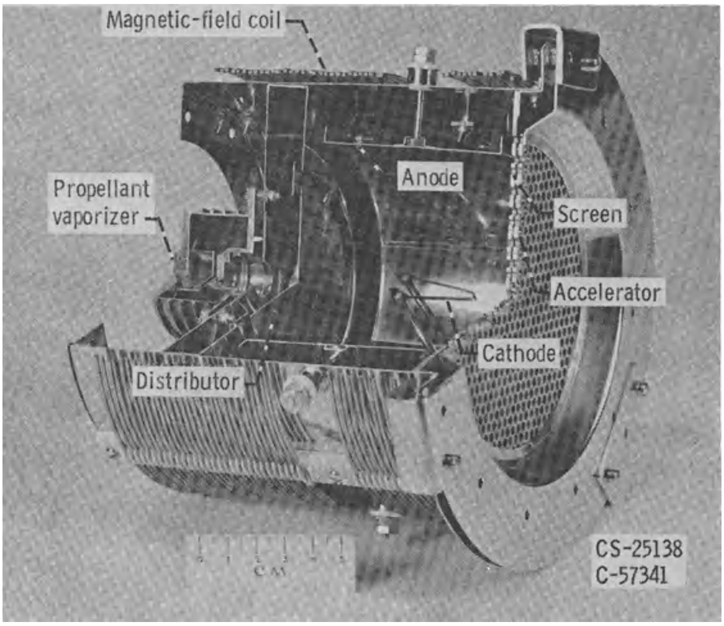

FIG. 2. Cutaway photograph of electron-bombardment ion thruster. With about 1 kW of power, this unit produces a thrust of 0.025 Newtons grams at a specific impulse of 5000 sec.

rent density. These limitations result from two sources: (1) space charge and (2) accelerator electrode erosion. The space-charge limited current is determined by the accelerating voltage and the distance between accelerator electrode and ion source. The voltage, in turn, is approximately fixed by the desired specific impulse, and the accelerator spacing is limited by electrical breakdown and thermal warping. The erosion limitation appears to be even more restrictive on thrust per unit area than space charge. As the current density is increased, there is greater impingement of ions on the accelerator electrode. For an accelerator lifetime of the order of 1 year, estimates indicate a limit for thrust per unit beam area of about 2 newtons (0.2 kg) per square meter (about 50 kW/m^2) at a specific impulse of 5000 seconds. Higher values are allowable as specific impulse increases.

Plasma thrusters, which operate on the principle of accelerating an electrically conducting gas (plasma) are not subject to the space charge limitation, and require no accelerator grid. Consequently, a higher thrust per unit area with adequate lifetime may be achievable. A variety of plasma thruster types have been investigated during the past decade,[8] but so far the efficiencies have been much lower than those of ion thrusters. Sizable effort has been devoted to the magnetoplasmadynamic (MPD) arc jet, which consists of a coaxial discharge between a central cathode and a surrounding anode in the presence of a magnetic field.[9]

Electrothermal thrusters are primarily of two types—the electric-arc jet and the electrically powered hydrogen heater (also called resistojet). The hydrogen heater is limited to specific impulses less than about 1000 seconds, because of the limitation on the wall temperature of the heater. High efficiencies, however, have been achieved.[10] The arc jet, which heats the propellant by means of continuous electric discharge as the propellant flows by, can achieve somewhat higher specific impulses (up to about 2000 seconds), but the efficiency is generally less than 50 per cent, due to losses involved in dissociation and ionization of the propellant atoms, and losses to the walls of the arc chamber and nozzle. Because of the lower specific impulse range, electrothermal thrusters are not useful for interplanetary missions, but may be used for more limited applications such as satellite orientation control and orbit correction.

History and Status The possibility of reducing propellant consumption by ejecting the propellant electrically at high velocities was recognized by early space flight and rocket pioneers, such as Goddard[11] and Oberth,[12] but the practical feasibility of such propulsion systems was not demonstrated. With the advent of nuclear-electric power and large rockets during and after World War II, more interest in electric propulsion was aroused, and between 1946 and 1956, a number of preliminary analyses of nuclear and solar electric systems were published.[13,14]

Comparative studies of the applicability of electric, nuclear, and chemical propulsion to future space missions, together with an engineering study of large electric power systems for space use were completed in 1957.[15] These and similar studies led to the initiation of major research programs in electric propulsion and power generation at U.S. government and industrial laboratories. Low-thrust trajectory studies and mission analyses[1,16,17] have further clarified the role of electric propulsion in future space missions.

The use of cesium-tungsten contact ionization for electrostatic thrusters was proposed by Stuhlinger,[14] and early experimental work in the United States, beginning in 1957, was concentrated on this approach.[18-20] However, the invention and development of the electron bombardment ion thruster[21] showed that it could achieve higher efficiencies with less sensitivity to fabrication techniques and materials. In 1964, the first successful space flight test of ion thrusters was accomplished with the launching of SERT-I (Space Electric Rocket Test I).[22] One cesium-tungsten and one electron bombardment thruster were launched into a 20-minute ballistic space trajectory. The cesium-tungsten thruster developed a high-voltage breakdown, but the electron bombardment thruster operated successfully. The test demonstrated that ion beam neutralization in space was no problem, and that the thrust level was the same as in ground test vacuum facilities. After further research and development of the electron bombardment thruster, a long-duration satellite orbital test (SERT II) was launched in February 1970 (Fig. 3).[23] A one-year operating period was planned. One of the thrusters operated continuously for five months and the other for three months before high-voltage short circuits occurred. Data analysis indicated that ion-beam erosion of the accelerator grid probably produced metal chips which shorted across to the screen grid. A long period of partial shading of the spacecraft occurred from 1972 through 1978, so that further testing was not possible. Almost continuous sun exposure again occurred for several periods from 1979 to May 1981. Early in 1979, the short circuit of one of the thrusters was cleared by maneuvering the spacecraft with the attitude control rockets. Thereafter, this thruster was operated normally during sun exposure periods until the mercury propellant was exhausted. Many startup and component performance tests were accomplished during these periods.[24] These remarkably successful tests of the long-time survivability of a solar-electric spacecraft and its thruster system provided evidence that solar electric propulsion was feasible for use in planetary missions.

Following the initial tests of SERT II (1971), further development of thrusters and solar-cell arrays was carried out by NASA. A Solar Electric Propulsion System (SEPS) program was initiated to produce a complete, reliable mission-ready system. Initial application was to be a Halley's Comet rendezvous mission in 1985, but budgetary restraints eliminated this program and other missions for SEPS.[25]

The performance parameters achieved for a

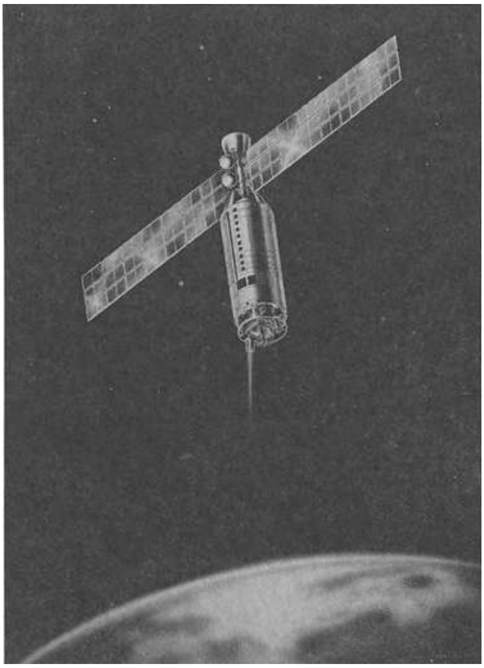

FIG. 3. Artist's drawing of SERT-II Spacecraft.

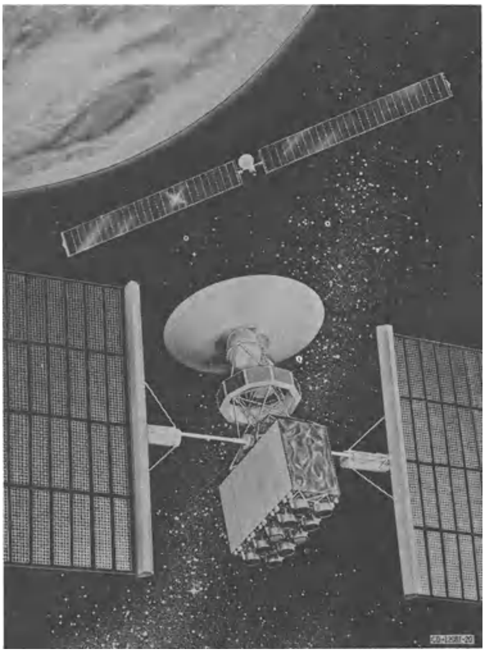

FIG. 4. Artist's representation of SEP (Solar Electric Propulsion System) Spacecraft. 25 KW power level.

25 killowatt version of SEPS are as follows (Fig. 4):

Solar Array Mass: 375 kg
Power Processing Subsystem Mass: 375 kg
Thruster system mass: 312 kg
Thruster system efficiency: 60%

Thus the overall specific mass was about 40 kg/kW. Operating the thrusters directly from the solar array (to eliminate power processing mass) is considered feasible in future systems so that specific mass below 30 kg/kW should be readily achievable.

Other research and development programs with more modest intended applications (attitude control, station-keeping and orbit control of satellites) have been carried out for many years in Europe[26] and Japan,[27] as well as the United States.[28,29] These programs have studied a variety of electric thruster types from pulsed plasma ejectors to smaller ion thrusters. In addition, research is underway to improve the performance of magneto-plasmadynamic (MPD) thrusters to make them more competitive with ion propulsion. Some research is also continuing on nuclear-thermionic power generation for electric propulsion.[29]

ELECTRICAL DISCHARGES IN GASES

Motion of Slow Electrons in Gases Suppose that a swarm of electrons traverses a gas in which a uniform electric field X exists. In general the distribution of energy among the electrons will depend on the distance x which they have traveled in the field. However, provided x is sufficiently large, the energy distribution attains a steady value independent of x. In this steady state, the average rate of supply of energy to an electron from the field is equal to the average rate of loss of energy in collisions with gas molecules.

Many important quantities in this subject are related to $eX\lambda$, the energy gained by an electron of charge e in traveling the mean distance λ between two successive collisions with gas molecules. Since λ is inversely proportional to the gas density, the above quantity can be expressed in the form X/P_0 where P_0 is the gas pressure reduced to some standard temperature.

The mean energy of an electron in the swarm, $\bar{\epsilon}$, is a function only of X/P_0 for a particular gas. Figure 1 shows the form of this variation for a monatomic gas (He) and a diatomic gas (N_2). Here $k = \bar{\epsilon}/\bar{\epsilon}_g$, where $\bar{\epsilon}_g$ is the mean kinetic energy of a gas molecule at 15°C (0.037 eV). It is seen that the mean electron energy greatly exceeds the mean energy of a gas molecule even when X/P_0 is small. This is due to the inefficient energy exchange in collisions between electrons and gas molecules. If the collisions are elastic, it is readily shown that f, the mean fractional energy lost by an electron in a collision, is $\sim 2m/M$ where m is electron mass and M is molecular mass. Clearly $f_{el} \ll 1$. At a given X/P_0, $\bar{\epsilon}$ is generally lower in polyatomic than in monatomic gases. Owing to the possibility of inelastic collisions involving vibrational or rotational excitation of the molecule, $f \gg 2m/M$ in the former case. In the latter case, only electronic excitation of the atom can occur and this requires much higher energies in general.

In addition to their random motion, the electrons must obviously possess a superimposed drift motion in the direction of the applied field. Figure 2 shows the variation of the drift velocity W_e with X/P_0; normally W_e is small compared to the mean random speed of the electrons.

Ionization by Electron Collision When the energy of an electron exceeds a certain critical value ϵ_i, ionization can occur at a collision with a gas molecule. As X/P_0, and hence $\bar{\epsilon}$, is increased, an increasing fraction of electrons in the swarm will have energies exceeding ϵ_i. The size of the electron swarm will then increase with the distance x traveled in the field direction.

This growth is most conveniently studied under conditions where $\bar{\epsilon}$ is kept constant. This can be done by releasing electrons from the cathode of a plane-parallel system and varying the electrode gap d and potential difference V in such a way that the electric field $X(=V/d)$ is fixed. It is then found that the electron current at the anode, i, increases exponentially with d or V. That is

$$i = i_0 \exp(\eta V) \qquad (1)$$

where i_0 is the electron current released from the cathode and η is the electron ionization coefficient: this is defined as the average number of ionizing collisions made by an electron in moving through a 1-volt potential difference.

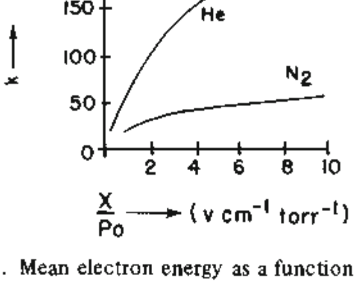

FIG. 1. Mean electron energy as a function of X/P_0 for He and N_2.

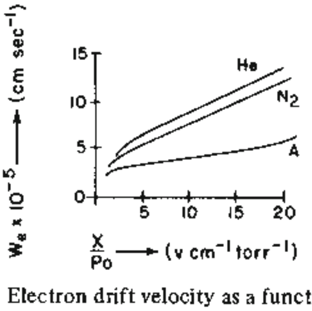

FIG. 2. Electron drift velocity as a function of X/P_0 for He, A and N_2.

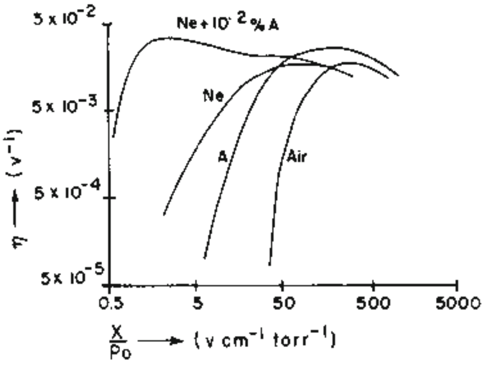

FIG. 3. Electron ionization coefficient as a function of X/P_0 for air, Ne, A, and Ne + 10^{-2} per cent A.

η is also a function only of X/P_0 for a given gas (Fig. 3).

It is important to note that the curve of η against X/P_0 passes through a maximum. The decrease in η at low X/P_0 is due to the increasing importance of excitation compared with ionization as X/P_0 decreases; since the excitation energy losses are larger in polyatomic than in monatomic gases, as remarked earlier, the decrease in η occurs more rapidly in air than in neon. The decrease in η at high X/P_0 (300 volts cm^{-1} torr^{-1}), where excitation losses are comparatively unimportant, is due to the fact that an increasingly large fraction of the energy supplied from the field is used in maintaining the kinetic energy of the swarm.

The curve for the gas mixture Ne + 10^{-2} per cent A is of great interest. Since the excitation potential of the most important metastable state of Ne (16.5 volts) exceeds the ionization potential of A (15.8 volts), the process $\text{Ne}^* + \text{A} \rightarrow \text{Ne} + \text{A}^+ + e$ can occur. This reaction has a very high probability, of the order unity per collision, and causes a great increase in η at low X/P_0 above the value for pure neon, since the effective excitation energy losses are now considerably reduced. The double maximum in the curve of η vs X/P_0 arises from the fact that the direct and indirect ionization processes have their maximum efficiencies at different X/P_0 values (~70 and 2 volts cm^{-1} torr^{-1}, respectively).

Secondary Ionization Processes It is found that Eq. (1) no longer holds at larger values of V; i now increases more rapidly leading ultimately to spark breakdown. This is due to the occurrence of secondary ionization processes, in addition to ionization by collision between electrons and gas molecules. In general, the most important secondary process is the release of electrons from the cathode surface. If various simplifying assumptions are made, it can be shown that the ionization current is now given by:

$$i = \frac{i_0 \exp(\eta V)}{1 - \gamma[\exp(\eta V) - 1]} \tag{2}$$

where γ is a generalized secondary ionization coefficient. This is defined as the probability of a secondary electron being released from the cathode per positive ion arriving at the cathode. Included in γ are contributions to the secondary emission arising from radiation quanta and metastable molecules.

Since γ depends largely on the mean energies of the electrons and ions, it is, like η, a function only of X/P_0 though the function now depends on the nature of the cathode as well as on the gas.

Spark Breakdown It is clear from the above equation that the ionization current tends to become very large as the potential difference across the gap approaches the value V_s given by:

$$\eta V_s = \log\left(1 + \frac{1}{\gamma}\right) \tag{3}$$

This is the condition for spark breakdown and can be best explained in the following manner.

Suppose that a primary electron current i_0 is released from the cathode when $V = V_s$. The electron current reaching the anode is then $i_0 \exp(\eta V_s)$. Hence, the positive ion current reaching the cathode due to the current i_0 is $i_0 [\exp(\eta V_s) - 1]$. This will give rise to a secondary electron current of value $\gamma i_0 [\exp(\eta V_s) - 1]$. If V_s is given by Eq. (3), then $\gamma [\exp(\eta V_s) - 1] = 1$ and the secondary current is equal to the original primary current i_0. Hence it is clear that the process can continue even if the initiating current ceases. When V is less than V_s, however, the discharge current i is proportional to i_0 [Eq. (2)]. Thus $i = 0$ when $i_0 = 0$. It follows that $V = V_s$ marks the transition from a non-self-maintained to a self-maintained discharge. V_s is best defined as the potential difference required to maintain a small discharge current i when the primary current $i_0 = 0$. V_s is independent of i provided this is sufficiently small to avoid space charge distortion of the field.

Since η and γ are both functions only of X/P_0 and $X = V_s/d_s$ at breakdown, it follows from Eq. (3) that

$$V_s = F(P_0 d_s) \tag{4}$$

Thus, for a given gas and cathode material, the breakdown potential between large plane-parallel electrodes depends only on the product of the reduced gas pressure and electrode separation. This result, which is known as Paschen's law, has been confirmed experimentally over a wide range of P_0 and d_s.

The variation of V_s with $P_0 d_s$ for a number of gases and cathode materials is shown in Fig. 4. It should be noted that the curves all exhibit a minimum; this corresponds to the maximum in the curve of η vs X/P_0. It will be seen that the rise of V_s at high values of $P_0 d_s$ is most marked in air, less in pure Ne, and less still in the Ne + A mixture. This is readily understood by reference

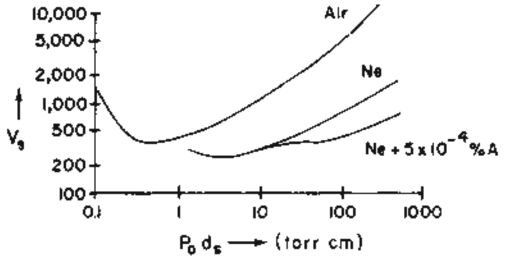

FIG. 4. Breakdown potential as a function of the product of the reduced gas pressure and electrode separation, P_0d_s for air, Ne, and Ne + 0.0005 per cent A with an iron cathode.

to the decrease in η at low X/P_0 ($=V_S/P_0d_S$) in these gases (Fig. 3).

Time Lag of Spark Breakdown If a potential difference $\geqslant V_S$ is suddenly applied to a discharge gap, a finite time elapses before the initial current i_0 has increased to a self-maintained discharge current ~10^{-7} ampere/cm^2. This time lag consists of two parts. First of all, there is a statistical lag which arises from the fact that the primary and secondary ionization processes are both subject to statistical fluctuations. Thus, although $V > V_S$ where γ [exp $(\eta V_S) - 1] = 1$ implies that on the average one electron leaving the cathode will give rise to one secondary electron, this may not happen in any particular case. Clearly the mean statistical lag t_S will decrease as the initial current is increased and it may be shown that

$$t_S = \frac{1}{PN_0} \tag{5}$$

where N_0 is the number of primary electrons leaving the cathode per second and P is the probability that any particular electron leads to breakdown. The latter quantity is zero at the sparking threshold V_s but increases rapidly for $V > V_S$. $P \simeq 1$ provided $V > 1.25\ V_S$.

The second component of the total time lag is the formative lag t_F. This can be regarded as the time that must elapse after the appearance of a suitable initiatory electron before the various ionization processes generate a self-maintained current of any given magnitude. This current can be chosen arbitrarily to specify breakdown of the gap and is generally taken to be ~10^{-7} ampere/cm^2. Clearly t_F will depend on the relative importance of the various secondary mechanisms mentioned earlier; positive ion transit times are typically ~10^{-6} second, while the time lags involved in the contribution of radiation quanta and metastable molecules to γ are ~10^{-8} and 10^{-3} second, respectively. The observed variation of t_F with overvoltage ΔV ($=V - V_s$) for various fixed values of X/P_0 in H_2 is shown in Fig. 5. Comparison with theory enables an estimate to be made of k, the relative contribution of photons at the cathode to the total γ. This ranges from 0.75 at $X/P_0 = 50$ to 0.50 at $X/P_0 = 300$ volts cm^{-1} torr^{-1}.

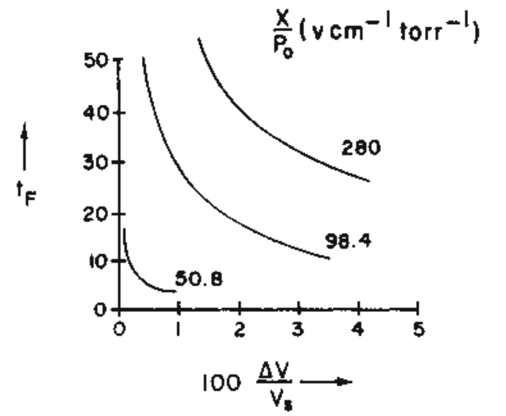

FIG. 5. Variation of formative time lag with overvoltage for various fixed values of X/P_0 in H_2 with copper electrodes.

Glow Discharge We have seen that any small current i can be maintained even in the absence of initiatory electrons when the potential difference between the electrodes reaches a value V_S given by Eq. (3). V is only independent of i when the latter is less than ~1 μA. At higher currents the space charge concentration becomes sufficient to cause X and hence η to vary across the gap, and ηV_S in Eq. (3) must be replaced by $\int \eta\, dV$. The static V-i characteristic is normally negative since the field redistribution produced by the space charge effects increases the over-all ionization efficiency. Once breakdown has taken place, the current increases to a value determined by the impedance of the voltage supply.

If the current density is sufficiently small (< 0.1 ampere/cm^2), the cathode is not heated to a high enough temperature for thermionic emission to be a significant factor in the maintenance of the discharge. This regime is termed a glow discharge and the field variation across the gap in a long cylindrical tube is indicated in Fig. 6. We can distinguish five main regions here:

(1) The cathode fall, in which the field decreases from a high value at the cathode to approximately zero.

(2) The negative glow, in which ionization and excitation are due largely to fast electrons arriving from the cathode fall. The length of this region is normally controlled by the distance traveled by the electrons before their energy is reduced below the minimum required for excitation.

(3) Faraday dark space. In many cases the ionization in the negative glow is so intense that the electron current here exceeds the total discharge current. A region is therefore required where electrons are lost by diffusion and not replenished by ionization; usually $X \leqslant 0$ here.

(4) The positive column, where X has a small constant value such that the corresponding elec-

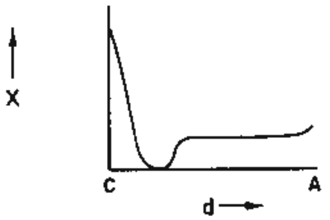

FIG. 6. Variation of axial field with distance from the cathode for a glow discharge in a long cylindrical tube.

tron energy distribution gives an ionization rate which just balances the loss of electrons and ions by radial diffusion to the walls.

(5) The anode fall, where X again increases.

Regions (1) and (2) are the most important regions of the discharge; the primary and secondary ionization by which the discharge is maintained take place here. The fall of potential across region (1), usually termed the cathode fall (V_c) is clearly an important parameter of the discharge.

It should be noted that the section extending from the negative glow to the anode has only a small field strength and small resultant space charge with $|n_i - n_e| \ll n_e$, where n_i and n_e are the ion and electron concentrations. This region is generally called a plasma. In many cases, the electrons here have a random motion which is large compared to their drift motion in the field direction. Our earlier discussion on electron swarms is valid here. On the other hand, the regions which occur near the cathode and the walls have a high field strength and resultant space charge with $n_i \gg n_e$. The electrons and ions behave here as a beam rather than as a swarm.

Ambipolar Diffusion The radial diffusion of ions and electrons to the wall in the plasma region (4), above, does not occur at the same rate as when only one type of carrier is present. Clearly, the electrons will tend to diffuse to the walls much more rapidly than the ions leaving an excess of positive charge. A space charge field is set up which retards electrons and accelerates positive ions so that their effective diffusion rates are equalized. This process can be described in terms of the ambipolar diffusion coefficient D_a which is given approximately by:

$$D_a \doteqdot D_i \left[1 + \frac{T_e}{T_i}\right] \qquad (6)$$

where D_i is the normal ion diffusion coefficient and T_e and T_i are the effective electron and ion temperatures, respectively.

Cathode Fall When the current is sufficiently small ($<$ 10 mA for a cathode of area ~ 1 cm^2), the discharge does not occupy the entire cathode area. The current density in the covered portion j_n is approximately constant, and the cathode fall of potential V_c is nearly independent of current and pressure. This is termed the normal cathode fall. The abnormal cathode fall occurs when $i > j_n S$, where S is the total cathode area. V_c now increases with current.

Arc and High Current Discharges If i is increased sufficiently, a stage will eventually be reached where the cathode temperature is high enough for thermionic emission to be important. V_c now decreases with further increase in i (Fig. 7), and we are in the region of the arc discharge. The transition current clearly depends on the rate of loss of heat from the cathode and only has a definite value when the surface is uniform. In some arc discharges (e.g., Hg), the emission mechanism is probably not thermionic; these are not fully understood however.

The current density is much higher in the arc than in the glow discharge. The charged particle density is typically in the range 10^{14} to 10^{18} electrons cm^{-3} in the core of the arc when the pressure is approximately atmospheric. Because of the very high frequency of collisions between the electrons, positive ions, and neutral molecules, thermal equilibrium is often established for all the groups of particles present in the arc positive column. The temperature at the axis of the arc is typically in the range 4 000 to 10 000 K. At high pressures the temperature diminishes laterally very quickly whereas at low pressures it remains constant over a large portion of the cross section.

We have assumed hitherto that the current is always sufficiently low for the magnetic field produced by the current to play an unimportant role in the discharge mechanism. At high currents this is no longer true, and the interaction of the self-magnetic field of the discharge and the current produces forces on the ionized gas comparable to the other forces acting. The required currents increase with the gas pressure p; at normal temperatures, $i > 10^3$ amperes and $p < 1$ torr are required. The force due to the magnetic field tends to constrict the discharge, and a column so constricted is said to be pinched. This pinch effect offers a possible method of confining the hot gas to a channel remote from the

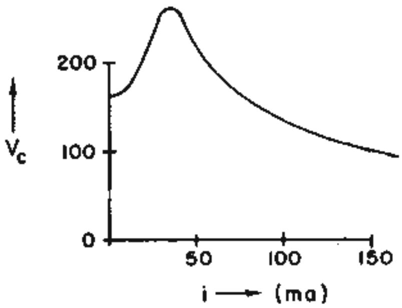

FIG. 7. Variation of cathode fall of potential with current for discharge in A at 30 torr pressure with spherical tungsten electrodes, 1.8 mm diameter.

walls of the containing vessel. However, a major obstacle to the achievement of a steady pinched discharge is the inherent instability of such a channel to lateral perturbations. This causes the pinched column to leave the axis of the containing tube and take up a helical path in contact with the walls. It is, however, possible that a suitable arrangement of magnetic fields may help to stabilize the discharge, leading to the prospect of continuous operation of a pinched discharge.

ELECTRICAL MEASUREMENTS

In an electrical measurement, one is concerned with the evaluation of an electrical quantity—resistance, capacitance, inductance, charge, current, voltage—or of a quantity that depends on some combination of them. The measurement means may be a ratio device, such as a potentiometer or bridge in which similar quantities are compared; or it may be an electromechanical system in which a force or torque is developed; or the heating effect of an electric current may be utilized; or some effect associated with quantum dynamics may be employed.

The basis of any meaningful measurement of an electrical quantity must ultimately be the *national reference standards* maintained by the National Bureau of Standards (NBS), and assigned by means of *absolute* measurements in which certain electrical quantities are determined in terms of appropriate mechanical quantities. The electrical units are related to the metric system of mechanical units in such a way that the units of power and energy are identical in both systems. In 1960 the name Système International (SI),[1] now in use throughout the world, was assigned to the measurement system based on the *meter, kilogram, second, ampere.*

Because four independent relations tie the six electrical quantities together, only two absolute measurements are needed to fix the national reference standards. Historically, these have been an *ohm* and an *ampere* determination.[2] In the ohm determination, a resistance is compared to the reactance at a known frequency of an inductor or capacitor whose magnitude is calculated from its measured dimensions together with the assigned magnetic constant ($4\pi \times 10^{-7}$ H/m in SI units), or in the case of a calculable capacitor, the corresponding electric constant derived from the magnetic constant and the speed of light in vacuum. Thus the *ohm* is assigned in terms of the *meter* and the *second.* In the ampere determination, a current carried by two coils is evaluated in terms of their measured dimensions, the magnetic constant, and the force with which they interact. This force is opposed by gravity acting on a known mass. The *ampere* is assigned in terms of the *meter*, *kilogram*, and *second.* The measured current is passed through a known resistor, and the *volt* is assigned using Ohm's law.

The National Reference Standards, in terms of which the *legal* electrical units are maintained, are groups of stable resistors, capacitors, and standard cells (Weston saturated cells) whose values have been assigned by *absolute* measurements. At NBS the reference standard of resistance is a group of 1-Ω resistors, fully annealed and mounted strain-free out of contact with the air, in sealed containers. The reference standard of capacitance is a group of 10 pF fused-silica-dielectric capacitors whose values are assigned in terms of the calculable capacitor used in the ohm determination. The reference standard of voltage is a group of standard cells maintained at a constant temperature. Their values are periodically reassigned by means of a "Josephson experiment" to be described below. The individuals within each reference group are intercompared routinely to detect any drift with respect to the group mean. Representatives of the group are compared with the national standards maintained by the national laboratories of other countries to detect any differences that could develop in their "as-maintained" units. These international comparisons are carried out by the Bureau International des Poids et Mesures (BIPM) in Sèvres, France. Stability of the national reference standards has also been monitored in recent years by experiments which relate an electrical unit directly to some atomic constant—a natural invariant. In one such experiment, the *ampere* is related to *proton gyromagnetic ratio*.[3] A characteristic magnetic moment and spin are associated with the proton—it behaves both as a magnet and a gyroscope—tending to align itself in a magnetic field and to precess about the field direction with an angular velocity proportional to field strength if its alignment is disturbed. In fact, proton precession frequency has become a widely used method of measuring magnetic field strength. Thus the repeatability of proton precession frequency in the field of a dimensionally stable solenoid, excited by a current established in terms of the *legal ohm* and *volt*, is a measure of the stability of the *legal ampere*. In another experiment use is made of the voltage appearing across a Josephson junction (made of two superconductors separated by a barrier), irradiated with microwave power and simultaneously biased with direct current.[4] The voltage across the junction increases with increasing bias current, in discrete quantum jumps related to the frequency of the microwave irradiation. This relation is $Nh\nu = 2eV_N$, where N is step number, h is Planck's constant, ν is the microwave frequency, e is elementary electron charge, and V_N is the junction voltage. Thus the stability of the *legal volt* is monitored in terms of frequency and the ratio of Planck's constant to electron charge by comparing the Josephson voltage to that of the cells in the national reference group.

The *legal volt* was reassigned on January 1, 1969, based on recent *ampere* determinations. This assignment was such that the number stating the emf of a standard cell was increased by 8.6 μV over its previous (1948-68) assignment. Other national laboratories also made adjustments such that all national reference standards of emf (including the standard at BIPM) were in agreement at that time. It was determined through Josephson volt experiments that the emf of the cells in the national reference group was slowly drifting (as much as 0.3 μV/year), and it was decided that the emf of these cells would be periodically reassigned to keep the *legal* volt at a constant value.[5] Thus, since July 1, 1972 the *legal* volt has been maintained in terms of an assigned frequency/voltage ratio through the Josephson volt experiment. Recent *ohm* determinations,[6] based on a calculable capacitor, indicate that the 1948 assignment of the national reference standard of resistance (USA) was correct within a microohm, and the value of the *legal ohm* continues to be maintained by a group of 1-Ω resistors on the basis of their 1948 assignment.

The *voltage divider* is the basic element of many measurement networks. In general it consists of a group of series-connected resistors (or impedors using resistance, inductance, capacitance, or some combination of them). Its operating principle is the following: when the series circuit is tapped at an intermediate point but no current is drawn from the tap, the ratio of the voltage between the tap point and a divider terminal to the voltage between terminals equals the ratio of tapped resistance (or impedance) to the total divider resistance (or impedance). Modern dc potentiometers are dividers that may achieve an accuracy of a few parts-per-million (ppm) in comparing direct voltages and, with appropriate range-extending dividers, can be used to measure voltages to 1500 V or more. Factors limiting accuracy in high-voltage dividers may be the heating effect of power dissipated in the divider and leakage currents across its insulating structure. Standard cells may be intercompared to a few parts in 10^8, using special potentiometers designed to minimize parasitic voltages. Direct currents can be measured to a few ppm by comparing the voltage drop the current produces in a known resistance, with a known reference voltage.

Two voltage dividers may be connected in parallel to the same source to form a *bridge*. Equality of divider ratios—indicated by zero potential difference at their tap points—permits accurate comparison of impedances and is relatively insensitive to minor variations in the level of supply voltage. For dc resistance measurement, the Wheatstone network is used. One of its two dividers provides a known ratio, and the other includes the unknown and a known resistor with which it is compared. In this simple form the Wheatstone bridge is used for resistors (usually greater than 1 Ω) which have only two terminals, i.e. whose potential and current connections coincide. For 4-terminal resistors, whose potential and current terminals are separate, the Kelvin bridge is used, with two dividers having known identical ratios in addition to the divider that incorporates the current circuits of the unknown and reference resistor. Using a direct substitution method with one of these bridges, nominally equal resistors can be compared at the ppm level or better, in the range 10^{-4}–10^4 Ω.

The more general impedance bridge is a 4-arm network, similar to the Wheatstone bridge—or a more complicated network that can be reduced to an equivalent 4-arm array by appropriate delta-wye transformations[7]—in which, by proper choice of components, inductances may be intercompared or measured in terms of capacitance and resistance, or capacitances may be intercompared. The accuracy of such bridges is usually limited by the stability of ratios and reference components. Additional limits may be imposed by coupling between bridge elements or to nearby objects or ground. Such coupling may be an ambient magnetic field inducing a parasitic emf in a bridge element or in an open loop between elements, or by capacitance or leakage between elements or to a source or to ground. Such effects can be reduced or eliminated by choice and arrangement of components and by the use of shields maintained at appropriate potentials to eliminate the effect on bridge balance of stray capacitance and leakage.

The *inductive voltage divider*, used extensively as a bridge element at power and audio-frequencies, is in principle a multi-decade, selectable tap-point auto-transformer whose decades may be wound on separate magnetic cores. With proper construction this type of divider can be operated at ppm or better accuracy.

Completely shielded bridges whose ratio arms are closely-coupled secondary windings of a transformer with a high-permeability core, (known as *transformer-ratio-arm bridges*) are capable of high accuracy and are widely used for capacitance measurements. For example, stable 3-terminal 10-pF capacitors can be routinely compared to one part in 10^8 in such a bridge. The voltage ratio supplied by the coupled secondaries may be 1/1, and is rarely more than 10/1. The conjugate of the transformer ratio-arm bridge is based on the *current comparator* and has much greater ratio flexibility.[8] In this arrangement, two currents are compared by equality of their opposed, uniformly distributed linkages with a common core, following Ampere's circuital law,

$$\oint Hdl = \sum I,$$

i.e., the line integral of magnetizing force along a closed loop is determined by the sum of the currents passing through the loop. The balance point, corresponding to zero flux density in the high-permeability core, is sensed by zero induced voltage in a detector winding around the core. There is generally an auxiliary winding into which a current can be injected to compensate the difference in ampere-turns of the ratio windings, and so bring the system to balance. The whole arrangement must be shielded from external magnetic fields. Current ratios as high as 1000/1 are feasible, with correspondingly high voltage ratios impressed on the elements being compared. This range of ratios makes possible a relatively simple bridge for the evaluation of high-voltage power cables, insulating structures, and energy-storage capacitors. DC versions of the current comparator have been adapted to use in potentiometers and bridges for the comparison of resistance standards and for the evaluation of current-carrying shunts.

Superconducting Quantum Interference Devices (*SQUIDs*) are very sensitive magnetic flux sensors. A SQUID comprising a superconductor formed into a loop interrupted by a Josephson junction can be used as a flux detector in a current comparator for the measurement of cryogenic resistance ratios.[9] Comparator sensitivity can amount to 0.5 nA-turns. Such an arrangement must be magnetically shielded and is inherently limited by the Johnson noise of the resistors at their operating temperature.

In any measurement network (such as a bridge or potentiometer) using voltage divider or current comparator techniques, a sensitive *detector* must be included to show the absence of current (or voltage difference) in an appropriate network branch. In a dc network the simplest detector is the D'Arsonval galvanometer, consisting of a coil of fine wire suspended by conducting filaments in a radial magnetic field. A light-beam reflected from a mirror attached to the moving system indicates rotation arising from current in the coil. The light beam may be focused on a scale for direct observation, or may be shared by differentially connected photocells whose output is supplied to a second galvanometer, producing an amplified deflection. If the galvanometer is isolated from mechanical disturbances, unbalance detection at the nanovolt level is possible in circuits having resistance up to several hundred ohms.

Electronic instruments which have been developed for low-level dc signal detection are more convenient, more rugged, and less susceptible to mechanical disturbances than is a D'Arsonval galvanometer. However, the measuring circuits of electronic detectors must use considerable filtering, shielding, and guarding to minimize electrical interference and noise. The galvanometer is an extremely efficient low-pass filter, and (when operated to make optimum use of its design characteristics) is still the most sensitive low-level dc detector. Electronic detectors generally use either a mechanical or transistor chopper driven by an oscillator whose frequency is chosen to avoid the local power frequency and its harmonics. This modulation converts the dc input signal to ac which is then amplified, demodulated, and displayed on an indicating instrument, fed to a recording device, or subjected to further processing.

Adjustable-frequency amplifier detectors are used with ac bridges and basically incorporate a low-noise preamplifier followed by a high-gain amplifier around which is a tunable feedback loop whose circuit has zero transmission at the selected frequency, so that the negative feedback circuit controls the overall transfer function of the detector to eliminate passage of signals at other than the chosen frequency. The display element which accepts the detector output may be a cathode-ray oscillograph (CRO) or a rectifier-type moving-coil instrument. Frequently a phase-selective element is interposed between the amplifier and display elements so that in-phase and quadrature bridge adjustments are independently displayed. If a CRO is used, the unbalance bridge signal may be impressed on the vertical deflection plates and a phase-adjustable signal derived from the bridge supply impressed on the horizontal plates. The result is an elliptical screen pattern (Lissajou figure), the slope of whose major axis (after appropriate phase adjustment) represents one of the quadrature unbalance signals, and whose minor axis represents the other. Balance is indicated when the ellipse is collapsed to a straight line and the line is brought to the horizontal. Nanovolt sensitivity is possible also in some types of ac detectors.

Indicating instruments are used to measure current, voltage, phase, and power. With special circuit arrangements they can be used for other electrical quantities or for nonelectrical quantities for which transducers can be devised that will convert the measurand into an electrical signal. Indicating instruments fall into two categories, *analog* and *digital. Analog* instruments generally have a pivoted rotating element driven by the electrical signal, the turning motion being opposed by springs so that equilibrium position of the system under driving and restoring torques is indicated on a scale by a pointer attached to the moving element, or by an optical system employing a mirror. The accuracy of such a system is limited by how well the pointer position can be read, generally a percent or so, a tenth percent in the best of pointer/scale instruments, and a hundredth percent for some mirror/light-beam readouts. Some analog instruments also have front-end electronics which can improve sensitivity and input impedance of electromechanically-based instruments. *Digital* instruments convert an electrical signal into a digital output which may be either displayed as a numeric readout or further processed in a computer. The accuracy of such a system is limited by its internal reference and by its critical network components such as the signal conditioner, sample-and-hold amplifier, and analog-to-digital converter. Additional limitations in many cases may be offset, gain, nonlinearity, quantization "noise," or other sources of error attributable to the analog-to-digital converter. Even though a digital instrument may have a 5-digit numeric display, its overall accuracy may be the equivalent of only 3 or 4 digits (0.1 or 0.01%), depending on the critical network components. A calibration service for precision analog-to-digital and digital-to-analog converters has been available since 1981 at NBS based on a reference digital-to-analog converter standard developed for this purpose.[10]

DC analog instruments usually have a permanent-magnet moving-coil system whose operation is identical with that of the D'Arsonval galvanometer, i.e., a response proportional to the average value of current in the moving coil.[11] In a milliammeter, the coil may directly carry the current to be measured; in an ammeter the bulk of the current is carried by a shunt; in a voltmeter a series resistance limits the current and the scale is marked in terms of the voltage drop between the instrument terminals.

An ac instrument requires an arrangement for which the direction of torque does not reverse with the direction of current at the instrument terminals. This requirement may be provided by four rectifier elements arranged in a square with the input across one diagonal and a D'Arsonval meter across the other, the rectifier arrangement being such that the current in the dc meter is the same for either direction of input current. Response is to *average* value of the rectified current, but because one is usually concerned with *effective* (rms) value, the scale is marked in terms of rms value for an assumed sine-wave input. Thus, a waveform error is present for a nonsinusoidal input. *Rectifier* instruments of this type are used as voltmeters and milliammeters in the power and audiofrequency range.

Thermocouple instruments use the heating effect of current in a fine wire or thin-walled tube to which a thermocouple is attached. (These structures and related devices are referred to as *thermoelements*, and they are also employed in thermal voltage and current converters as transfer elements.) In the analog-type instrument the thermocouple output goes to a low-range dc millivoltmeter. Since temperature rise of the heater elements is proportional to the square of the current, there is no waveform error in the indication of effective (rms) value. This type of instrument may be used for current measurement from dc to rf range (200 MHz or more with some constructions). As a voltmeter, thermal converter-based instruments are usually restricted to audio frequencies, but if a multiplier having low distributed capacitance is used, the range may be extended to a megahertz or more without serious error.

In *moving-iron* instruments a soft-iron piece forms the moving element. It is immersed in the field of a coil that carries the current to be measured, and its motion is such as to increase the inductance of the system with increasing current. Energy storage, and hence torque, depend on current squared, and there is no waveform error for rms indication. By suitably shaping fixed and movable iron pieces, the scale can be made nearly linear over the upper 80% of its range. In other arrangements, part of the scale can be compressed and a small portion of total range expanded to cover much of the scale. This scheme is useful in a voltmeter that monitors a nearly constant voltage.

Electrodynamic instruments have a moving coil immersed in the field of a fixed-coil system. The interaction of their fields produces a torque proportional to the square of the current for a series (voltmeter) connection, or to the product of the currents in a shunt (ammeter) connection, so that the scale indication is of effective (rms) value as in a moving-iron instrument. However, eddy currents can be much less, and electrodynamic instruments are generally useful over an extended low-frequency range. Also, since there is no magnetic polarization (present on dc in a soft-iron instrument), the dc response can be error-free if the coil arrangement is astatic or is shielded from ambient magnetic fields. Electrodynamic instruments are also used as *wattmeters* to measure power at frequencies up to 1 KHz. The moving coil with a series resistance is connected across the supply as the voltage circuit of the wattmeter. The fixed coils are connected to carry the load current. At any instant, the driving torque is proportional to the instantaneous product of line voltage and load current; the moving coil, by reason of its inertia, takes up a position that represents average power over a cycle.

A *digital voltmeter* (DVM) compares a direct voltage input to an internally generated reference voltage. This comparison may be done by successive approximations in an automatic self-balancing potentiometer; the reference voltage may be used to generate a ramp function that opens a counting gate when the ramp equals the input signal and closes the gate when the ramp voltage is zero, resulting in a voltage-to-time conversion; a ramp voltage may be generated at a rate proportional to the input until it equals a reference value, returned to zero, and repeated. The number of repetitions in a fixed time (proportional to the input voltage) is counted and displayed, the time interval being chosen so that the number of pulses makes the meter direct-reading. In a dual-slope instrument, the input signal may be made to charge a capacitor at a proportional rate, switch to a reference voltage of opposite polarity, and discharge the capacitor at a constant rate, the discharge time being used to gate clock pulses to a counter for voltage-time conversion. For ac measurements the DVM is preceded by an ac/dc signal converter. If this converter is a rectifier followed by a filter, to obtain an average value of the rectified signal, the display of an equivalent rms value (for an assumed sine-wave input) will be subject to error for other than sinusoidal waveforms. Alternatively, thermoelements can be employed to provide accurate measurement of the true rms value of ac voltages, irrespective of wave shape. Typically, the thermoelement output is part of a feedback network which provides a dc output voltage equal to (or proportional to) the true rms value of the ac input voltage. The thermoelement may be switched alternately to the ac input and then to the dc output as shown schematically in Fig. 1. With either input applied to the thermoelement, the output emf of the thermocouple is balanced against an opposing emf (produced automatically by the feedback loop). Equivalency between the input rms ac voltage and the dc output voltage is thus obtained by virtue of detecting a null voltage under both input conditions.

The reference voltage of a DVM is usually based on the reverse breakdown of a Zener diode, and (depending on selection, aging, and compensation of temperature coefficient) may achieve 5-place accuracy. In fact, portable direct voltage standards of this type can, with temperature control, achieve short-time accuracy of a ppm and stability of 2ppm/year or better.[12] Such a voltage standard can replace a standard cell for many applications, although an inherently higher noise level is to be expected.

The *ac-dc transfer* function is an important one, since the basic standards of resistance and emf, and the potentiometer techniques for accurately measuring current and voltage, are available only on dc. Electrodynamic instruments have been used as ac-dc transfer standards in the range below a kilohertz.[13] Thermoelements with appropriate shunt and series resistors are used over an extended frequency

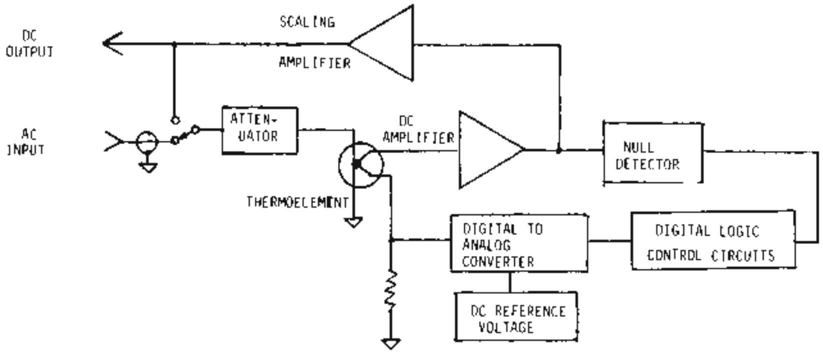

FIG. 1. Automatic thermoelement-based rms ac voltmeter.

range, and are both portable and convenient to use.

A recent electrical measuring instrument development is that of the *transient digitizer* or *waveform recorder.* These kinds of instruments have grown out of a need for measurements with the speed of a CRO and the accuracy of a DVM. The waveform recorder typically consists of a wide-band amplifier, high-speed sample-and-hold and analog-to-digital converter circuits, and a temporary (or buffer storage) memory. Similar to most oscilloscopes, the position and duration of the captured segment of the input waveform can be selected. Both digital and reconstructed analog output interfaces are also incorporated. Some of the best waveform recorders claim 20–100 MHz sampling rates with 0.25–0.1% resolution[14] Accuracy specification for these instruments is a subject that is receiving considerable attention and one in which physical as well as performance standards must be developed.

Instrument transformers are used at power frequencies to extend current and voltage measurement capability beyond the nominal input range of indicating instruments. *Current* transformers rated at 20 kA are used in some installations, as are *voltage* transformers rated at 350 kV. Low-range current transformers of special construction are capable of accurate operation throughout the audio-frequency range. Instrument transformers, consisting of a primary and secondary winding coupled by a magnetic core, are designed to accurately reproduce the primary current (or voltage) on a reduced scale in the secondary circuit. They are quite different from power transformers in details of design and operation, although their basic operating principle is the same. The usual current transformer, designed for use with a 5-A ammeter and to supply the current circuit of a wattmeter or watthourmeter, is capable of delivering only the small amount of power required by these instruments. Current transformers operate under nearly short-circuit conditions with their magnetic core at low flux density. The usual voltage transformer, designed for use with a 120-V voltmeter and the voltage circuit of a wattmeter or watthourmeter, also has a low power rating, and operates under nearly open-circuit condition with its magnetic core approaching saturation. Instrument transformers of good design may be expected to have errors of only a few hundredths percent when operated within their design limits. Performance of a current transformer may be evaluated in terms of a *current comparator*, whose magnetic core operates at zero flux density and is therefore free from the major sources of error that arise from core excitation in a transformer.

In power measurements and ac impedance measurements in general, audio *phase angle* is an important electrical quantity. Although analog phase-angle meters using precision bridges and rotating coil indicators are still in use (with accuracies on the order of 0.5%), digital phase-angle meters are rapidly displacing them, where resolutions of 0.01 degree and 0.05 degree accuracy are possible.[15] As with a DVM however, there are certain limitations with respect to input signal levels, zero offset, and full-scale (gain) corrections, as well as nonlinearities which must be taken into account to achieve the best accuracy possible with digital phase meters. A precision audio-frequency phase-angle calibration standard has been developed at NBS, which uses digital waveform synthesis techniques to produce a reference and variable pair of sinusoidal waveforms whose relative phase displacement can be accurately controlled to within 0.005 degree.

The *induction watthourmeter*, for measurement of electrical energy, is probably the most familiar and widely used of all electrical instruments. More than 9×10^7 are in continuous use to meter electrical energy consumed in the USA, representing in excess of 30 billion dollars per year. The essential features of an induction watthourmeter are indicated schematically in Fig. 2. The voltage winding has many turns of fine wire and carries a current that is almost in quadrature with the line voltage; special lag arrangements ensure that the magnetic field of the voltage pole V lags the line voltage by 90 degrees. The current coils (a few turns of coarse wire) carry the load current, and the field of the current poles C–C is in phase with the load current. The eddy currents produced in the disk by the field from the current poles are in quadrature with this field, and hence have a component in phase with the field from the voltage pole, corresponding to the in-phase (power) component of the load current. The reaction of this component of current-pole-induced eddy currents in the disk, with the voltage-pole field, produces a driving torque on the disk. Similarly, eddy currents in the disk, induced by the voltage-pole, are in phase with the field associated with the power component of the load current in the current-poles; this also produces a driving torque proportional to power through the meter. A braking torque proportional to disk speed

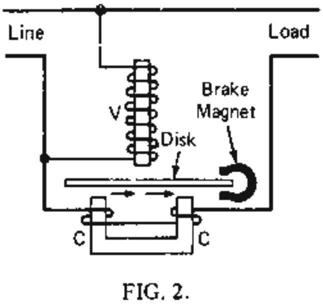

FIG. 2.

results from interaction of the brake magnet field with the eddy currents it induces in the moving disk. As a result, disk speed is proportional to load power, and the number of disk revolutions (read from a counter geared to the disk) is a measure of the total energy consumed by the load.

Electric power and energy can also be measured by processing and combining current and voltage signals electrically. This can be accomplished either by some form of analog multiplication, e.g., using a time-division multiplier,[16] or by sampling the instantaneous currents and voltages periodically, i.e., digitizing the samples so obtained and computing the power from the digital values obtained. In general, higher accuracies can be obtained than with the methods previously described, but the instrumentation required is quite complex. A portable system for measuring ac voltage, current, power, and energy,[17] based on a thermal converter which compares a current derived from the quantity being measured with an equivalent direct current, has been found to have an accuracy of 20 ppm in an international comparison of power measurements at unity and 50% power factor.

ELECTRICITY

Electricity is the material interaction that arises from electromagnetic forces between *electric charges* at rest and in motion. The properties of charge that are responsible for the main features of electrical phenomena are:

1. *Superposition*. The effects of a group of charges are the sum of the independent effects of each one, both in producing fields of force and in being acted on by them. The principle of superposition gives significance to the total amount of charge q or Q on an object or in a system, and also to the concepts of *volume charge density* ρ, *surface charge density* σ, and *linear charge density* λ. The *current density* vector $\mathbf{J}$ gives the direction and magnitude of the rate per unit area at which charge moves through a surface perpendicular to its velocity. The total *current* through a surface $\mathbf{S}$ is then $I = \int_S \mathbf{J} \cdot d\mathbf{S}$ taken over the surface.

2. *Conservation*. Positive and negative charges have opposite effects in the superposition sums, and tend to be present in nearly equal numbers in most circumstances so that electric neutrality is widely prevalent in matter. The algebraic sum of the charges present in any closed system is strictly constant, a fact which is represented by the differential equation

$$\nabla \cdot \mathbf{J} + \partial\rho/\partial t = 0. \qquad (1)$$

A current of positive charges in the positive direction is equivalent in the absence of magnetic fields to a current of negative charges in the opposite direction.

3. *Quantization*. In ordinary matter, not subject to high energy interactions (300 MeV or more), negative charge is carried exclusively by *electrons*, and positive charge by protons, including those in nuclei. Electrons and protons have quantum-mechanical properties:

(a) Charge is quantized so that each electron has the same charge $-e$ and each proton has $+e$, where $e = 1.6092 \ldots \times 10^{-19}$ coulomb. This value is so small that the quantization of charge is not noticeable in macroscopic electromagnetic effects. Nevertheless a quantity of charge q may be defined in principle as an integer multiple of $\pm e$.

(b) Wherever situated, electrons and protons have available distinct quantized values or *levels of energy*, and each may generally be considered to occupy a single level at a time.

(c) The wave properties of electrons mean that on a microscopic scale electrons can not be localized at points of space but are represented by a quantum-mechanical charge density. These properties allow electrons to move freely through condensed matter provided they can be excited into appropriate energy levels.

4. *Mobility*. Charge can move through solid matter in electron waves, through liquids in the form of ions in solution, and through gases as both electrons and ions. Without external forcing, charge mobility always tends to neutralize the containing matter.

5. *Force*. A small piece of matter or particle with a charge q moving at a speed v in some frame of reference will experience a force given by the *Lorentz force law*:

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \qquad (2)$$

where the vectors $\mathbf{E}(x, y, z)$ and $\mathbf{B}(x, y, z)$ are, respectively, the *electric* and *magnetic field vectors* at the position (x, y, z) of q, and are determined by the magnitudes, positions, and velocities of all the other charges in the neighborhood. The magnetic force $q\mathbf{v} \times \mathbf{B}$ is responsible for the motor and generator effects (see ELECTRIC MOTORS, ELECTRIC POWER GENERATION). It is readily seen that **E** is an ordinary or polar vector, whereas **B** is a pseudovector or axial vector (see VECTORS). For each vector there is defined the *flux* through an arbitrary surface **S** by

$$\Phi_{\mathbf{E}} = \int_{\mathbf{S}} \mathbf{E} \cdot d\mathbf{S}, \qquad \Phi_{\mathbf{B}} = \int_{\mathbf{S}} \mathbf{B} \cdot d\mathbf{S}. \qquad (3)$$

The variations of **E** and **B** in a region may be represented by *lines of force* which are tangent at every point to the respective vector at that point.

6. *Potential*. When the charges responsible for **E** are stationary, and in cases where they move so that the currents are steady, the electric field is conservative. That is, $\mathbf{E}(x, y, z)$ is derivable from a single-valued *scalar potential* $V(x, y, z)$:

$$\mathbf{E}(x, y, z) = -\nabla V(x, y, z). \qquad (4a)$$

Equivalently, V can be found from **E** in a region by integration along an arbitrary line in space:

$$V(x, y, z) = -\int_{P_0}^{P} \mathbf{E} \cdot d\mathbf{l} \qquad (4b)$$

where P is the point (x, y, z) and P_0 is an arbitrary reference point. $V(x, y, z)$ is the potential energy per unit charge of a small test charge placed at P, considering its energy to be zero at P_0. A line of electric force can be seen to proceed always from higher to lower potential and can never cross or come back to itself. The variation of potential in a region can be described by constructing a set of *equipotential surfaces*, which are everywhere perpendicular to the electric lines of force. (See Fig. 1.)

7. *Coulomb's Inverse Square Law*. When a charge is at rest or moving at a speed much lower than the speed of light c, it produces a field **E** at a distant point P given by *Coulomb's Law*:

$$E = \frac{q\hat{\mathbf{r}}}{4\pi\epsilon_0 r^2} \qquad (5)$$

where $\hat{\mathbf{r}}$ is the unit vector from q to P and r is the distance. The constant ϵ_0 is found to have the value $\epsilon_0 = 8.845 \ldots \times 10^{-12}$ in SI units. The field produced at P by many q_k's at different places is given by a vector sum of (5) over all the q_k's.

From *Coulomb's Law* may be deduced the *Gauss Flux Law* for the electric flux through an arbitrary closed surface:

$$\oint \mathbf{E} \cdot d\mathbf{S} = \sum_i q_i/\epsilon_0 \qquad (6)$$

where the flux is calculated through a closed arbitrary surface and the q_i are the charges within the surface and no others. The *Maxwell*

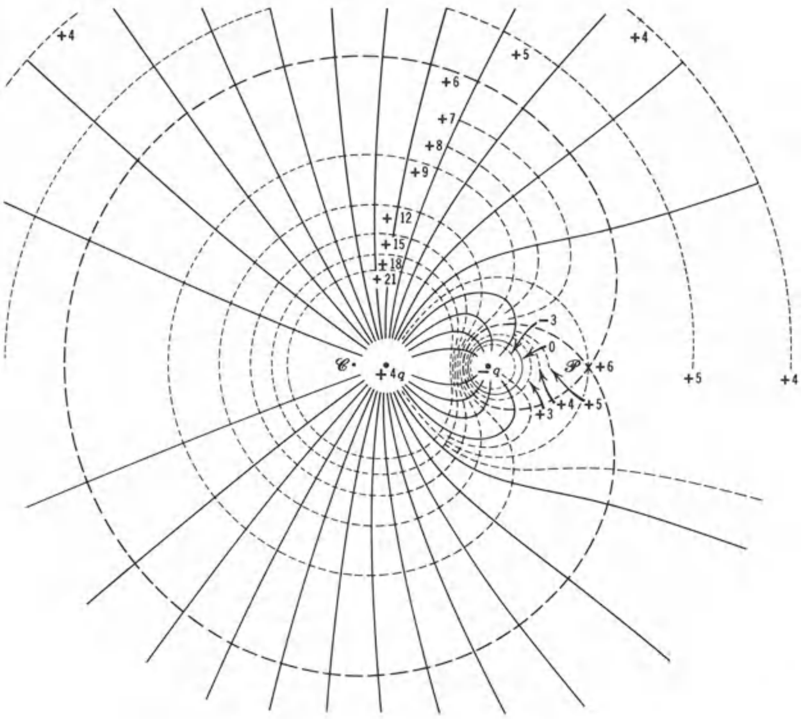

FIG. 1. Equipotentials and lines of force for $+4q$ and $-q$. The light dashed line through P separates flux that passes from $+4q$ to $-q$ from flux that passes from $+4q$ to infinity. (From Scott, p. 52; originally from Garrett, Milan Wayne, "Electricity and Magnetism," Ypsilanti, MI, University Litho-Printers, 1941, p. 48, Fig. 4, 7.)

differential-equation form of Gauss' Law is

$$\nabla \cdot \mathbf{E} = \rho/\epsilon_0. \tag{7}$$

A *tube of flux* in free space, the sides of which are composed of flux lines, contains the same flux across any section; the flux passes from positive charge at one end of the tube to negative charge at the other. Gauss' Law can be used to find the electric field in situations of high symmetry. The intensity of the field outside an infinite uniform plane distribution of charge density σ is $E = \sigma/2\epsilon_0$ regardless of distance; outside a uniform line of charge density λ it is $E = \lambda/2\pi\epsilon_0 r$, where r is the cylindrical radius coordinate; and outside a spherically symmetric distribution of total charge Q it is $E = Q/4\pi\epsilon_0 r^2$, with r being the spherical radius coordinate. Just outside a conductor with charges at rest, at a point where the surface density is σ, E is normal to the surface with intensity $E = \sigma/\epsilon_0$.

In the general case in which all charges can be treated as volume distributions and are at rest or slowly moving, the scalar potential can be found from Coulomb's Law by

$$V(x, y, z) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho \, d\tau}{r} \tag{8}$$

where r is the distance from the volume element $d\tau$ to the point (x, y, z).

8. *The Poisson and Laplace Equations.* From (4) and (7) we find *Poisson's Equation*:

$$\nabla^2 V(x, y, z) = \rho/\epsilon_0 \tag{9}$$

which in charge-free space becomes *Laplace's Equation*:

$$\nabla^2 V(x, y, z) = 0. \tag{10}$$

A unique solution of (9) exists for a set of fixed conductors with each conductor having either a given value of V or a given value of total charge Q, so that the fields between the conductors and the charge distributions on them can be determined.

9. *Capacitance.* For a bundle of flux leaving a portion of the surface of one conductor and ending on another, the ratio of the charge at the positive end to the potential difference between the two conductors is the *capacitance* of that pair of conductor areas. In general, the charges on the conductors are linear functions of the potentials:

$$Q_j = \sum_{k=1}^{n} C_{jk} V_k \tag{11}$$

where the C_{jk} are coefficients of capacitance. When only two conductors are present, and $Q_1 - Q_2 = Q$, we call the pair a capacitor and set

$$Q = CV \tag{12}$$

where V is the potential difference between the two, C is the capacitance, and Q is the charge on the positively charged conductor.

10. *Energy in Electrostatic Systems.* The energy in a capacitor is

$$U = \frac{1}{2}CV^2 = \frac{1}{2}Q^2/C \tag{13}$$

and for a set of n conductors is

$$\begin{aligned} U &= \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} C_{ij}V_iV_j \\ &= \frac{1}{2}\sum_{i=1}^{n} Q_iV_i \end{aligned} \tag{14}$$

which can be converted into a volume integral over the intervening space

$$U = \frac{1}{2}\epsilon_0 \int E^2\, d\tau. \tag{15}$$

11. *The Ampere-Biot-Savart Law.* A charge q moving at a nonrelativistic velocity $\mathbf{v}$ creates a magnetic field $\mathbf{B}$ at a distant point P given by

$$\mathbf{B} = \frac{\mu_0 q}{4\pi}\,\frac{\mathbf{v} x \hat{\mathbf{r}}}{r^2} \tag{16}$$

where $\hat{\mathbf{r}}$ is the unit vector from the charge q to the point P and r is the distance. The constant μ_0 is given the value $4\pi \times 10^{-7}$ in SI units. An element of current of strength I and length $d\mathbf{l}$ makes a field $d\mathbf{B}$ given by replacing $q\mathbf{v}$ by $Id\mathbf{l}$, so that for a finite length l of current we have

$$\mathbf{B} = \frac{\mu_0 I}{4\pi}\int_l \frac{d\mathbf{l} \times \hat{\mathbf{r}}}{r^2}. \tag{17}$$

For a closed loop of current, it can be shown from (17) that

$$\mathbf{B} = -\frac{\mu_0 i}{\pi}\nabla\Omega \equiv -\mu_0 \nabla V_m \tag{18}$$

where Ω is the solid angle subtended by the current loop at the point where $\mathbf{B}$ is sought. The quantity V_m is the occasionally used multiple-valued magnetic scalar potential. Equations (17) and (18) can be used to obtain the magnetic fields of a number of shapes of wires and coils, and when applied to microscopic current loops can account for the phenomena of magnetism.

If $\mathbf{B}$ in (16) is integrated around an arbitrary close loop l' as in Fig. 2, it can be shown that

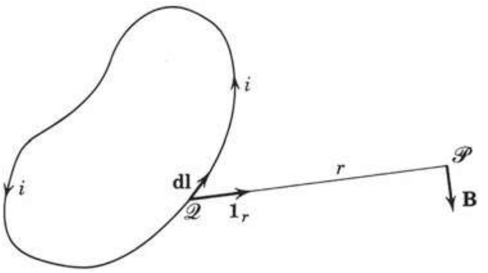

FIG. 2. Ampere-Biot-Savart law, Eq. (17).

$$\oint_{l'} \mathbf{B} \cdot d\mathbf{l}' = \mu_0\epsilon_0\, d\Phi_E/dt. \tag{19}$$

The quantity $\epsilon_0\, d\Phi_E/dt$ is called the *displacement current*, where Φ_E is the electric flux from q through l'. For a finite segment of current using (17) we find

$$\oint_{l'} \mathbf{B} \cdot d\mathbf{l}' = \frac{\mu_0 I}{4\pi}\Delta\Omega \tag{20}$$

where $\Delta\Omega$ is the difference between the solid angles subtended by l' at the ends of the current segment. (See Fig. 3.) $\Delta\Omega$ is 4π for a closed loop. For a combination of closed current loops I_k and moving or variable charge elements q_j, we have *Ampere's generalized circuital law*:

$$\oint_{l'} \mathbf{B} \cdot d\mathbf{l}' = \mu_0 \sum_k I_k + \mu_0\epsilon_0\, d\Phi_E/dt \tag{21}$$

where the sum is over all the current loops that thread through l' and Φ_E is the total electric flux produced by the net charges in the region. Segments of current that are not closed, as in the case of a capacitor being charged, may be counted either in the first term as currents *or* in the second as changing charges at the ends of current segments.

The corresponding Maxwell differential equa-

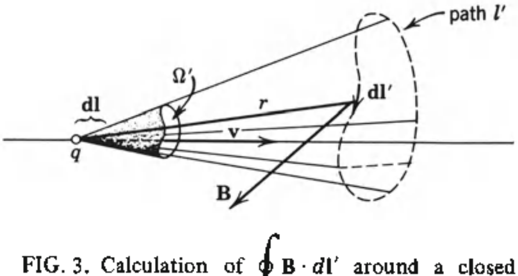

FIG. 3. Calculation of $\oint \mathbf{B} \cdot d\mathbf{l}'$ around a closed path in the neighborhood of a moving charge q subtending a solid angle Ω'.

tion is

$$\nabla \times \mathbf{B} = \mu_0(\mathbf{J} + \epsilon_0 \partial \mathbf{E}/\partial t) \qquad (22)$$

12. *Vector potential.* From (17) it also follows that **B** can be found from a *vector potential* **A**:

$$\mathbf{B} = \nabla \times \mathbf{A}; \qquad \mathbf{A} = \mu_0 \sum_k \frac{I_k}{4\pi} \int \frac{d\mathbf{l}}{r^2} \qquad (23)$$

where the sum is over all the closed or open loops into which the current sources of **B** can be analyzed. The flux through an arbitrary loop l' can be rewritten in two ways:

$$\Phi_B = \int_S \mathbf{B} \cdot d\mathbf{S} = \oint_{l'} \mathbf{A} \cdot d\mathbf{l}' \qquad (24)$$

From (23) the third Maxwell equation follows:

$$\nabla \cdot \mathbf{B} = 0 \qquad (25)$$

which asserts that the flux through any closed surface is zero, $\oint \mathbf{B} \cdot d\mathbf{S} = 0$. The lines of **B** have no beginnings or ends; they generally circulate indefinitely without closing.

13. *Faraday's Law of Induction.* For any closed loop in space, whether moving or stationary, *Faraday's Law* asserts that

$$\mathcal{E} = \int_l \mathbf{E} \cdot d\mathbf{l} = -d\Phi_B/dt = -d\left[\oint_l \mathbf{A} \cdot d\mathbf{l}\right]\Big/dt \qquad (26)$$

where ϵ is the electromotive force (emf) around the loop l and Φ_B is the magnetic flux through l. The loop may be stationary or moving. From (26) it follows that the electric field of magnetic origin is not conservative and is given by $\mathbf{E} = -\partial \mathbf{A}/\partial t$, so that the complete expression for electric field in terms of potentials is

$$\mathbf{E} = -\nabla V - \partial \mathbf{A}/\partial t. \qquad (27)$$

The corresponding Maxwell equation is

$$\nabla \times \mathbf{E} = -\partial \mathbf{B}/\partial t. \qquad (28)$$

From (17) and (26) it follows that any circuit with a changing current will induce an emf in any neighboring circuit, or in itself. In the latter case, the negative sign in (26) guarantees that the induced emf will oppose the current changes producing it (*Lenz' Law*). We have

$$\mathcal{E}_{jk} = -M_{jk}\, dI_k/dt \qquad (29)$$

for the emf in circuit j produced by a changing current in circuit k, where M_{jk} is the *mutual inductance* and obeys the rule $M_{jk} = M_{kj}$. *Self-inductance L* is defined by the analogous relation

$$\mathcal{E} = -L\, dI/dt. \qquad (30)$$

It may be shown that the magnetic energy in a collection of circuits is

$$U = \tfrac{1}{2}\sum_k L_k I_k{}^2 + \tfrac{1}{2}\sum_{k,j} M_{kj} I_k I_j \qquad (31)$$

which can be written as an integral over the volumes of all the wires

$$U = \tfrac{1}{2}\int_{\text{wires}} \mathbf{J} \cdot \mathbf{A}\, d\tau \qquad (32)$$

and over all space as

$$U = \frac{1}{2\mu_0}\int_{\text{space}} B^2\, d\tau. \qquad (33)$$

14. *Relative Motion.* From (2) it is easy to see that if the source of **B** moves at $-\mathbf{v}$ and q remains at rest, the moving source must create an electric field at the position of q:

$$\mathbf{E}' = \mathbf{v} \times \mathbf{B}. \qquad (34)$$

From (16) it is easy to see that if a collection of charges which creates a field **E** at a point is all set into motion at a common speed **v**, the moving source of **E** creates a **B**$'$ according to

$$\mathbf{B}' = \mu_0\epsilon_0 \mathbf{v} \times \mathbf{E}. \qquad (35)$$

Motion of Charges in Matter

1. *Solids.* (a) Levels for the electrons in solids that take part in binding lie in continuous bands separated by finite gaps. Because electrons are fermions with spin $\frac{1}{2}$, each level can hold at most two electrons; at equilibrium each band is filled up from the bottom. The average energy of a group of electrons added to or removed from a solid is called the *Fermi level* (F.l.) and lies essentially at the top of the filled group of levels. A change in the electric potential of a region in the piece of matter by ΔV will change the F.l. by $-e\Delta V$.

(b) A conductor has its F.l. below the top of a partly filled band called the conduction band. When a gradient $\nabla V = -\mathbf{E}$ is established in the conductor, the gradient in F.l. causes electrons to jump freely into slightly higher levels corresponding to motion in the direction of $-\mathbf{E}$, thus producing a current density

$$\mathbf{J} = \sigma_c \mathbf{E} \qquad (36)$$

where σ_c is the conductivity. Eq. (34) is a form of *Ohm's Law*. Applied to a wire of length l and cross-section S, (36) becomes

$$V = \int_0^l \mathbf{E} \cdot d\mathbf{l} = I\int_0^l \frac{dl}{\sigma S} = IR \qquad (37)$$

where R is the resistance and V is the potential drop along the wire. The power dissipated into electron transitions at crystal imperfections is $IV = I^2R$. This power can be proved (Poynting theorem) to enter the segment of wire through the sides, not the ends.

No current in a conductor implies $\mathbf{J} = \sigma\mathbf{E} = 0$ in the interior of the conductor, which becomes an equipotential volume. By (7), ρ also becomes zero in the interior; any net charge on the conductor must reside on its surface. Application of Gauss' law to a surface in the material surrounding an empty cavity in the conductor shows that there can be no charge on the inside surface and no field in the cavity. The potential in such a cavity must therefore be the same as the potential of the conductor found by use of (8), and will be called the *cavity potential*.

(c) A thin wire carrying steady current must have $\mathbf{J}$ and $\mathbf{E}$ within it parallel to it sides. The surface charges of its distributed capacitance must move with $\mathbf{J}$. They are locally responsible for a normal component of $\mathbf{E}$ outside the wire, and over the whole circuit are the main sources of the field both inside and outside the conductors.

(d) The energy difference per unit charge between the F.l. and a point in a field-free cavity in the conductor is called the *work function* ϕ of the solid. When two conductors of the same cavity potential and differing ϕ's are placed in electrical contact, electrons will transfer toward the lower of the two F.l.'s until the F.l.'s come to equality with a difference $\Delta V = \Delta\phi$ between the two potentials, which is the *contact potential difference*. (See Fig. 4.)

(e) When a temperature gradient exists in a conductor, the varying extent of thermal electron jumps will tend to cause a current. Ohm's law becomes

$$\mathbf{J} = \sigma(-\nabla V + S^*\nabla T) \qquad (38)$$

where S^*, the *entropy transport per unit charge*, is responsible for thermoelectricity. (See THERMOELECTRICITY.)

(f) An insulator has all the levels of one band filled and a substantial gap below the next, empty band. The presence of a small field $\mathbf{E}$ will shift electrons only within molecular distances, creating dipoles in the phenomenon of dielectric polarization. (See DIELECTRIC THEORY.) A sufficiently large $\mathbf{E}$ may transfer some electrons to the empty band and provide them enough energy of motion to cause dielectric breakdown.

(g) A semiconductor is an insulator with a narrow interband gap, which contains either donor levels from atoms with excess electrons not covalently bound, or acceptor levels requiring the addition of electrons to satisfy their covalent bonds. In the former case (n-type) the donated electrons are readily lifted into conductor levels, above the gap, and in the latter (p-type) the residual "holes" become transferred down to the filled band and function as positive carriers. (See SEMICONDUCTORS.)

2. *Aqueous liquids* are like insulators in having no accessible levels corresponding to macroscopic electron transfer. However, electrons can transfer between molecules or atoms, and the resulting positive and negative ions are free to move under the influence of an electric field. The conductivity of a positive or negative ionic species is expressed by

$$v_\pm = \pm u_\pm E \quad \text{and} \quad J_\pm = neZ_\pm v_\pm \qquad (39)$$

where $v_\pm$ is the *ionic velocity*, $u_\pm$ the *mobility*, E the local field intensity, Z the *valence*, n the *ionic density*, and $J_\pm$ the partial current density due to one positive or negative species.

In a liquid with a particular ionic constitution there is always a highest occupied electron level and a lowest empty one. If a metallic electrode is inserted, equilibrium will generally be established between one of these levels and the Fermi level in the metal; the electron transfer between phases often results in deposition of neutral atoms on the metal or removal from the metal. The F.l. of the electrode thus takes up a definite position in relation to the cavity potential

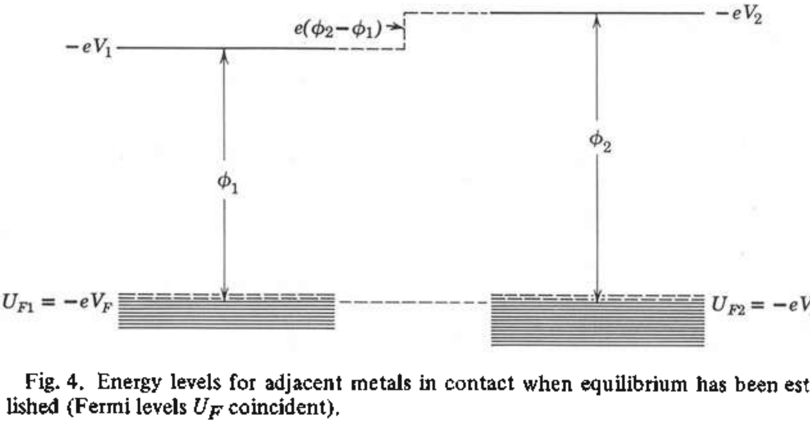

Fig. 4. Energy levels for adjacent metals in contact when equilibrium has been established (Fermi levels U_F coincident).

of the solution. A *cell* is an arrangement with two electrodes in which a solution has two different constitutions at the electrodes that are capable of reacting by electron transfer but cannot react directly with each other because of physical separation. The two electrode F.l.'s came to different positions in relation to the solution cavity potential, the difference being the electomotive force (emf) $\mathcal{E}$ of the cell.

When current passes through a cell, the suppressed reaction can proceed via electron transfer through the outer circuit. Owing to internal resistance r in the cell, the external potential or F.l. difference becomes $V = \mathcal{E} - Ir$. The amount of reaction at either electrode is such that one mole of reactant of valence Z will be deposited or dissolved when the charge transferred is $Q = It = N_A Ze$, an expression of Faraday's laws of electrochemistry. The transition between two or more types of current carriers in the solution and one type only at the electrode is accomplished by the occurrence of diffusion processes.

3. In *gases*, electrons can move freely between molecules once knocked loose by molecular collision or by energetic charged particles. Local fields will accelerate electrons and ions in between collisions. A field strength of about 3×10^6 v/m is enough to initiate a breakdown in air at S.T.P. by allowing electrons to gain enough energy between collisions to ionize more molecules. Somewhat lesser fields can render a gas partially conducting. In a highly ionized condition, the gas becomes a plasma (PLASMA).

Electrostatic phenomena of charge transfer make use of gaseous conduction, of charge redistribution in conductors under the influence of fields, and of forces exerted on the charges that reside on the surfaces of conductors. For the production of fields by charges moving at relativistic velocities, see PROPAGATION OF ELECTROMAGNETIC WAVES.

ELECTROACOUSTICS

Introduction Electroacoustics is concerned with the transduction of acoustical to electrical energy and vice versa. Devices which convert acoustical signals into electrical signals are referred to as *microphones* or *hydrophones* depending on whether the acoustic medium is air or water. Devices which convert electrical signals into acoustical waves are referred to as *loudspeakers* (or *earphones*) in air and *projectors* in water.

Transduction Mechanisms *Piezoelectricity* Certain crystals produce charge on their surfaces when strained and conversely become strained when placed in an electric field. Important piezoelectric crystals include quartz, ADP, lithium sulfate, rochelle salt, and tourmaline. Lithium sulfate and tourmaline are *volume expanders*, that is, their volume changes when subjected to an electric field in the proper direction. Such crystals can detect hydrostatic pressure directly. Crystals which are not volume expanders must have one or more surfaces shielded from the pressure field in order to convert the pressure to a uniaxial strain which can be detected. Tourmaline is relatively insensitive and used primarily in blast gauges. Quartz is used principally in high-Q ultrasonic transducers.

Certain ceramics such as lead zirconate titanate (PZT), barium titanate, and lead metaniobate become piezoelectric when polarized. They exhibit relatively high electromechanical coupling, are capable of producing very large forces, and are used extensively as sources and receivers for underwater sound. PZT and barium titanate have only a small volume sensitivity hence must have one or more surfaces shielded in order to detect sound efficiently. Piezoelectric ceramics have extraordinarily high dielectric coefficients and hence high capacitance and are thus capable of driving long cables without preamplifiers.

Recently, it has been discovered that certain polymers, notably polyvinylidene fluoride, are piezoelectric when stretched. Such piezoelectric polymers are finding use in directional microphones and ultrasonic hydrophones.

Magnetostriction Some ferromagnetic materials become strained when subjected to a magnetic field. The effect is quadratic in the field so a bias field or dc current is required for linear operation. Important magnetostrictive metals and alloys include nickel and permendur. At one time, magnetostrictive transducers were used extensively in active sonars but have now been largely replaced by ceramic transducers. Magnetostrictive transducers are rugged and reliable but inefficient and configurationally awkward. Recently, it has been discovered that certain rare earth iron alloys such as terbium-dysprosium-iron possess extremely large magnetostrictions (as much as 100 times that of nickel). They have relatively low eddy current losses but require large bias fields, are fragile, and have yet to find significant applications. Metallic glasses have also recently been considered for magnetostrictive transducers.

Electrodynamics Electrodynamic transducers exploit the forces produced on a current-carrying conductor in a magnetic field and, conversely, the currents produced by a conductor moving in a magnetic field. Direct-radiation moving-coil transducers dominate the loudspeaker field. Prototypes of high power underwater projectors have been constructed using superconducting magnets. Electrodynamic microphones, particularly the directional ribbon microphones, are also common.

Electrostatics Electrostatic sources utilize the force of attraction between charged capacitor plates. The force is independent of the sign of the voltage so a bias voltage is necessary for linear operation. The forces are relatively weak so a large area is needed to obtain significant acoustic output. The effect is reciprocal, with the change in the separation of the plates (i.e., the capacitance) produced by an incident acoustic pressure generating a voltage. The impedance of a condenser microphone, however, is high, so a preamplifier located close to the sensor is required. Condenser microphones are very flat and extremely sensitive. The change in capacitance induced by an acoustic field can also be detected by making the capacitor a part of a bridge circuit, or alternatively part of an oscillator circuit. The acoustic signal will then appear as either an amplitude or frequency modulation of some ac carrier. The charge storage properties of electrets have been exploited to produce electrostatic microphones which do not require a bias voltage.

Magnetism Magnetic transducers utilize the force of attraction between magnetic poles and, reciprocally, the voltages produced when the reluctance of a magnetic circuit is changed. Magnetic speakers are used extensively in telephone receivers.

Hydraulics Nonreversible, low frequency, high power underwater projectors can be constructed utilizing hydraulic forces acting to move large pistons. Electroacoustic transduction is achieved by modulating the hydraulic pressure with a spool valve actuated by an electrostrictive (PZT) stack.

Fiber Optics An acoustic field acting on an optical fiber will change the optical path length by changing the length and index of refraction of the fiber. Extremely sensitive hydrophones and microphones can be made by using a fiber exposed to an acoustic field as one leg of an optical interferometer. Path length changes of the order of 10^{-6} optical wavelengths can be detected. The principal advantages of such sensors are their configurational flexibility, their sensitivity, and their suitability for use with fiber optic cables. Fiber optic sensors which utilize amplitude modulation of the light (microbend transducers) are also being developed.

Parametric Transducers The nonlinear interaction of sound waves can be used to produce highly directional sound sources with no side lobes and small physical aperture. In spite of their inherent inefficiency, substantial source levels can be achieved and such "parametric sonars" have found a number of underwater applications. Parametric receivers have also been investigated but practical applications have yet to be found.

Carbon Microphones Carbon microphones utilize a change in electrical resistance with pressure and are used extensively in telephones.

Sensitivty and Source Level A microphone or hydrophone is characterized by its free-field voltage sensitivity M, which is defined as the ratio of the output voltage E to the free-field amplitude of an incident plane acoustic wave. That is, for an incident wave which *in the absence of the transducer* is given by

$$P = P_0 \cos(\mathbf{k} \cdot \mathbf{R} - \omega t), \tag{1}$$

M is defined by

$$M = E/P_0. \tag{2}$$

In general M will be a function of frequency and the orientation of the transducer with respect to the wave vector k (i.e., the direction of incidence of the wave). Thus, for a given frequency, M is proportional to the directivity of the transducer. It is usually desirable for a microphone or hydrophone to have a flat (i.e., frequency independent) free field voltage sensitivity over the broadest possible range of frequencies to assure fidelity of the output electrical signal.

A loudspeaker or projector is characterized in a similar manner by its transmitting current response S which is defined as the ratio of the acoustic source level to the driving current I. In the farfield of a transducer the acoustic pressure is a spherical wave which can be expressed as

$$P(R) = P_s(\theta, \phi)\,(R_0/R) \cos(kR - \omega t) \tag{3}$$

where θ and ϕ are elevation and azimuth angles and R_0 an arbitrary reference distance (usually 1 meter). $P_s(\theta, \phi)$ is defined as the source level. Thus S is given by

$$S = P_s(\theta, \phi)/I \tag{4}$$

which is a function of θ and ϕ and the frequency ω. For high fidelity sound reproduction S should be as flat as possible over the broadest possible bandwidth. For some purposes, however, such as ultrasonic cleaning or long range underwater acoustic propagation, fidelity is unnecessary and high-Q resonant transducers are employed to produce high intensity sound over a narrow bandwidth.

Reciprocity Most conventional transducers are *reversible*, that is, they can be used as either sources or receivers of sound (a carbon microphone and a fiber optic hydrophone are examples of transducers which are *not* reversible). A transducer is said to be *linear* if the input and output variables are linearly proportional (hot-wire microphones and unbiased magnetostrictive transducers are examples of *nonlinear* transducers). A transducer is said to be *passive* if the only source of energy is the input electrical or acoustical signal (a microphone with a built in preamplifier and a parametric receiver are examples of *nonpassive* transducers). Most transducers which are linear, passive and reversible exhibit a remarkable property called *reciprocity*. For a *reciprocal* transducer of any kind (moving coil, piezoelectric, magnetostrictive, electrostatic, magnetic etc.) the ratio of the free field voltage sensitivity to the transmitting current response is equal to the reciprocity factor J, which is independent of the geometry and construction of the transducer. That is:

$$\frac{M(\omega, \theta, \phi)}{S(\omega, \theta, \phi)} = J(\omega) = \frac{4\pi R_0}{\rho_0 \omega} \tag{5}$$

where ρ_0 is the density of the medium and R_0 is the reference distance used in defining the source level. Equation (5) has a number of useful consequences: (1) the receiving and transmitting beam patterns of a reciprocal transducer are identical, (2) a transducer cannot be simultaneously flat as a receiver and transmitter since S has an additional factor of ω, and (3) Eq. (5) provides the basis for the three transducer reciprocity calibration technique whereby an absolute calibration of a hydrophone or microphone can be obtained from purely electrical measurements.

Canonical Equations and Electroacoustic Coupling Simple acoustic transducers can be characterized by the following canonical equations:

$$E = Z_e I + T_{em} V \tag{6}$$

$$F = T_{me} I + Z_m V \tag{7}$$

where V is the velocity of the radiating or receiving surface, F is the total force acting on the surface (including acoustic reaction forces), Z_e is the blocked ($V = 0$) electrical impedance, Z_m is the open circuit mechanical impedance and T_{em} and T_{me} are the electromechanical coupling coefficients. For reciprocal transducers $T_{em} = \pm T_{me}$. For example, for a moving coil transducer where the "motor" is a coil in a radial magnetic field B,

$$T_{em} = -T_{me} = BL \tag{8}$$

where L is the length of the wire in the coil and the electrical impedence Z_e is largely inductive. For a piston transducer with a piezoelectric "motor"

$$T_{me} = T_{em} = -id_{33}/(\epsilon^T s\omega) \tag{9}$$

where d_{33} is the piezoelectric strain coefficient, s is the compliance, ϵ^T is the permittivity at constant stress, and the electrical impedance Z_e is largely capacitive.

If a piston transducer is placed in an acoustic field such that the average pressure over the surface of the piston is P_B then $F = P_B A$, where A is the area of the piston, and for a receiver $I = 0$, so

$$E = (T_{em} A/Z_m) P_B. \tag{10}$$

If the transducer is small compared with an acoustic wave length $P_B \approx P_0$ (in general $P_B = DP_0$, where D is the diffraction constant) and the free field voltage sensitivity is given by

$$M = T_{em} A/Z_m. \tag{11}$$

From Eq. (5) the transmitting current response is

$$S = \frac{\rho_0 \omega T_{em} A}{4\pi R_0 Z_m}. \tag{12}$$

From these simple considerations a number of principles of practical transducer design can be deduced. The mechanical impedance Z_m is in general given by

$$Z_m = \frac{K_m}{i\omega} + i\omega M + R_m \tag{13}$$

where K_m is an effective spring constant, M the mass, and R_m the mechanical resistance. For a piezoelectric transducer (Eq. (9)) T_{em} is inversely proportional to frequency, hence from Eqs. (10) and (11) we see that a piezoelectric transducer will have a flat receiving sensitivity below resonance (i.e., where its behavior is controlled by stiffness). On the other hand a moving coil microphone must have a resistive mechanical impedance to have a flat response. From Eq. (12) we derive the fundamental tenet of loudspeaker design, that a moving coil loudspeaker will have a flat transmitting current response above resonance (i.e., where it is mass controlled). Accordingly, moving coil loudspeakers are designed to have the lowest possible resonant frequency (by means of a high compliance, since the output is inversely proportional to the mass) and piezoelectric hydrophones are designed to have the highest possible resonant frequency.

An interesting and important consequence of electromechanical coupling is the effect of the motion of the transducer on the electrical impedance. In the absence of external forces (including radiation reactance) from Eqs. (6) and (7)

$$E = \left(Z_e - \frac{T_{em}T_{me}}{Z_m}\right) I. \qquad (14)$$

That is, the electrical impedance has a "motional" component given by $T_{em}T_{me}/Z_m$. The motional component can be quite significant near resonance where Z_m is small. This effect is the basis of crystal controlled oscillators.

Radiation Impedance An oscillating surface produces a reaction force F_R on its surface given by

$$F_R = -Z_R V \qquad (15)$$

where Z_R is the radiation impedance. We can thus rewrite Eq. (7) as

$$F_{\text{ext}} = T_{em} I + (Z_R + Z_m) V \qquad (16)$$

where F_{ext} now includes only external forces. For an acoustically small baffled circular piston of radius a,

$$Z_R = \pi a^4 \rho_0 \omega^2 / 2c - i(8/3)\omega\rho_0 a^3. \quad (17)$$

The radiation impedance thus has a masslike reactance with an equivalent "radiation mass" of $(8/3)\rho_0 a^3$ and a small resistive component proportional to ω^2 responsible for the radiated power. A transducer will thus have a lower resonant frequency when operated underwater than when operated in air or vacuum. The total radiated power of the piston transducer is given by

$$\mathcal{P} = R_e Z_R \left|V\right|^2 = (\pi a^4 \rho_0 \omega^2 / 2c) V^2. \quad (18)$$

Most transducers are displacement limited so for a direct radiating transducer V in Eq. (18) is limited. To obtain the most output power the piston should have the largest possible surface area consistent with keeping the transducer omnidirectional (the transducer will become directional when $a \gtrsim \lambda$). This is easy to do in air but difficult in water, since it is hard to make pistons which are both lightweight and stiff enough to hold their shape in water. Alternatively, the driver can be placed at the apex of a horn. For a conical horn the fluid velocity at end of the horn (where the radius is a_e) will be reduced to $V(a/a_e)$ but the radiating piston will now have an effective radius of a_e so the radiated power will increase by a factor of $(a_e/a)^2$ For high power operation at a single frequency the driver can be placed at the end of a quarter wave resonator.

Directivity It is often desirable for transducers to be directional. Directional sound sources are needed in diagnostic and therapeutic medical ultrasonics, for acoustic depth sounders and to reduce the power requirements and reverberation in active sonars, etc. Directional microphones are useful to reduce unwanted noise (e.g., to pick up the voice of a speaker and not the audience), directional hydrophones or hydrophone arrays increase signal-to-noise and aid in target localization. One way to achieve directionality is to make the radiating surface large. A baffled circular piston has a directivity given by

$$D_\theta = 2J_1(ka \sin\theta)/ka \sin\theta \qquad (19)$$

D_θ equals unity for $\theta = 0$ and $\frac{1}{2}$ when $ka \sin\theta = 2.2$. For small values of ka, D_θ is near unity for all angles.

Some transducers respond to the gradient of the acoustic pressure rather than pressure, for example, the ribbon microphone which works by detecting the motion of a thin conducting strip orthogonal to a magnetic field. Such transducers have a directivity which is dipole in nature, i.e.,

$$D_\theta = \cos\theta. \qquad (20)$$

Note that since the force in this case is proportional not to P_0 but to kP_0, a ribbon microphone (which like a moving coil microphone is electrodynamic) will have flat receiving sensitivity when its impedance is mass controlled. By combining a dipole receiver with a monopole receiver one obtains a unidirectional cardioid receiver with

$$D_\theta = (1 + \cos\theta) \qquad (21)$$

ELECTROCHEMISTRY

Electrochemistry is that branch of science which deals with the interconversion of chemical and electrical energies, i.e., with chemical changes produced by electricity as in electrolysis or with the production of electricity by chemical action as in electric cells or batteries. The science of electrochemistry began about the turn of the eighteenth century. In 1796 Alessandro Volta observed that an electric current was produced if unlike metals separated by paper or hide moistened with water or a salt solution were brought into contact. Volta used the sensation of pain to detect the electric current. His observation was similar to that observed ten years earlier by Luigi Galvani who noted that a frog's leg could be made to twitch if copper and iron, attached respectively to a nerve and a muscle, were brought into contact.

In his original design Volta stacked couples of unlike metals one upon another in order to increase the intensity of the current. This arrangement became known as the "voltaic pile." He studied many metallic combinations and was able to arrange the metals in an "electromotive series" in which each metal was positive when connected to the one below it in the series. Volta's pile was the precursor of modern batteries (see BATTERIES).

In 1800 William Nicholson and Anthony Carlisle decomposed water into hydrogen and oxygen by an electric current supplied by a voltaic pile. Whereas Volta had produced electricity from chemical action these experimenters reversed the process and utilized electricity to produce chemical changes. In 1807 Sir Humphry Davy discovered two new elements, potassium and sodium, by the electrolysis of the respective solid hydroxides, utilizing a voltaic pile as the source of electric power. These electrolytic processes were the forerunners of the many industrial electrolytic processes used today to obtain aluminum, chlorine, hydrogen, or oxygen, for example, or in the electroplating of metals such as silver or chromium.

Since in the interconversion of electrical and chemical energies, electrical energy flows to or from the system in which chemical changes take place, it is essential that the system be, in large part, conducting or consist of electrical conductors. These are of two general types—electronic and electrolytic—though some materials exhibit both types of conduction. Metals are the most common electronic conductors. Typical electrolytic conductors are molten salts and aqueous solutions of acids, bases, and salts. Owing, in general, to the low solubility and ionization of solutes in nonaqueous solvents, ethyl alcohol for example, nonaqueous solutions usually have much lower electrical conductivity than aqueous systems and as a consequence find less use in electrochemical applications. Molten salts, on the other hand, are ionic fluids, freely mix, and have high electrical conductivity but are restricted to electrochemical uses at high temperatures.

A current of electricity in an electronic conductor is due to a stream of electrons, particles of subatomic size, and the current causes no net transfer of matter. The flow is, therefore, in a direction contrary to what is conventionally known as the "direction of the current." In electrolytic conductors, the carriers are charged particles of atomic or molecular size called *ions*, and under a potential gradient, a transfer of matter occurs.

An electrolytic solution contains an equivalent quantity of positively and negatively charged ions whereby electroneutrality prevails. Under a potential gradient, the positive and negative ions move in opposite directions with their own characteristic velocities and each accordingly carries a different fraction of the total current through any one solution. Each fraction is referred to as the ionic transference number. Furthermore, the velocity increases with temperature causing a corresponding increase in electrolytic conductivity. This characteristic is opposite to that observed for most electronic conductors which show less conductivity as their temperature is increased.

The concept that charged particles are responsible for the transport of electric charges through electrolytic solutions was accepted early in the history of electrochemistry. The existence of ions was first postulated by Michael Faraday in 1834; he called negative ions "anions" and positive ones "cations." In 1853, Hittorf showed that ions move with different velocities and exist as separate entities and not momentarily as believed by Faraday. In 1887, Svante Arrhenius postulated that solute molecules dissociated spontaneously into *free ions* having no influence on each other. However, it is known that ions are subject to coulombic forces, and only at infinite dilution do ions behave ideally, i.e., independently of other ions in the solution. Ionization is influenced by the nature of the solvent and solute, the ion size, and solute-solvent interaction. The dielectric constant and viscosity of the solvent play dominant roles in conductivity. The higher the dielectric constant, the less are the electrostatic forces between ions and the greater is the conductivity. The higher the viscosity of the solvent, the greater are the frictional forces between ions and solvent molecules and the lower is the electrolytic conductivity.

In 1923 Debye and Hückel presented a theory which took into account the effect of coulombic forces between ions. They introduced the concept of the ion atmosphere, or continuous charge distribution, which is a continuous function of r, the radial distance from a central or reference ion rather than a discrete or discontinuous charge distribution. The ion atmosphere acts electrostatically somewhat like a sphere of charge $-\epsilon$ at some average distance from a central or reference ion of charge $+\epsilon$, with the value of the average distance approximating that of the ionic radii of ionic crystals. This interionic attraction leads to two effects on the electrolytic conductivity. Under a potential gradient, an ion moves in a certain direction. However, the ion cloud, being of opposite sign will tend to move in the opposite direction, and because of its attraction for the central ion, will have a retarding effect on the ion velocity and thereby lead to a lowering in the electrolytic conductivity. On the other hand, the central ion will tend to pull the ion cloud with it to a new location. The ion atmosphere will adjust to its new location in time, but not instantaneously, and the delay results in a dissymmetry in the potential field around the ion. This also causes a lowering in the conductance of the solution. These effects become more pronounced as the concentration of the solution is increased; for dilute solutions, below about 0.1 molal, the equivalent conductance decreases with the square root of the concentration. For more concentrated solutions, the relation between conductivity and concentration is much more complex and depends more specifically on individual solute properties.

Interionic attraction in dilute solutions also leads to an effective ionic concentration or activity which is less than the stoichiometric value. The *activity* of an ion species is its thermodynamic concentration, i.e., the ion concentration corrected for the deviation from ideal behavior. For dilute solutions the activity of ions is less than one, for concentrated solutions it may be greater than one. It is the ionic activity that is used in expressing the variation of electrode potentials, and other electrochemical phenomena, with composition.

When electricity passes through a circuit consisting of both types of electrical conductors, a chemical reaction always occurs at their interface. These reactions are electrochemical. When electrons flow from the electrolytic conductor, oxidation occurs at the interface while reduction occurs if electrons flow in the opposite direction. These electronic-electrolytic interfaces are referred to as *electrodes*; those at which oxidation occurs are known as *anodes* and those at which reduction occurs, as *cathodes*. An anode is also defined as that electrode by which "conventional" current enters an electrolytic solution, a cathode as that electrode by which "conventional" current leaves. Positive ions, for example, ions of hydrogen and the metals, are called *cations* while negative ions, for example, acid radicals and ions of nonmetals are called *anions*.

In 1833, Michael Faraday enunciated two laws of electrolysis which give the relation between chemical changes and the product of the current and time, i.e., the total charge (coulombs) passed through a solution. These laws are: (1) the amount of chemical change, e.g., chemical decomposition, dissolution, deposition, oxidation, or reduction, produced by an electric current is directly proportional to the quantity of electricity passed through the solution; (2) the amounts of different substances decomposed, dissolved, deposited, oxidized, or reduced are proportional to their chemical equivalent weights. A chemical equivalent weight of an element or a radical is given by the atomic or molecular weight of the element or radical divided by its valence; the valence used depends on the electrochemical reaction involved. The electric charge on an ion is equal to the electronic charge or some integral multiple of it. Accordingly, a univalent negative ion has a charge equal in magnitude and of the same sign as a single electron, and its chemical equivalent weight is equal to its atomic weight, if an element, or to its molecular weight, if a radical. A trivalent ion has +3 or −3 electronic charges, depending on whether it is a positive or a negative trivalent ion. For trivalent ions, then, the equivalent weight would be equal to its atomic weight, if an element, or to its molecular weight, if a radical, divided by three.

The quantity of electricity required to produce a gram-equivalent weight of chemical change is known as the *faraday*. A faraday corresponds, then, to an *Avogadro number of charges*. The most accurate determination of the faraday has been made by a silver-perchloric acid coulometer in which the amount of silver electrolytically dissolved in an aqueous solution of perchloric acid is measured. This method gives 96487 coulombs (or ampere-seconds) per gram-equivalent for the faraday on the unified C^{12} scale of atomic weights.

The *electrochemical equivalent* or, preferably, the *coulomb equivalent* of an element or radical is that weight in grams which is equivalent to one coulomb of electricity and is given by the gram-equivalent weight divided by the faraday (96487 coulombs per gram-equivalent); for example, the electrochemical equivalent of silver is given by 107.870/96487 or 0.00111797 g/coulomb where 107.870 is the atomic weight of silver based on the unified C^{12} scale. The electrochemical equivalents of other elements may be calculated in like fashion.

In electrolysis and in any electric cell or battery, there is an electromotive force (emf) or voltage across the terminals. This emf is expressed in the practical unit, the volt, which is equal to the electromagnetic unit in the meter-kilogram-second system. In any one cell, the emf is the sum of the potentials of the two electrodes and of any liquid-junction potentials that may be present. Neither of the individual electrode potentials can be evaluated without reference to a chosen reference electrode of assigned value. For this purpose, the hydrogen electrode has been universally adopted and is arbitrarily assigned a zero potential for all temperatures when the hydrogen ion is at unit activity and the hydrogen gas is at atmospheric pressure. A hydrogen electrode consists of a stream of hydrogen gas bubbling over platinized platinum or gold foil and immersed in a solution containing hydrogen ions; the electrochemical reaction is: $1/2H_2(\text{gas}) = H^+(\text{solution}) + \epsilon$, where ϵ represents the electron. The potential of the hydrogen electrode, E_H, as a function of hydrogen-ion concentration and hydrogen-gas pressure is given by

$$\begin{aligned} E_H &= E_H{}^0 - (RT/nF)\ln(a_{H^+}/p_{H_2}{}^{1/2}) \\ &= E_H{}^0 - (RT/nF)\ln(c_{H^+}f_{H^+}/p_{H_2}{}^{1/2}). \end{aligned}$$

where $E_H{}^0$ is the standard quantity assigned a value of zero, R is the gas constant, T the absolute temperature, n the number of equivalents, F the faraday, p_{H_2} the pressure of hydrogen, and a_{H^+}, c_{H^+} and f_{H^+}, respectively, the activity, concentration, and activity coefficient of hydrogen ions. When a_{H^+} and $p_{H_2}{}^{1/2}$ equal one, $E_H = E_H{}^0$. For very dilute solutions below 0.01 molal f_{H^+} may be taken as unity without appreciable error.

The standard potentials, E^0, of other electrodes are obtained by direct or indirect comparison with the hydrogen electrode. Values thus obtained at 25°C for some typical elements are listed in Table 1.

The reducing power of the elements decreases on going down the column. These values are for the ions at unit activity, and reversible or thermodynamic values as a function of metal or radical concentration are given by equations similar to the one above. For the general reaction: $M = M^{n+} + n\epsilon$, the potential is given by $E_M = E_M{}^0 - (RT/nF)\ln a_M{}^{n+}$.

In electrolysis, at very low current densities, the potentials of the electrodes approximate in magnitude their reversible values and deviate somewhat from these values because of an *IR* drop in the solution and possible concentration polarization (the concentration at the electrode surface may differ from that in the bulk of the solution). Also for high current densities, especially for the generation of gases such as hydrogen, oxygen or chlorine, the voltage required exceeds the reversible voltage; the excess voltage is known as overvoltage, or overpotential for a single electrode, and arises from energy barriers at the electrode. Overpotential, in general, increases logarithmically with an increase in current density.

The electrochemistry of the solid state is similar in many ways to that of aqueous solutions. The basic problems of ionic crystals can be treated in many cases by analogy to aqueous solutions. Differences do occur. In silver halides, for example, practically only cations are mobile, while in lead chloride and bromide only anionic conduction occurs. Mixed conductance, in that both anions and cations migrate, is exhibited by alkali halides and lead iodide. Other solids at temperatures below about 600°C, cuprous oxide for example, show only electronic migration, while above this temperature they exhibit in addition some cationic conduction. Ionic conduction in the solid state is attributed superordinately to lattice defects. Even for pure substances lattice defects which may contribute to the electrical conductivity may be due to interstitial cations, cation vacancies, interstitial anions, anion vacancies, excess electrons, or electron holes. Conduction occurs, for instance, when a cation in one interstitial site jumps to an adjacent interstitial site. Lattice defects in pure substances may be artificially produced by trace doping with an unlike substance of proper characteristics. When, for example, silicon, a semiconductor with four valence electrons, is doped with a five-valence-electron element, such as antimony, arsenic, or phosphorus, loosely bound electrons are introduced into the lattice of silicon which are free to migrate leading to electrical conduction. Such a semiconductor is known as an *n*-type. A *p*-type semiconductor is produced if silicon is doped with a three-valence-electron element, such as boron, indium, or gallium, whereby a hole in

the silicon lattice is produced which can move about and impart conductivity.

The passage of electricity through gases is sometimes included under electrochemistry. However, in electrical discharges in gases, the principles are entirely different from what they are in the electrolysis of electrolytic solutions. Whereas in the latter, ionic dissociation occurs spontaneously as a result of forces between solvent and solute and without the application of an external field, for gases relatively high voltages must be applied to accelerate the electrons from the electrode to a velocity at which they can ionize the gas molecules they strike. In this case, the resulting chemical reaction taking place between ions, free radicals, and molecules occurs in the gas phase and not at the electrodes as in the electrolysis of solutions. Studies of the electrical conduction of gases, accordingly, are generally considered under the physics of gases.

In addition to the above topics, it is frequently customary to include under electrochemistry: (1) processes for which the net reaction is physical transfer, e.g., concentration cells; (2) electrokinetic phenomena, e.g., electrophoresis, electroosmosis, streaming potential; (3) properties of electrolytic solutions if determined by electrochemical or other means, e.g., activity coefficients and hydrogen-ion concentration; (4) processes in which electrical energy is first converted to heat which in turn causes a chemical reaction to occur that would not do so spontaneously at ordinary temperature. The first three are frequently considered a portion of physical chemistry, and the last one is a part of electrothermics or electrometallurgy.

Electrochemistry finds wide application. In addition to industrial electrolytic processes, electroplating, and the manufacture and use of batteries already mentioned, the principles of electrochemistry are used in chemical analysis, e.g., polarography, and electrometric or conductometric titrations; in chemical synthesis, e.g., dyestuffs, fertilizers, plastics, insecticides; in biology and medicine, e.g., electrophoretic separation of proteins, membrane potentials; in metallurgy, e.g., corrosion prevention, electrorefining; and in electricity, e.g., electrolytic rectifiers, electrolytic capacitors, Josephson junctions.

ELECTROLUMINESCENCE

Electroluminescence is a process which generates light in crystals by conversion of energy supplied by electric contacts, in the absence of incandescence, cathodo- or photoluminescence.

It occurs in several forms. The first observation of the presently most important form, "radiative recombination in *p-n* junctions," was made in 1907 by Round, then more thoroughly by Lossev from 1923 on, when point electrodes were placed on certain silicon carbide crystals and current passed through them. Explanation and improvement of this effect became possible only after the development of modern solid-state science since 1947.

If minority carriers are injected into a semiconductor, i.e., electrons are injected into a *p*-type material, or "holes" into *n*-type material, they recombine with the majority carriers, either directly via the bandgap, or through exciton states, or via impurity levels within the bandgap, thereby emitting the recombination energy as photons. Part of the recombinations occur nonradiatively, producing only heat.

Exploitation of the effect was strongly dependent on progress in compound semiconductor crystal preparation and solid-state electronics, since crystal perfection (absence of defects) is of prime importance. At present, single-crystalline dome-shaped *p-n* diodes made of gallium arsenide, GaAs, a "III-V compound" (from groups III and V of the periodic system), yield the highest efficiencies (40 percent of the electrical power input converted into optical power output) in the near-infrared, and diodes made of gallium phosphide, GaP, doped with oxygen and zinc, yield red and infrared light, efficiency peaked at 10 percent. GaP diodes doped with nitrogen emit green light, with .5 percent efficiency. Very important are alloys such as $In_xGa_{1-x}P$, $Al_xGa_{1-x}As$, and especially $GaAs_xP_{1-x}$ (red-emitting), where the color of luminescence can be changed by changing the composition. For high efficiency, it is important that the material have a "direct" bandgap, allow-

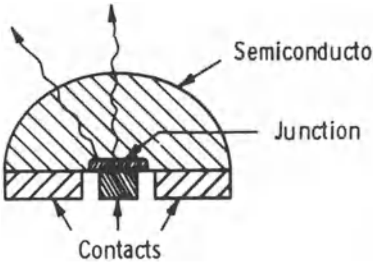

FIG. 1. Light-emitting diode.

ing electron-hole recombination without phonon participation. Wavelengths of light emitted by III-V crystals range from 6300 Å to 30 μ.

An important phenomenon, "injection laser action," was discovered in GaAs diodes in 1962. The crystal faces at the ends of a *p-n* junction are made optically parallel so as to form a Fabry-Perot optical cavity. Beyond a certain injection current density, (the "threshold current") the individual recombination processes no longer occur randomly and independently of each other, but in phase, so that a near-parallel beam of coherent light (~9000 Å) of enormous intensity (10^7 W/cm^2 in pulsed operation) is emitted. The efficiency has been improved by using graded bandgap $Al_xGa_{1-x}As$ heterojunctions and special doping profiles so that the lasing region near the *p-n* junction acts as a "light pipe," preventing light straying out sideways. AlAs has the same lattice constant as GaAs, yet higher bandgap. Therefore, these junctions are free of strain-generated imperfections. The current threshold for lasing is now reduced to 200 A/cm^2 at room temperature, allowing continuous operation at low total power, to prevent heating.

These coherent or incoherent electroluminescent *p-n* diodes are small point sources used for pilot lights, alpha-numeric readouts, optoelectronic processing, ranging systems, direct-sight communication, and as IR-lamps for night vision devices.

Another kind of electroluminescence, discovered by Destriau in 1936, uses inexpensive powders consisting of small particles of essentially copper-doped zinc sulfide, ZnS, a II-VI compound, embedded in an insulating resin and formed into a large flat plate capacitor with one plate transparent (e.g., SnO_2-coated glass). If an ac voltage is applied, light is emitted (blue, green, red, depending on the exact material composition) twice per cycle, with brightnesses up to thousands of foot-lamberts. Brightness increases linearly with drive frequency, and exponentially with voltage, until saturation occurs. The efficiency is about 1 percent but it decreases with increasing brightness.

Microscopic examination of the interior of an individual particle reveals that the light is emitted inhomogeneously, in the form of two sets of comet-like striations which light up alternatingly, each set once per cycle. These comets coincide with long, thin conducting copper sulfide precipitates which form along crystal imperfections. The applied field relaxes in these needles and concentrates at the tips, so that electrons and holes are alternatingly field-emitted into the surrounding insulating luminescent ZnS. The holes are trapped there until they recombine with the more mobile electrons, emitting the typical luminescent spectra. The local brightness can be as high as 10^5 foot-lamberts.

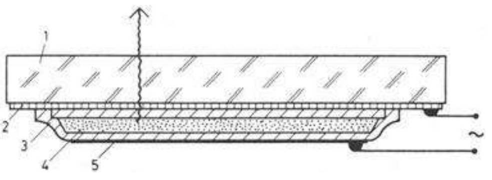

FIG. 3. AC-driven thin-film electroluminescent device. (1) Glass substrate; (2) transp. cond. In_2O_3-Sn front electrode; (3) insul. film of high permittivity; (4) ZnS:Mn EL film, ca. 500 nm thick; (5) black back electrode.

Instead of these powder particles embedded in an insulating resin one also uses contiguous, vacuum-evaporated or sputtered or epitaxially grown ZnS:Mn films sandwiched between similarly prepared inorganic insulator films (Fig. 3). With 150 volt, 5000 cps applied, yellow light emission (brightness up to 3000 fL) takes place twice per cycle in this ZnS:Mn film, due to multiple avalanche breakdown in close-spaced channels. The current is capacitively limited by the insulating films. The manganese centers are excited by impact with field-accelerated avalanche electrons. The optical contrast of these transparent film structures is increased by using black back electrodes which absorb the ambient light so that the addressed segments stand out bright against the black background even in sunlight. The operational longevity of these film structures is

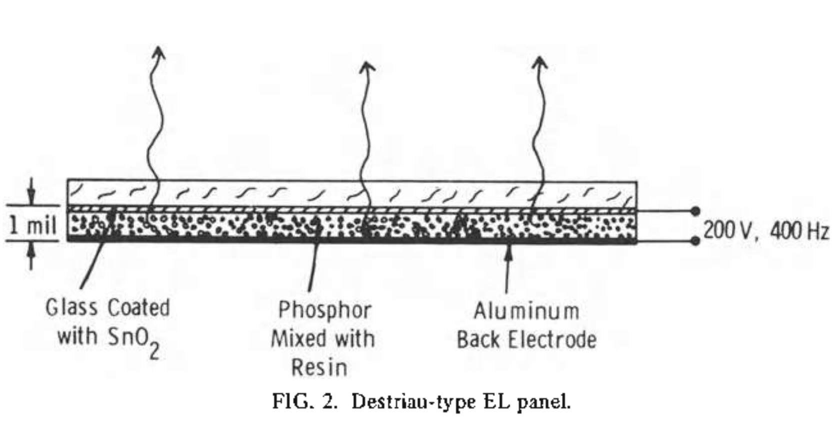

FIG. 2. Destriau-type EL panel.

very good, probably owing to the absence of copper doping.

Low voltage dc-driven-electroluminescence of polycrystalline films of ZnS on glass, doped with copper and manganese, has also been achieved. The mechanism involves high-field-aided hole injection. The operation with DC simplifies the addressing of multi-element display panels. Longevity is still not satisfactory. However, operation with low-voltage DC instead of high-voltage AC would be very desirable to simplify the addressing of multi-element displays.

Simpler to produce in large areas are DC-EL layers consisting of ZnS:Mn particles coated with conducting copper sulfide. They are held together by a minimum of organic binder so that there are many random interparticle contacts. During a "forming" process, the copper sulfide diffuses away from the ZnS particle surfaces that get the warmest, creating a high voltage drop there, with the concomitant appearance of electroluminescence owing to avalanche injection at conducting spikes. The copper-sulfide-coated particles before and behind the light-emitting ones act as current-limiting series resistors to prevent local breakdown. This is a requirement for all DC-EL devices, just as the capacitive current limitation is a requirement for all AC-EL devices. By using rare earth doping instead of manganese, and CaS host material instead of ZnS, blue, green and red emission has been achieved also (Fig. 4).

The latest advance is a combination of the most desirable features such as low DC voltage operation, and high contrast in bright ambient due to black back electrodes. This requires film structures, not powder layers. It consists of an *n*-type conducting, luminescent film of II-VI material on a transparent conducting front glass substrate, backed by a resistive *p*-type cermet layer which provides multiple hole-injecting contacts, current limitation, and black background. Such EL area sources are of great interest for use in luminous dials, instrument faces, alphanumeric computer readouts, and ultimately in flat image display panels (Fig. 5).

ELECTROMAGNETIC THEORY

The task of electromagnetic theory is to account for the effects of electrical charges in various states of motion. Although historically electromagnetic theory was developed from Coulomb's celebrated law, it is at present more economic to develop it differently.[11,12] The macroscopic effects are described with remarkable accuracy by the following set of equations (rationalized mks system of units)

$$\mathbf{F} = q\mathbf{E} + q\mathbf{v} \times \mathbf{B} \qquad (1)$$

$$\nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t} = 0 \qquad (2)$$

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} + \mathbf{J} \qquad (3)$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (4)$$

$$\mathbf{D} = f_1(\mathbf{E}) \quad (5)$$

$$\mathbf{B} = f_2(\mathbf{H}) \quad (6)$$

$$\mathbf{J} = f_3(\mathbf{E}, \mathbf{H}) \quad (7)$$

provided the functional relationships indicated in Eqs. (5), (6), and (7) are known explicitly. With these equations and the laws of mechanics, classical electromagnetic theory becomes essentially a branch of applied mathematics.

Equation (1), sometimes known as the Lorentz force equation, defines the field quantities, **E**, the electric field intensity, and **B**, the magnetic induction, in terms of an observable, the force **F** on a charge q. In Eq. (1), **v** is the velocity of the charge relative to the observer. Equation (2) is a statement of the law of conservation of electric charge in terms of the charge density ρ and the total current density **J**. Equation (3) is the differential form of Ampère's law,

$$\oint_{c \text{ of } s} \mathbf{H} \cdot d\mathbf{l} = \iint_s \mathbf{J} \cdot d\mathbf{S} = I$$

which relates the magnetic field intensity **H** to the current, but includes also the displacement current density term $\partial \mathbf{D}/\partial t$, which was added by Maxwell to make the law applicable to time-varying fields. The term **J** represents the total current density. Equation (4) is the differential form of Faraday's law of electromagnetic induction. Equations (5), (6), and (7) are functional relationships, for the most part determined experimentally, by means of which the effects of different materials are accounted for. Mathematically, these equations are employed to reduce Eq. (3) and (4) to a pair of equations in only two unknowns. In free space, Eq. (5), (6) and (7) take their simplest form, respectively, $\mathbf{D} = \epsilon_0 \mathbf{E}$, $\mathbf{B} = \mu_0 \mathbf{H}$, $\mathbf{J} = 0$ (or $J = J_s$, a source current independent of **E** and **H**), where ϵ_0 and μ_0 are constants whose value depends on the system of units (in the mks system $\epsilon_0 = 8.854 \times 10^{-12}$ farad/meter, $\mu_0 = 4\pi \times 10^{-7}$ henry/meter). Since matter itself is a relatively dilute collection of charged particles, it is always theoretically possible to define terms so that the theory is a description of the effects and interactions of charges in free space, with consequently no essential distinction between **D** and **E** or between, **B** and **H**, as indicated above. In practice however effects of materials are usually best handled in another way.[3,8,9,10,11,12] Dielectric polarization effects are accounted for by making the **D** vector include the electric dipole moment density **P**, $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$, and then introducing a material constant, the permittivity ϵ, such that $\mathbf{D} = \epsilon \mathbf{E}$. The relative permittivity of a dielectric material is then equal to one plus the electric susceptibility. Magnetic polarization effects are handled similarly by defining the field vector **B** so that it includes the magnetic dipole moment density **M**, $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$. The material permeability is then introduced so that it depends upon the magnetic susceptibility analogously, and $\mathbf{B} = \mu \mathbf{H}$. Effects of conductors are represented by a material conductivity σ, such that $\mathbf{J}_c = \sigma \mathbf{E}$. With these simple forms for Eq. (5), (6) and (7), Eq. (3) and (4) take on the useful form

$$\nabla \times \mathbf{H} = \epsilon \frac{\partial \mathbf{E}}{\partial t} + \sigma \mathbf{E} + \mathbf{J}_1 \quad (8)$$

$$\nabla \times \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \quad (9)$$

provided μ and ϵ are constant in time. The term $\mathbf{J}_1$ here includes currents arising from charges in free space plus any (source) currents which are independent of **E** and **H**. If there are no free charges in the region, $\mathbf{J}_1$ includes only the source currents; these latter are known, so Eq. (8) and (9) may be solved for **E** and **H**. Since the equations are partial differential equations, boundary conditions over closed surfaces are required for unique solutions. Boundary conditions on the field quantities, which must hold at any boundary between two regions, may be derived from these equations. The conditions are: across a boundary (a) tangential **E** must be continuous, (b) tangential **H** must be continuous, (c) normal **D** and normal **B** must be continuous. Idealizations of material properties are sometimes helpful. For example, a perfect conductor has no non-static fields inside it, and at its surface, tangential **E** and normal **B** are zero, tangential **H** is equal and perpendicular to any surface current density, and normal **D** is equal to any surface charge density.

Two additional equations, especially useful in static problems, may be deduced from Eq. (2), (3) and (4):

$$\nabla \cdot \mathbf{D} = \rho \quad (10)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (11)$$

Solutions to the field equations are most readily obtained by imposing a restriction on the time dependence. If the fields are assumed to be independent of time (static), then Eq. (3) and (4) or (8) and (9) decouple. One of the equations becomes $\nabla \times \mathbf{E} = 0$. This means that **E** is irrotational and may be represented by a scalar potential function ϕ, $\mathbf{E} = -\nabla\phi$. Combining this with Eq. (10) gives the fundamental equation of electrostatics,

$$\nabla^2 \phi = -\rho/\epsilon \quad (12)$$

Poisson's equation. This equation for the electrostatic potential is solved by the standard methods of partial differential equations. The boundary conditions on the potential may be found from the boundary conditions on the fields.[11,12] In practice, it is frequently necessary to solve for the potential and electric field in a restricted region in which the charge density is zero, but the potential at the boundary is held at some particular value(s). The problem then is to solve Laplace's equation, $\nabla^2\phi = 0$, subject to the stated boundary conditions. The standard techniques for solving boundary value problems are employed. However, if the region of interest is partially open, known analytical techniques are sometimes inadequate to solve the problem. In two-dimensional problems of such a difficult type, the method of conformal transformations (conjugate functions) is often helpful.[10,12] The widespread availability of high speed digital computers having large memories has made it feasible to obtain acceptable solutions to a myriad of problems which previously could not be handled. The most useful general methods are called the *finite difference method* and the *finite element method*.[1,2] The finite difference method essentially determines the potential at a finite number of points (the grid) by means of a numerical solution of the appropriate differential equation. The finite element method divides the region into element spaces and finds a solution for each element space via a matrix solution of an integral equation obtained from an energy or a variational constraint.

The main applications of electrostatic theory are in (a) the theory of material properties, (b) the calculation of charged particle trajectories in electron guns, deflection systems, and accelerators (here in conjunction with magnetostatic theory), (c) the calculation of circuit component values, such as capacitance, and (d) the determination of potentials, potential gradients, and induced currents in connection with insulation breakdowns and safety questions.[14]

Magnetostatic theory is developed from Eq. (11) and (8). Since **B** is divergenceless, it can be represented by the curl of a vector **A**, which is known as the magnetic vector potential. Equation (8) can usually be written in terms of this potential as follows:

$$\nabla^2 \mathbf{A} = -\mu \mathbf{J} \qquad (13)$$

Taken one rectangular component at a time, this equation is of the same form as Poisson's equation [Eq. (12)] and may be solved in the same way. The boundary conditions on **A** may be found from those on **B** and **H**. In regions with no current, Eq. (8) becomes $\nabla \times \mathbf{H} = 0$ so that **H** may be represented by a scalar potential function $\mathbf{H} = -\nabla\phi_m$. In such regions then, in view of Eq. (11), the magnetic scalar potential, ϕ_m, must satisfy Laplace's equation

$$\nabla^2 \phi_m = 0 \qquad (14)$$

provided $\nabla\mu = 0$ in the region. The techniques and solutions of electrostatics are applicable to many magnetostatic problems. Unfortunately, however, in practice many of the systems designed to establish a given magnetic field incorporate ferromagnetic materials. For such materials, the magnetic susceptibility (and hence the permeability) is not independent of the field intensity and the field equations become nonlinear. Present mathematical techniques for handling nonlinear problems are severely limited. Practical magnetostatic problems are, therefore, frequently solved by some approximation. One of the simplest and most useful approximations is a representation by a magnetic circuit.[8,10,12] Series and parallel branches of the magnetic circuit may be recognized, and the techniques of linear and nonlinear circuit analysis can be applied to obtain a solution. When more accurate solutions are required, digital computational techniques of the types mentioned above for electrostatic problems are employed widely.[1,2]

Magnetostatic theory is applicable to a myriad of magnetic devices, including deflection systems, motors, generators, relays, magnetic pickup devices, permanent magnets, memories, transducers, coils, magnetic containment and suspension systems. Although, historically, the need for particular solutions arose before sound computational techniques were available, earlier empirical techniques are being supplemented and replaced by numerical solutions.

Energy is required to establish electric and magnetic fields, and such energy is associated with the fields. The field energy in a given volume may be computed in most cases from a volume integral of one or both of the following energy density expressions $W_e = \frac{1}{2}\epsilon E^2$, $W_m = \frac{1}{2}\mu H^2$, respectively the electrostatic and magnetostatic values.

When the fields are time varying, Eq. (8) and (9) are coupled and must be solved simultaneously. Almost invariably, a potential function such as a vector potential or a Hertz potential is introduced.[11,12] For example, Eq. (11) implies that **B** may be replaced by a vector potential such that $\mathbf{B} = \nabla \times \mathbf{A}$. Equation (9) then suggests the convenience of thinking of the electric field as being the sum of two parts:

$$\mathbf{E} = -\nabla\phi - \frac{\partial \mathbf{A}}{\partial t}. \qquad (15)$$

Then **H** and **E** may be replaced in Eq. (8), and with the condition on **A**, $\nabla \cdot \mathbf{A} = \mu\epsilon\partial\phi/\partial t$, the following equations may be obtained for **A** and ϕ (σ assumed zero here)

$$\nabla^2 \mathbf{A} - \mu\epsilon \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\mu \mathbf{J} \qquad (16)$$

$$\nabla^2 \phi - \mu\epsilon \frac{\partial^2 \phi}{\partial t^2} = -\rho/\epsilon \qquad (17)$$

That is, both the vector potential **A** and the scalar potential ϕ satisfy a differential equation known as the inhomogeneous wave equation.

Because of their simplicity and practical importance, solutions for those sources and fields which simply oscillate at a single frequency have been studied extensively.[7,11,12] In this case, the time is eliminated as an independent variable, as if by a transform operation. (In fact, transform methods are often the best means of obtaining transient field solutions.) In the equations, the time derivatives are replaced by frequency multipliers so that the resulting equations are functions of the space variables only. The vector potential may then be found by standard techniques of partial differential equations and boundary value problems. Having **A**, the field quantity **B** is found from $\mathbf{B} = \nabla \times \mathbf{A}$ and **E** is found from Eq. (8). In practice, a theorem which can be derived from the field equations, called the reciprocity theorem,[7,12] is often helpful. The theorem relates the fields $\mathbf{E}_a$ and $\mathbf{E}_b$ produced respectively by a pair of current distributions $\mathbf{J}_a$ and $\mathbf{J}_b$. The theorem is

$$\iiint \mathbf{E}_a \cdot \mathbf{J}_b dv = \iiint \mathbf{E}_b \cdot \mathbf{J}_a dv \tag{18}$$

For example, if $\mathbf{J}_b$ is selected to be a point current at point P, directed along x (represented mathematically by a Dirac delta function), then Equation (18), $E_{ax}(P) = \iiint \mathbf{E}_b \cdot \mathbf{J}_a dv$, gives a formula for the computation of the field due to $\mathbf{J}_a$ which is equivalent to a superposition integral involving a Greens function.

Perhaps the most fundamental problem of electromagnetic theory is the determination of the fields of a point charge, at rest, in oscillation, or in some general state of motion. For a point charge q, at rest in free space, the solution may be obtained by solving Eq. (12) in spherical coordinates. With the point charge at the origin, symmetry conditions may be employed to eliminate the angular variation, and the remaining differential equation in r can be solved subject to Eq. (10) to give $\phi_G = q/4\pi\epsilon_0 r$ for the potential associated with the point charge. A superposition integral

$$\phi = \iiint \frac{\rho \, dv}{4\pi\epsilon_0 r} \tag{19}$$

may then be employed to find the potentials associated with more complicated distributions. The field of an oscillating dipole, which is equivalent to a point alternating current, is also of great interest. This solution may be obtained from Eq. (16) (single frequency version). If the point current is directed along z, the z-component of the vector potential may be found by a procedure similar to that employed for a point charge. The final result is

$$A_{zG} = \frac{I\Delta z}{4\pi\mu_0 r} \cos \omega(t - \sqrt{\mu_0\epsilon_0} r) \tag{20}$$

where $I\Delta z$, the current moment, is equal to $\omega q \Delta z$, the maximum dipole moment of the oscillating dipole. The factor $(t - \sqrt{\mu_0\epsilon_0} r)$ exhibits the time delay required for the effects of the oscillating charges to propagate to distant points. The electric and magnetic fields may be computed from Eq. (20) as indicated above. The magnetic field strength produced by an oscillating dipole (point current) is, for example, in the spherical coordinate system (r, θ, φ)

$$H_\varphi = \frac{I\Delta z}{4\pi} \sin \theta \left[\frac{\cos \omega(t - \sqrt{\mu_0\epsilon_0} r)}{r^2} - \frac{\omega\sqrt{\mu_0\epsilon_0}}{r} \sin \omega(t - \sqrt{\mu_0\epsilon_0} r) \right]$$

This form, like Eq. (20), shows that the crests and valleys of the field oscillations are propagated in spherical waves at the speed of light $v = (\mu_0\epsilon_0)^{-1/2}$. The solution for a point current may be employed in an integral similar to Eq. (19) to find the vector potential of a more complicated distribution of current. Such solutions may also be employed to find the radiation patterns and input impedances of antennas.[13] In practice, however, the distribution of currents on antenna structures is not known a priori, i.e., the antenna currents are not truly source currents. High speed digital computers have made it possible to employ a numerical technique related to the finite element method, known as the method of moments,[5] for the determination of the currents on antennas and scattering bodies of rather arbitrary shapes, given the boundary and source conditions. Once these currents have been determined, the fields and impedances are then calculated as indicated above.

The potentials and fields produced by a charge moving in an arbitrary way may also be obtained.[6,11] The results may be found in Stratton.[11,pp.475-476]

In regions free of source currents and charges, the fields and potential satisfy the homogeneous wave equation [for example Eq. (16) with $\mathbf{J} = 0$]. Then one of the simpler solutions which can be obtained is that of the plane electromagnetic wave. With appropriate orientation of the rectangular coordinate system, the solutions show that plane waves may progress along z, with components as follows:

$$E_x = E_0 \cos \omega(t - \sqrt{\mu_0\epsilon_0} z)$$

$$H_y = E_0 \sqrt{\frac{\epsilon_0}{\mu_0}} \cos \omega(t - \sqrt{\mu_0\epsilon_0} z)$$

where E_0 is an arbitrary constant amplitude. Note that **E**, **H** and the direction of propagation are all perpendicular to one another. The Poynting vector, $\mathbf{S} = \mathbf{E} \times \mathbf{H}$, points in the direction of propagation. Moreover, the power carried through a closed surface by an electromagnetic field may be computed from a surface integral of the Poynting vector.

With single frequency fields in source free regions, both **H** and **E** can be represented by vector potentials,[11,12] $\mathbf{H}_1 = \nabla \times \mathbf{A}_1$, $\mathbf{E}_2 = \nabla \times \mathbf{A}_2$, and moreover the coordinate systems may be oriented so that $\mathbf{A}_1$ and $\mathbf{A}_2$ each have a single component.[12] In cylindrical systems, this single component is commonly along z. $\mathbf{H}_1$ is then transverse to z (TM) and the set of fields, $\mathbf{E}_1$, $\mathbf{H}_1$, derivable from $\mathbf{A}_1$, are called TM fields. $\mathbf{E}_2$ is likewise transverse to z and the set of fields, $\mathbf{E}_2$, $\mathbf{H}_2$, derivable from $\mathbf{A}_2$, are called TE fields. This procedure is particularly helpful in problems involving transmission lines and WAVEGUIDES and is developed in detail in Weeks.[12, Ch. 4-6]

Some of the most interesting and fundamental problems of electromagnetic theory are concerned with the scattering and diffraction of electromagnetic waves.[6,7,10-12] For example, exact solutions are available for the scattering by cylinders and spheres, as well as an infinitely long slit. Approximate solutions are available for many other shapes. The methods are the analytical and numerical ones outlined above, supplemented by generalizations of the principles of Huygens and Babinet.

Another topic of wide interest is the nature of fields in ionized gases or plasmas. The applications range from ionospheric propagation to microwave devices to nuclear apparatus to magneto-hydrodynamics to satellite re-entry problems. The simplest theory for these effects is developed from Eq. (3) and (4) (single frequency version) by separating the ion current term $\mathbf{J}_e = \rho \mathbf{v}$ from **J**, and employing Newton's law to eliminate **v** in favor of **E**, **H** and whatever mechanical constraints are applicable[3,11,12] (see PLASMAS).

Effects peculiar to charges moving with very high velocities have not been included in this discussion (see RELATIVITY THEORY). Quantum effects are also discussed elsewhere (see QUANTUM ELECTRODYNAMICS and QUANTUM THEORY).

ELECTRON

The electron is the smallest known electrically charged particle. Its existence and characteristics were inferred from many experiments clustered in and around the last decade of the nineteenth century. In the 1830's, Faraday had tentatively suggested that his experiments in ELECTROCHEMISTRY could be interpreted in terms of a small unit of charge attached to ions. This notion of individual "atoms of charge" was somewhat eclipsed, however, by the enormous success of Maxwell's theory of electromagnetism, which was generally interpreted, by 1880, as favoring a view that electrical phenomena were due to continuous charge distributions and motions. G. Johnstone Stoney, in 1874, and Helmholtz, in 1881, had suggested again an atomic interpretation of electricity, but it was not until the brilliant experiments of Perrin, J. J. Thomson, Zeeman, and others in the 1890's that the concept of the electron received firm experimental foundation. Later experiments and theory (Millikan, Bohr, etc.) established the constancy of the electronic charge and interwove the concept of an electron of definite charge and mass into the basic structure of the atom.

The Cathode Ray Controversy After the discovery of the cathode ray in high-vacuum discharge tubes by Plücker in 1858, there developed, with the experiments of Goldstein, Crookes, Hertz, Lenard, and Schuster, a controversy over the nature of the rays. A predominately German school held that the rays were a peculiar form of electromagnetic rays. The British physicists thought they were negatively charged particles. The controversy provides a classic "case history" of the typical scientific controversy in which two quite different models both explain most, but not all, of the observable facts. The proponents of each model designed ingenious experiments, but in some cases were so trapped in their preconceptions that they badly misinterpreted their observations. The Germans were especially impressed by the fact that the rays could go through thin foils—something no known particles could do. The British were firm in pointing out that the rays could be deflected by magnetic fields—something not possible with electromagnetic waves. Hertz, in what he thought was a crucial experiment, was unable to detect deflection of the rays by electric fields, but this very phenomenon was demonstrated by J. J. Thomson and made the basis for his conclusive experiments that the rays had velocities less than that of light. Thomson showed, further, that if one assumed that the rays were composed of particles, then the particles had the same ratio of charge to mass regardless of the cathode material or the nature of the residual gas. Perrin's classic experiment, meanwhile, proved that the rays did indeed convey negative charge. In the decade between 1896 and 1906, Thomson and others showed that negatively charged particles from sources other than cathode rays had the same ratio of charge to mass: the negative particles emitted by hot filaments in the Edison effect, the beta rays emitted by some radioactive materials, and the negative particles emitted in the photoelectric effect that had so ironically been discovered by Heinrich Hertz in his great experiment which demonstrated the electromagnetic rays predicted by Maxwell's equations.

Thomson's Determination of e/m In 1897 Thomson devised an apparatus in which he could deflect a beam of cathode rays with a magnetic field of induction B and also with an electric field of strength E. If the fields are perpendicular to each other, and to the original path of the beam, and if they occupy the same region, then (with proper polarities and magnitudes of fields) the electric force on the beam can equal the magnetic force, so that the beam hits the same point on a fluorescent screen as when no fields are applied. If e is the charge of a given particle, m its mass, and v its velocity, $v = E/B$. Thus, velocities of typical cathode ray beams could be measured. If the magnetic field is used alone, and the radius of curvature R of the beam is measured, then one can equate centripetal and magnetic field forces: $mv^2/R = Bev$, and then deduce $e/m = v/BR$. With v known from the previous experiment, e/m can be calculated. Thomson's early values were not very precise, but later experiments of a similar type gave values close to 1.76×10^{11} coulomb/kg. More recent evaluations, drawing on measurements of many kinds, give $e/m = 1.7588 \times 10^{11}$ coulombs/kg as a 1982 value calculated from values for e and m given under CONSTANTS, FUNDAMENTAL, in this book.

The Zeeman Effect In 1896 Zeeman discovered the broadening of spectral lines when a light source was in a strong magnetic field. Experimental refinements of Zeeman and others, and theoretical work by Lorentz and Zeeman, permitted the interpretation of this effect as due to the influence of the magnetic field on oscillating or orbiting negatively charged particles within the light-emitting or absorbing atoms. From the spectroscopic data, the ratio of charge to mass of these hypothetical particles, and the sign of their charge, could be shown to be equal to that of cathode rays. The Zeeman effect thus provided the first experimental evidence that the negative particles emitted by atoms when heated (Edison effect) or subject to high fields and/or ionic bombardment (cathode rays) or bombarded by short-wavelength light (photoelectric effect) were, indeed, actual constituents of the atoms and were probably responsible for the emission and absorption of light.

The Charge on the Electron In the decade following 1897, many different methods were evolved for determination of ionic charges. Some methods depended upon measuring the total charge of a number of ions used as nuclei for cloud droplet formation. Other methods were more indirect—experiments, for example, which, combined with the kinetic theory of gases, could give crude values for avogadro's number, N (see MOLE CONCEPT). By dividing the Faraday constant (the charge carried in electrolysis by ions formed from one gram-atom of a univalent element) by N, one could determine the average charge per ion. Similarly, the constants in Planck's theory of blackbody radiation, when evaluated experimentally, could provide a numerical value for N, as could certain experiments in radioactivity. All such methods gave values of N of the order of 6×10^{23}, and hence 1.6×10^{-19} coulomb for the ionic charge. None of these methods measured individual charges; strictly speaking, the value for the ionic charge could be thought of only as an average value.

Millikan's experiments with single oil drops, beginning in 1906, provided a method for measuring extremely small charges with precision. He was able to show that the charge on his drops was *always ne*, with $e = 1.60 \times 10^{-19}$ coulomb (modern value) and n a positive or negative integer.

He observed the motions of very small charged oil drops in uniform vertical electric fields. The drops were so small that they moved with constant velocity (except for Brownian fluctuations) for a given force. The force in each case was due to gravity acting on the mass of the drop and to the electric field (if any) acting on the charge, q, on the drop. The charge on a given drop could be changed by shining x-rays upon it. Using Stokes' Law, in a form modified to correct for the fact that the drops were *not* large in comparison to the inhomogenieties of the surrounding air, and the velocity of a drop in free (gravitational)fall, Millikan could infer the diameter and mass of a given drop, and then calculate its charge. The charge q always equaled ne. (See reference 1 or 2 for experimental details.) A few other physicists, in similar experiments, thought they had detected electric charges smaller than Millikan's e, but their experimental techniques were probably faulty.

Millikan's experiment did not prove, of course, that the charge on the cathode ray, beta ray, photoelectric, or Zeeman particle was e. But if we call all such particles electrons, and assume that they have $e/m = 1.76 \times 10^{11}$ coulomb/kg, and $e = 1.60 \times 10^{-19}$ coulomb (and hence $m = 9.1 \times 10^{-31}$ kg), we find that they fit very well into Bohr's theory of the hydrogen atom and successive, more comprehensive atomic theories, into Richardson's equations for thermionic emission, into Fermi's theory of beta decay, and so on. In other words, a whole web of modern theory and experiment defines the electron. (The best current value of e (June, 1982) = 1.6028×10^{-19} coulomb (see CONSTANTS, FUNDAMENTAL).

The Wave Nature of the Electron In 1924, L. DeBroglie suggested that the behavior of electrons within atoms could be better understood if it were assumed that the motion of an electron depends upon some sort of accompanying wave, the length of which would be h/p (h = Planck's constant and p the momentum of the electron). This suggestion led to the development of QUANTUM MECHANICS by Schrödinger, Heisenberg, and others. The concept of electron waves provided an explanation for experiments on reflection of electron beams by metallic crystals, carried out from 1921 onward by Davisson and others, and provided an impetus for the experiments of G. P. Thomson on the diffraction of electron beams by thin films (see ELECTRON DIFFRACTION).

Other Characteristics of Electrons In applying quantum mechanics to certain problems in atomic spectroscopy, in 1925 and 1926, Pauli, and Goudsmit and Uhlenbeck found that electrons must possess angular momentum of amount $\pm \frac{1}{2}(h/2\pi)$. Dirac's work on a generalized quantum theory of the electron showed that it possessed a related magnetic dipole moment of magnitude $eh/4\pi mc$ (see ELECTRON SPIN). The ratio of the dipole moment to the angular momentum (e/mc) is larger than can be accounted for in classical terms with any homogeneous wholly negative model. The concept of electronic dipole magnetic moment is essential not only in spectroscopy but in theories of ferromagnetism (see MAGNETISM).

One may speak of the "classical radius of the electron," $a = e^2/mc^2$, derived by setting the self-energy of the coulomb field of a charge e contained at a radius a equal to the relativistic rest energy, mc^2 of the electron. This $a = 2.82 \times 10^{-13}$ cm, comfortably smaller than any atom, but larger than the usual estimates of sizes of protons and neutrons.

Positive Electrons Dirac's paper in 1928 could be interpreted as predicting the existence of electrons that are positive. But until such particles were found experimentally by C. D. Anderson in 1932 in cloud chamber pictures of cosmic ray particle tracks, most physicists preferred other interpretations of Dirac's paper. Positive electrons, or POSITRONS are now known (1) to occur as decay products from certain radioactive isotopes, (2) to be produced (paired with a negative electron) in certain interactions of high-energy gamma rays with intense electric fields near nuclei, and (3) to be the product of certain decays of certain mesons. In principle, positrons could form anti-atoms with nuclei made from anti-protons and anti-neutrons, but in practice almost all positrons produced in ordinary matter quickly meet their end by annihilating themselves together with some hapless negative electron. The end product of a positron-electron annihilation is a pair of gamma rays.

Recent Theoretical Developments The relativistic quantum mechanical theory of the electron, in its earlier forms, led to embarrassing predictions of infinite electronic mass and charge. Schwinger and others have developed methods for coping with these infinities, so the theory, in general, now satisfactorily agrees with observations. Further developments are not unlikely. (See QUANTUM ELECTRODYNAMICS).

Experiments and theory, first in radioactive decay, and more recently in elementary particle physics, have made it clear that electrons can be thought of as members of a class of particles called "leptons." These particles, which include neutrinos (see NEUTRINO) and muons (see ELEMENTARY PARTICLES) interact with each other and with other particles in so-called "weak interactions," apart from whatever other reactions they may share, such as gravitational, magnetic, and electrical interactions.

Applications of Electrons Aside from their inherent usefulness in physical theories of magnetic, electrical, optical, and mechanical properties of matter, electrons either in beams or in conductors can be made to do all sorts of useful things. Cathode ray oscilloscopes, electron microscopes, image converters, certain memory devices for computers, television picture tubes, and most "radio tubes" depend upon beams of electrons controlled by electric or magnetic fields (see ELECTRON OPTICS). In ordinary metallic conductors, electricity is carried primarily by electrons. The behavior of electrons in SEMICONDUCTORS and in superconductors (see SUPERCONDUCTIVITY) has in recent years been the basis both of intense theoretical interest and of interesting and useful devices.

ELECTRON DIFFRACTION

The discovery of electron diffraction independently by C. J. Davisson and L. H. Germer (1927) and G. P. Thomson (1927) verified L. de Broglie's earlier hypothesis (1924) that matter exhibits both corpuscular and wavelike characteristics. This hypothesis served as a stimulus for the formal development of quantum mechanics by E. Schrödinger, M. Born, W. Heisenberg, and others. Following this momentous discovery, which eventually resulted in the award of a Nobel Prize to Davisson and Thomson, electron diffraction was immediately utilized as a tool for the study of the structure of matter.

Electron, x-ray and neutron diffraction are all used for structure studies. Electron diffraction is used particularly for those structural studies that involve small numbers of atoms. This is due to the strong interaction of electrons with matter. Thus the principal area of application of electron diffraction is for the study of thin films, surfaces, gases, crystalline defects, and small samples.

The different energy ranges that were used in the Davisson-Germer and Thomson experiments provide a natural division for a description of the types of equipment, areas of application, and analytical techniques that have evolved since 1927. These classic experiments were performed with electrons having energies in the vicinity of 150 eV and 15 keV, respectively. De Broglie's relationship $\lambda = h/m\nu$, where h is Planck's constant and λ is the wavelength associated with a mass m traveling with a group velocity ν, reduces to $\lambda = \sqrt{150/V}$ for electrons in the nonrelativistic limit, where V is the accelerating voltage and λ is expressed in Ångstroms. The two experiments thus used electrons having a wavelength of approximately 1 and 0.1 Å. The longer wavelength is comparable to the spacing between atoms in crystals.

While 50-100 keV electrons, which are used in commercial electron diffraction instruments, penetrate to a depth of about 10^3 Å into a crystal, 150 eV electrons penetrate only about 10 Å. Since the higher-energy electrons are capable of passing through the several layers of adsorbed foreign material that normally are present on the surface of a crystal, surface cleanness and therefore the vacuum requirements for 100 keV electron diffraction are not as stringent as those for low-energy electron diffraction. This fact, in addition to the relative ease in focusing intense high-voltage beams, and individual interests, resulted in the wide application of high-energy electron diffraction for structure studies. A typical instrument of this type operates at about 50 keV, has provisions for producing and focusing the electrons, contains specimen manipulators, means to record the diffraction patterns and typically is contained in a chamber capable of being evacuated to 10^{-6} torr. Diffraction patterns are obtained either by transmission of the beam through very thin specimens or by working at grazing incidence and reflection.

One common use of high-energy electron diffraction by transmission or reflection is the study of films on amorphous, polycrystalline, and single crystal substrates. This includes films that have been formed by the oxidation or corrosion of a surface as well as those formed by the deposition of material on a substrate. In many instances these films consist of crystallites having an orientation that is related to the structure and orientation of the substrate material.

The transmission ELECTRON MICROSCOPE has been used widely for the study of atomic arrangements at structural imperfections, such as dislocations and stacking faults. Image contrast is obtained by local differences in the intensities of diffracted beams. In addition, many electron microscopes are constructed in such a way that it is possible to obtain the diffraction pattern associated with the material in the area being studied. Considerable information on the crystallography of domain structures, order-disorder phenomena, and phase transitions has been obtained by this selective area diffraction technique.

Electron diffraction in this high-energy range is also useful for the determination of the atomic arrangements, bond distances, bond angles, and mean square atomic vibrational amplitudes in gaseous molecules.

Low-energy electron diffraction was used sparingly until approximately 1960. Improved diffraction equipment, which enabled the direct display of the diffraction pattern on a fluorescent screen by accelerating the diffracted electrons after they had passed through grids, and the commercial availability of ultrahigh (10^{-10} torr) vacuum equipment, resulted in a resurgence of interest in this field. The structure of clean surfaces, the arrangements of foreign atoms on these surfaces at a monolayer or less coverage, and many aspects of the initial stages in the oriented overgrowth of thin films have been studied with electrons having energies in the range of 2 to 10^3 eV. It has been revealed that the atomic arrangement at the clean surfaces of semiconductors such as germanium and silicon is quite unlike that found in the bulk of these materials. At low coverages, foreign atoms are normally adsorbed in structures that have a symmetry and dimensions that are simply related to the orientation of the substrate plane. A multitude of such structures has been found on semiconductors and metals. Their atomic array is dependent on many parameters, such as the amount of adsorbed material, the temperature, orientation and cleanness of the substrate. This same equipment is also used to determine the presence of impurity atoms on the surface by the technique of Auger spectroscopy. The energy of the secondary electrons is characteristic of the surface atoms and can be used to make a quantitative identification of surface impurities, which can assume an important role in affecting surface structures.

While electron diffraction techniques are widely used, interpretation of much of the data can be challenging. This is due to the strong interaction of the incident and scattered electrons with the substrate atoms. It is often necessary to apply dynamical scattering theory to explain observations. While interpretation of results has been very successful at the high energies of 100 keV, it has been less successful in the low energy regime of 100 eV. Here, the dependence of the scattered beams' intensity on incident electron energy is complex and is indicative of large and energy dependent scattering cross sections, multiple scattering, strong absorption of incident and scattered electrons, and effects that are substrate dependent. However, considerable progress has been made in recent years in the understanding of these interactions and in the development of computational tools. This has led to the interpretation of data to obtain surface atom spacings, surface atom vibrational amplitudes and relatively simple surface structures. This has provided an improved understanding of chemical bonding at surfaces. Other important and successful applications of low-energy electron diffraction have been made in studying crystal surface defects such as steps, islands, and domain structures. It is expected that work of this type will result in detailed understanding of surface phenomena such as bonding, catalysis, and corrosion.

ELECTRON MICROSCOPE

Introduction The standard light microscope uses light in the visible range to produce a magnified image. The electron microscope (EM) uses electrons for magnification. Since electrons are easily absorbed in air at atmospheric pressure the EM has to operate in a vacuum. The imaging electrons are usually accelerated to between 30 and 100 kV. The EM magnifies in two or three stages by means of electromagnetic or electrostatic lenses.

Resolution In 1978 Ernst Abbé and, independently, H. von Helmholtz proved that in the light microscope the resolution is limited by the wavelength of the illuminating light. No matter how perfect and free of aberrations the optical system is, the image of a geometrical point is not a point but a disc, the "Airy disc." Regardless of any further magnification, two separate points cannot be resolved as separate unless their centers are the distance d apart, whereby d is the radius of the Airy disc referred to the object plane:

$$d = \frac{0.5\,\lambda}{n \sin \alpha} \qquad (1)$$

where

λ = wavelength of the illuminating light
n = index of refraction of medium between object and lens (in air, $n = 1$)
α = aperture of lens, i.e., half-angle of collected light beam
$n \sin \alpha = NA$ = numerical aperture of lens (in air, $NA_{\max} = 0.95$).

The wavelength of green light for which the eye is most sensitive is:

$$\lambda_{\text{green}} \simeq 500 \text{ nm*} \quad (5000 \text{ Å}).$$

The resolution of the light microscope is, therefore:

$$d \simeq 250 \text{ nm} \quad (2500 \text{ Å}).$$

Even if we go to the extreme of using the ultraviolet line of mercury ($\lambda = 253.7$ nm) oil immersion optics ($NA = 1.4$), quartz lenses and microphotography, the best resolution obtainable with the light microscope is still:

$$d \simeq 100 \text{ nm} \quad (1000 \text{ Å})$$

The electron microscope makes use of the wave properties of the moving electron. Its "de Broglie" wavelength is:

$$\lambda = \frac{h}{mv} = \frac{1.23}{V^{1/2}} \text{ [nm]} \tag{2a}$$

for nonrelativistic electrons (below 100 kV) and

$$\lambda = \frac{1.23}{(V + 10^{-6}\, V^2)^{1/2}} \text{ [nm]} \tag{2b}$$

for relativistic electrons, where

h = Planck's constant
m = mass of electron
v = velocity of electron
V = accelerating voltage in volts.

For electrons of V = 50 kV the wavelength is

$$\lambda_{50\text{kV}} = 0.00535 \text{ nm}$$

Objective lenses for electrons, unlike those for light optics, cannot be made free of spherical aberrations. They have to operate with numerical apertures that are 500 to 1000 times lower. The best theoretical resolution for magnetic lenses working with electrons of 50 kV energy is:[1]

$$\ddot{\delta} = 0.21 \text{ nm}$$

The best practical resolution is between 0.5 and 1 nm (5–10 Å).

Early History The first electron microscope was developed by M. Knoll and E. Ruska at the Technical University of Berlin early in 1931.[2] Ruska obtained the first magnification in two stages by means of electromagnetic lenses on 7 April 1931.[3] The EM celebrated, therefore, its 50th anniversary on that date in 1981. The greatest magnification obtained with this first somewhat crude instrument was 17X. Knoll and Ruska improved the electron microscope step by step. They added a condenser lens and built an iron shield with a narrow center gap around their magnetic lens. Ruska, working from 1932 by himself, equipped the magnetic lenses with narrow pole pieces and was able to demonstrate in 1933 a resolution of 50 nm better than the best resolution obtainable with the light microscope (magnification 12,000X).[4] Figure 1 shows a functional diagram of his supermicroscope. Figure 2 shows the details of one of his lenses.†

The first commercially available EM was developed by Ruska together with von Borries at Siemens & Halske, Berlin, in 1939. The first American commercial EM came out in 1941 by RCA.

Parallel to the development of the magnetic electron microscope went the development of an electrostatic one. In 1931, Brüche and Johannson of the Research Institute of A.E.G. in Berlin imaged the emitting surface of the cathode with an electrostatic immersion objective. In 1932, they employed unipotential or Einzellenses.

Electron Lenses *Magnetic Lenses.* A charged particle entering a uniform magnetic field moving parallel to the lines of force will not be deflected. It will move in a straight line. Moving perpendicular to them it will describe a circle. The radius of this circle, the "cyclotron radius," is:

$$\rho = \frac{m}{e}\,\frac{v}{B}. \tag{3}$$

where

m = mass of particle
e = charge of particle
v = velocity
B = magnetic field intensity (gauss).

The circle described by an electron is

$$\rho_e = 3.372\,\frac{\sqrt{V}}{B} \text{ [cm]} \tag{4a}$$

for nonrelativistic electrons,

$$\rho_e = \frac{1}{B}\sqrt{11.3V + 1.11 \times 10^{-5} V^2} \text{ [cm]} \tag{4b}$$

for relativistic electrons,

where V is in volts and B is in gauss.

The time it takes a particle to describe a cyclotron circle is:

$$\tau = \frac{2\pi\rho}{v} = 2\pi\,\frac{m}{e}\,\frac{1}{B} \text{ [sec]} \tag{5}$$

*1 nanometer (nm) = 10^{-9} meter (m) = 1 millimicron (mμ) = 10 angstrom units (Å).

†The two first EM were destroyed during WW II. Ruska has recently constructed exact replicas of them which were shown at various EM Congresses in Europe and are scheduled to be permanently exhibited at Deutsches Museum, Munich.

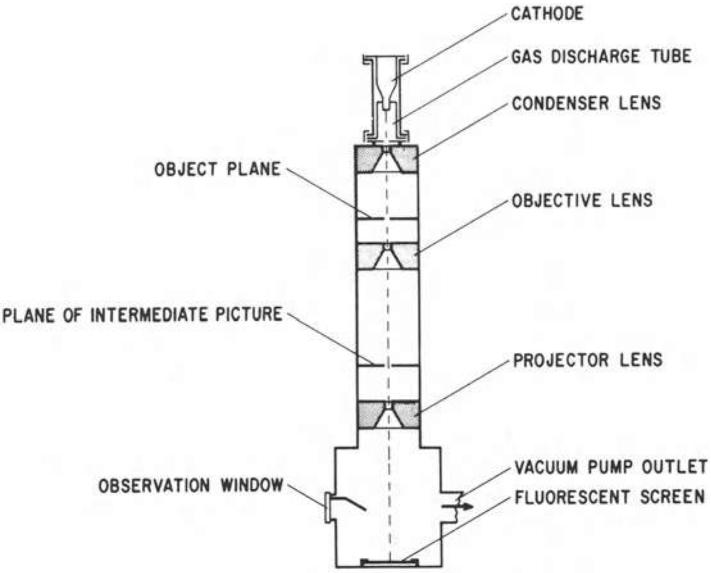

FIG. 1. First Supermicroscope (Ruska 1934, Ref. 4).

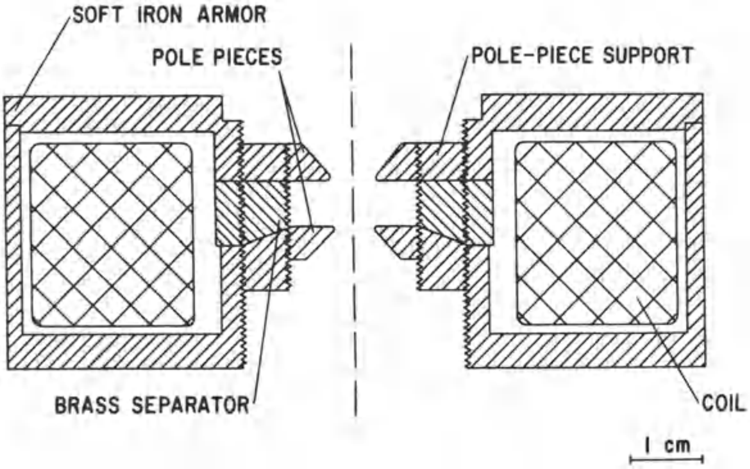

FIG. 2. Magnetic Lens (Ruska 1934, Ref. 4).

A charged particle entering a uniform magnetic field at an angle will describe a cycloid. While its velocity component normal to the field lines causes it to describe a circle, the velocity component parallel to the field lines remains unchanged. Since the time required to describe a circle is independent of the normal velocity, all circles, large or small, are traversed in the same time interval. In an electron beam with low divergence where, therefore, the velocities parallel to the magnetic field (v_z) are identical, all electrons leaving one point P on the axis will meet downstream at another point P′ at a distance

$$d = \frac{v_z}{T} \tag{6}$$

with angles to the axis identical to those they had at point P (see Fig. 3).

A "long" magnetic lens, having a uniform magnetic field extending from the object to the image point, will form an upright picture of the object with an image to object ratio of 1 to 1.

A "thin" magnetic lens is a lens with a magnetic field short compared to the object-to-image distance. A "weak" thin lens is a lens

with the focal length large compared to the axial length of the magnetic field. The refractive power, i.e., the reciprocal of the focal length, of such a lens is determined by:

$$\frac{1}{f} = \frac{0.022}{V}\int_{-\infty}^{+\infty} B_z{}^2 d_z \text{ [cm}^{-1}\text{]} \qquad (7)$$

It images according to the general optical equation:

$$\frac{1}{f} = \frac{1}{a} + \frac{1}{b} \qquad (8)$$

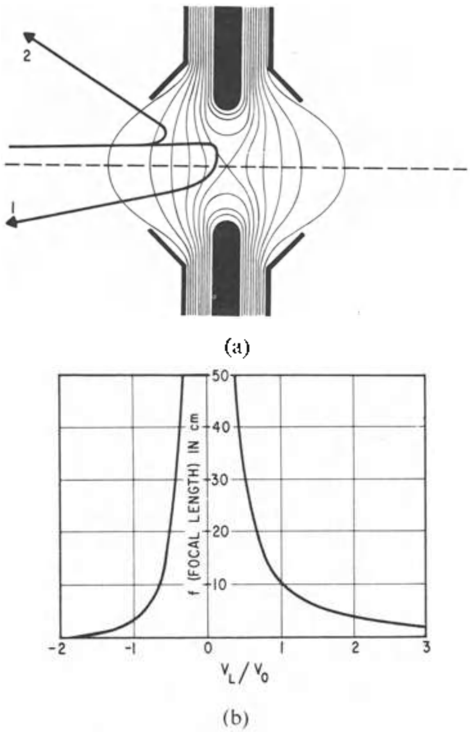
where f is the focal length, a is the object distance and b is the image distance. The picture is turned around from the position of the object. The angle it is turned is determined by:

$$\theta_1 = \frac{0.149}{\sqrt{V}}\int_{-\infty}^{+\infty} B_z d_z \text{ [radians]} \qquad (9)$$

The objective and projector lenses of the electron microscope require extremely short focal lengths in order to obtain high magnifications without going to extremely long microscopes. These lenses have, therefore, pole pieces which limit the extent of the magnetic field, both in the axial and radial dimensions. The treatment of strong, thin magnetic lenses can be found in references 5 and 6.

Electrostatic Lenses *Immersion lenses* consist of two apertures or two coaxial cylinders at different potentials. They are important as lenses for television or oscillograph cathode-ray tubes. The lenses used in electrostatic transmission electron microscopes are usually *unipotential* or *Einzel-lenses.* They have the same potential on either side of the lens. They consist of three apertures: the two outer apertures are at ground or anode potential, and the center electrode can have either a positive or negative potential. Regardless of whether a positive or a negative potential is applied, the lens will always be convergent. Figure 4(a) shows the equipotential lines of such a lens; Fig. 4(b) shows the focal length vs V_L/V_0 for this lens, where V_L is the voltage applied to the center electrode and V_0 the cathode potential. Figure 5 shows the design of a typical electrostatic lens.

The Standard Transmission Microscope (TEM) The best known electron microscope is the magnetic transmission microscope where the image is formed by electrons which have passed through the specimen. It is composed of the following major sections: electron gun, condenser lens, specimen chamber, objective lens, projector lens, viewing and photographing chamber. It has the following ancillary equipment: (1) power supplies for high voltage, cathode heater voltage, and focusing currents; (2) vacuum systems.



(a)

(b)

FIG. 4. Unipotential or Einzel-lens: (a) equipotential lines (Ref. 7); (b) focal length vs V_L/V_0 (Ref. 8).

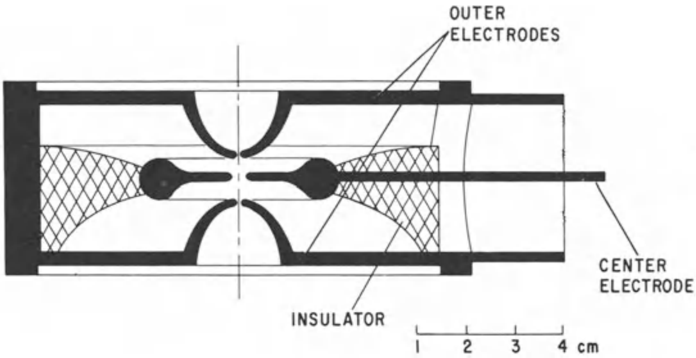


FIG. 5. Typical electrostatic lens (see ref. 9).

The *electron gun* generates the electron beam which illuminates the object. It has to provide the required electron density within a certain limited divergence. It consists of the cathode, a hairpin tungsten filament, enclosed in a cup-shaped electrode at cathode or a more negative potential called the grid, shield or Wehnelt cylinder. The fine emitting point of the cathode must be accurately aligned with the aperture of the grid. The negative grid bias against the cathode determines the beam current that passes through the grid. The "crossover point" which is located near the grid aperture has the smallest beam diameter inside the gun. While the anode facing the grid is at ground potential, the cathode is maintained at a high negative potential, usually between 50 and 100 kV.

The *condenser lens* or lenses increase the electron density reaching the specimen by concentrating the beam. An aperture in the condenser lens of 0.25 to 0.5 mm diameter reduces the amount of stray electrons reaching the specimen.

The *objective lens* provides the first magnification. It is a strong, thin lens with a high refractive power. It has, therefore, narrow precision pole pieces. An aperture of 25 to 100μ diameter is usually inserted in the gap of this lens to limit the beam divergence. The specimen is mounted either close above or inside the magnetic gap.

The *projector* or *image lens* selects a small portion of the intermediate image produced by the objective lens and magnifies it again. A third electron-optical magnification is in many cases produced by a second projector lens. The magnetic lenses are usually wirewound coils. In some cases permanent magnets are used with or without additional coils for fine adjustment.

The *specimen chamber* is located above the objective lens. It can be opened to the outside for inserting new specimens. It is pumped out before reconnecting it to the main column. Adjustments by means of micrometer screws permit shifting the specimen in the object plane in order to locate accurately the area of interest. In many cases a number of different specimens can be moved under the electron beam by rotating or sliding specimen holders. Some models have special facilities to keep the specimen at certain high or low temperatures.

The *viewing chamber* at the bottom of the microscope column contains the fine-grain fluorescent screen that can be observed through glass windows either directly or through a telescope. If a permanent record is desired, the fluorescent screen is moved aside and a photographic plate inside a plate holder is exposed. The electrons produce a latent image directly. Each plate can be removed from the vacuum separately. A film pack may be used instead of plates. Rollfilm is used when a whole series of pictures are to be taken.

In some cases when an extremely high magnification, for instance 100 000 times, is desired, it may pay to magnify electron-optically to a somewhat lower magnification and to add a final photographic enlargement later; the adjustment of the electron microscope is then much easier, since the field of vision is so much larger.

The *vacuum system*, generally maintaining a vacuum of 10^{-4} to 10^{-5} torr (1 torr = 1 mm Hg), consists usually of an oil diffusion pump backed by a mechanical forepump. A second mechanical pump is used to purge the specimen chamber and the photographic chamber before they are opened to the main vacuum column. A water or liquid-nitrogen-cooled baffle is used to reduce backstreaming of oil vapor into the chamber.

While this type of vacuum system may be satisfactory for a great number of applications, it proved to be unsatisfactory for more demanding investigations. It is impossible to prevent completely the backstreaming of diffusion pump oil into the system. The electron beam interacts with the oil molecules, causing hydrocarbon "varnish" to be deposited on the specimen and on critical apertures. This limits the exposure time and requires frequent cleaning of apertures. Heating or cooling the specimen stage will improve the situation, but the vacuum may still not be satisfactory, especially in cases where film depositions are studied.

When a dry vacuum is desired, getter ion pumps or turbomolecular pumps are used, often in conjunction with titanium sublimation pumps. To bring the system down to the pressure where these pumps take over, rotary oil pumps or liquid-nitrogen-cooled zeolite molecular sieve traps are used.

Scientists who converted their system from oil diffusion pumps to dry pumps report a longer cathode life, reduced exposure time, sharper pictures, and practically the elimination of the varnish problem. They report a reduction in varnish build-up from .5 to 1 nm sec^{-1} down to .1 to .5 nm min^{-1}.*)

To reduce the contamination from elastomer o-rings, they are sometimes replaced in critical locations, for instance in the specimen chamber, by metal gaskets—usually oxygen-free copper rings. Viton A o-rings are used for less critical seals. These o-rings have to be outgassed for many hours in vacuum at a temperature of 150°C before they can be installed in the system. Photographic plates must be outgassed too before they can be placed in the chamber.

Rotating or sliding motion which is usually accomplished by rods fed through O-ring seals or through greased glands can in critical cases be done by means of metal bellows.

Power Supplies. The voltage regulation required for the power supplies of the *electrostatic* microscope is not very critical. As long as the lens voltage and cathode potential maintain the same linear ratio—very often they are identical—a good image is obtained.

The refractive power of the *magnetic* lens depends directly on the square of the magnetic flux, which is proportional to the lens current—if the magnetic circuit is not saturated—and varies inversely with the cathode potential [see Eq. (7)]. It is, therefore, paramount that all power supplies be extremely well-regulated.

Image Formation. In the light microscope the image is formed by the difference in the absorption of light in the various sections of the object. There is very little absorption of electrons in the TEM. The image is formed essentially by the scattering of electrons during their passage through the specimen. Those sections that are denser or thicker or are composed of heavier atoms will scatter more electrons and will, therefore, appear darker in the final image on the fluorescent screen. They will be lighter on the photographic plate.

Three types of electrons emerge after transit through the specimen: unscattered electrons, elastically scattered electrons, and inelastically scattered electrons. The *unscattered* electrons are those that did not interact with the atoms of the specimen. They traversed it without deviating from their trajectory. The *elastically scattered* electrons interacted with the nuclei of atoms in their path. The interaction is especially strong with heavy nuclei. The number of elastically scattered electrons is proportional to the $\frac{4}{3}$ power of Z, the atomic number of the atoms. The elastically scattered electrons did not lose kinetic energy but changed their direction significantly. They are removed, to a large extent, by the limiting aperture in the gap of the objective lens. *Inelastically scattered* electrons did interact with the electrons of the atoms in their path. They emerge within a narrow angle but have given up some of their energy. Their number is proportional to the $\frac{1}{3}$ power of Z. Inelastically scattered electrons cause chromatic aberrations. They are focused in a plane other than the image plane of the unscattered electrons. They degrade the image to some extent.

Picture Enhancement. The microscope picture can be improved by means independent of the microscope. It can be intensified by using closed-circuit television. In this case it is projected from the fluorescent screen onto the face of a television pick-up tube and is, after amplification, displayed on the face of a television picture tube. This can be accomplished, for instance, by using a fiber-optic window at the end of the viewing chamber. Such a window makes it possible also to take contact photographs of the fluorescent screen without bringing the photographic material into the vacuum. It is also feasible to feed the fluorescent image directly into a high-voltage image intensifier. The picture contrast and resolution can be improved using data correlation techniques (see, for example, Ref. 10). It can also be sharpened considerably by means of holographic technology by using optical deburring filters.[11]

Other Types of Transmission Electron Microscopes *Electrostatic EM.* Its development is as old as the development of the magnetic electron microscope.[12] It uses mostly unipotential lenses. Electrostatic transmission electron microscopes are used where a high resolution is not required. Since electrostatic lenses do not require highly regulated power supplies, they are in general less costly than magnetic microscopes.

Million Volt Electron Microscope. The first extra high voltage microscope went into operation in 1960. It was built by Dupouy and Perrier at the Laboratoire d'Optique Electronique, Toulouse, France.[13] It was designed for 1.5 MV operation. The first 1 MV microscope in the United States started operation in 1967 at the U. S. Steel Corp. Research Center at Monroeville, Pennsylvania.

The ever increasing number of these rather expensive instruments indicates that they are able to provide information that is not obtainable in any other way. The MV microscope has

*The build-up is measured by observing the decrease in the radius of a small hole, approximately 1 μ in diameter, in a carbon film deposited on a thin substrate.

the advantage of a higher resolution due to the shorter wavelength of the electrons at the higher voltage. It has a five to eight times greater penetration power than the conventional transmission microscope. It permits, therefore, the investigation of specimens of greater thickness. Biological specimens can be examined that could not be penetrated and that had to be sectioned before. Bulk properties of various materials, for instance of crystalline materials, can be investigated that may be different from those of thin foils. Materials can be studied that could not be sliced thin enough or that would be affected or contaminated by the slicing process. Another advantage is that, at the higher voltage, the electrons have a lower cross section for inelastic scattering. This leads to lower radiation damage in materials such as polymers that are easily damaged at voltages between 15 and 100 kV. The reduced inelastic scattering leads also to reduced chromatic aberration.

Scanning Electron Microscope (SEM) While in the standard transmission electron microscope the total area under observation is irradiated at the same time by the electron beam, only a single element of this area is irradiated at any one time by the "probe" in the scanning electron microscope (SEM). This probe is a very fine electron beam that has been demagnified by magnetic lenses. It scans the specimen in a television-type raster. The finer the probe, the higher is the resolution of the microscope. The signal originating from each element while it is under irradiation modulates the electron beam of a display tube. The beam of the display tube is deflected in synchronism with the probe scan.

A system of this type without probe demagnification, and therefore, with low resolution was first used by M. Knoll in 1935.[14] A demagnified probe was used by M. von Ardenne in 1938. The SEM has been developed since that time into an extremely useful tool through the work of many researchers. Many models are now commercially available.

The SEM can operate in a number of different modes that will supply different information about the specimen. The SEM can make use of:

(a) Secondary electrons from the surface of a thick specimen.

(b) Backscattered electrons from the surface.

(c) Transmitted electrons.

(d) Cathodo-luminescence and x-rays.

The SEM operates in its most common form at a voltage between 5 kV and 50 kV. It has a tungsten hairpin cathode and two demagnifying lenses that are built like the lenses of the standard transmission microscope but have a short image distance compared to a long object distance (see Fig. 6). The final lens has built inside its inner cylinder two sets of vertical and horizontal scanning coils. One set near the top of the lens deflects the beam away from the axis, while the second set deflects it in the opposite direction towards the axis, so that the beam crosses the axis in the exit aperture of the lens. Stigmators are used to correct imperfections of the lens.

The specimen is held several millimeters below the exit aperture of the final lens at a tilting angle between 30° and 60°. The distance has to be great enough to prevent the magnetic field of the lens from interfering with the measurement. Backscattered electrons are collected by a ring electrode mounted below the exit aperture of the lens. Secondary electrons are collected by a collector mounted on the side, facing the specimen. The collector is at a high enough positive potential to attract the secondary electrons that leave the specimen with an energy of a few volts. Inside the collector box is a scintillation crystal e.g., europium activated calcium fluoride [CaFe(Eu)] at a still higher positive potential. The light flashes produced by the electrons impinging on the crystal are conducted through a light pipe to a photomultiplier tube located outside the vacuum chamber. The signal from the photomultiplier is amplified and used to modulate the beam of the display cathode ray tube. The display tube has, usually, a long-persistent phosphor screen. The micro-

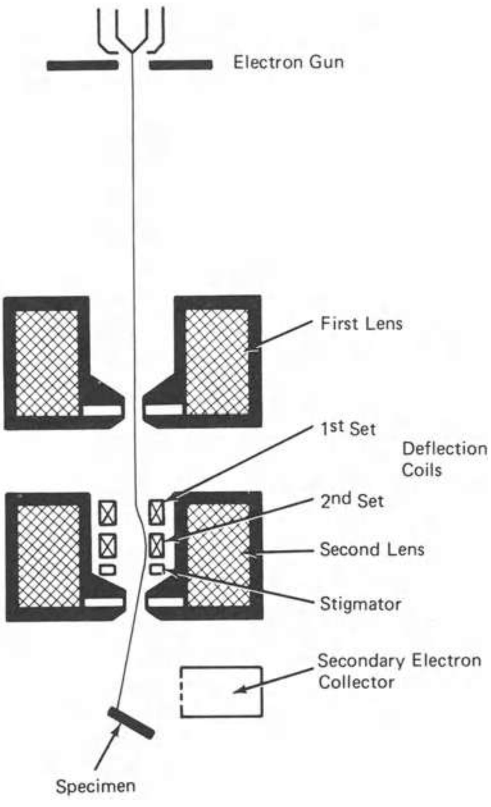

FIG. 6. Typical scanning electron microscope (SEM).

graph is taken photographically from the face of the display tube. It is possible to display different signals side by side that are obtained from different types of collectors. Storage tubes may be used in place of ordinary display tubes. The signal can also be stored on magnetic tape or on a magnetic drum and can be fed to a computer for image enhancement. The magnification of the SEM is determined by the ratio of the size of the raster on the display tube to the size of the raster on the specimen. The number of scanning lines per frame can be varied between 250 and 1000 lines or more. The time per scan can be varied from a fraction of a second, for observation, to several minutes for recording. Since the probe currents are very small, on the order of 10^{-12} to 10^{-10} A, long exposure times are necessary in order to obtain a good signal-to-noise ratio. The exposure time is limited by the stability of the voltage supplies and the difficulty of eliminating mechanical vibrations completely.

The SEM has a very small beam-convergence angle–between .005 and .01 radian. This means that it has a great depth of focus, much greater than that of optical or standard transmission microscopes. This accounts for the three-dimensional qualities of its pictures.

In the secondary emission mode the contrast in the picture is generated by a change in the composition of the specimen, causing a change in the secondary emission ratio. Where the composition of the specimen surface is so uniform that the secondary emission ratio varies very little, the contrast may be produced by the topography of the surface. The reason for this is that the secondary emission ratio increases as the angle of incidence of the primary electron increases.

The resolution of the SEM described above is limited to 10 to 25 nm (100 to 250 Å). This limitation is determined by the size of the electron probe. This in turn is determined by the diameter of the crossover near the aperture of the grid, by the demagnification of the electron optical system, and by the increase in spot size due to the range in kinetic energy of the electrons emerging from the cathode. The hot tungsten cathode has a low emission density even when operated at the highest temperature compatible with a useful life (approx. 2900°K). Owing to its high temperature, the emitted elec-

trons have a great range in kinetic energy (approximately 0.9 V). A different cathode at a lower temperature and higher emission density would permit a smaller limiting aperture for the same optical system and the same probe current. The lanthanum hexaboride [LaB_6] cathode introduced by A. N. Broers[15] is a great improvement over the tungsten filament.

Scanning Transmission Microscope (STEM). Another major improvement was achieved by A. V. Crewe of the University of Chicago by introducing a field emission electron source.[16] The field emission technique was invented in 1937 by E. W. Müller (see FIELD EMISSION). In Crewe's STEM (see Fig. 7) the field emission cathode, which requires a vacuum of 10^{-9} to 10^{-10} torr, consists of a fine tungsten point. A negative potential of 3 kV is applied to the cathode against a spherical first anode. A second anode at ground potential is at a potential of 30 kV against the cathode. The two anodes together form an immersion lens. Though the tunsten emitting point has a diameter of 100 nm the electrons seem to emanate from a virtual electron source that has a diameter of only 3 to 10 nm (30 to 100 Å) due to the very strong electric field close to the cathode. Emission currents of several microamperes are obtainable.

Since the tungsten tip is at room temperature, the range of kinetic energy of the emitted electrons is less than 0.2 V. With a demagnifying magnetic lens, a probe diameter of 0.5 nm (5 Å) is possible with a probe current of 10^{-11} to 10^{-10} A.

Crewe collects separately the three types of electrons that emerge after passing through the specimen, namely: unscattered, elastically scattered, and inelastically scattered electrons. A ring electrode mounted underneath the specimen collects essentially all elastically scattered electrons that have changed their direction significantly. The opening in the ring permits the unscattered and the inelastically scattered electrons to pass. A magnetic—or electrostatic—analyzer separates the two types. In a homogeneous magnetic field perpendicular to the electron path, the inelastically scattered electrons will describe a circle of smaller radius than the unscattered electrons due to their lower energy. Two different detectors can then collect the two types separately. Since the number of elastically scattered electrons increases much faster than the number of inelastically scattered electrons with increasing atomic number, the signals can be used to determine the atomic number of the atoms at the spot under investigation.

ELECTRON OPTICS

The invention of wave mechanics in 1926 by Heisenberg and Schrödinger saw a revolution in physics. It became apparent that the ideas of classical dynamics could be formally replaced when a stream of particles was considered. According to the well-known De Broglie hypothesis, a wavelength λ can be assigned to any material particle such that

$$\lambda = h/mv \tag{1}$$

where h is Planck's constant, m is the particle mass, and v is the particle velocity.

As one of the many consequences of these ideas, the new science of electron optics emerged. In the same year, Busch demonstrated that the action of a short axially symmetrical magnetic field on a beam of electrons was similar to that of a glass lens on light. Terms used before then in optics found their use in describing electron devices. Electron "lenses" and "mirrors" having "focal lengths" and "resolutions and aberrations" were described. This analogy has proved useful in the study of the behavior of electrons in electronic valves, magnetrons and klystrons, traveling wave tubes, cathode ray tubes, and electron microscopes, to name only a few devices. The original concept of the electron microscope was evolved by direct analogy with the light microscope.

An electron which has fallen through a potential V has a kinetic energy $\Gamma = \frac{1}{2}mv^2 = eV$. Hence $v = (2eV)^{1/2}/m^{1/2}$, and using Eq. (1), we obtain the useful formula expressing electron wavelength in terms of volts

$$\lambda = \left(\frac{150}{V}\right)^{1/2} \tag{2}$$

where λ is in angstroms.

In light optics, the least resolvable distance S between two objects is given by the Abbe expression $S = \lambda/(2n \sin i)$, where n is the refractive index of the material between object and lens and $2i$ is the angle subtended at the lens by the object; $n \sin i$ is called the numerical aperture. In the case of white light of equivalent wavelength $\lambda = 5600$ Å,

$$S_{(\text{minimum, light})} = 1800 \text{ Å, i.e., } 1.8 \times 10^{-5} \text{ cm.}$$

Using the same expression and Eq. (2), which gives λ for an electron = 0.04 Å for $V = 100$ kV,

$$S_{(\text{minimum, electrons})} \simeq 0.04 \text{ Å}$$

i.e., small fractions of an angstrom can be resolved. However, the theory does not take into account the fact that lenses are imperfect. Spherical aberrations drastically affect the situation. In addition, certain diffraction defects and scattering impose limitations. These facts and others make it impossible to obtain resolutions near the theoretical maximum. Instead, 2.0 Å is a better theoretical value. Practical limiting resolutions obtained are of the order of 2.5 Å to 3.0 Å.

Source of Electrons The basic source of electrons in electron tubes is the heated filament or disk. The well-known equation $J = AT^2 \exp(-\phi/kT)$ describes the emission, where J is the current density, T is the temperature, ϕ is the work function of the emitting material, A is a constant, and k is Boltzmann's constant. J is enhanced by increasing T or reducing ϕ. Typical cathode materials used are tungsten, tantalum, and the oxides of barium and strontium.

A voltage is applied to accelerate the emitted electrons, and the current density is given by $J = AT^2 \exp(-\phi/kT)$ if they are removed to the anode. However, many electrons stay near the cathode and repel other emitted electrons back to the cathode. Most devices operate in this "space-charge limited" way. For any electrode configuration, the current density is then $J = GV$ where V is the applied voltage and G is a constant for the particular electrode configuration. G is roughly equivalent to electrical conductance and is called the "perveance." The constant is fundamentally important. The higher G is in value, the greater is the efficiency of the beam system.

In simple designs, the axial portion of the cathode is overloaded, producing excessive emission and cathode burn-out. To avoid this situation, carefully shaped electrodes must be used, but the acceptable design depends upon the application. A bent hairpin point cathode is used in, for example, the electron microscope. It produces low perveance but high emission density. Since G is low, the field at the cathode can be high, and this tends to reduce ϕ, giving emission at lower temperature. The electron guns for klystrons, traveling wave tubes, and metallurgical applications such as vacuum melting and welding require higher efficiency and current density. Hence they are high-perveance guns.

Beam Control Electrostatic and magnetic fields control the motion of an electron according to the following equation:

$$\overline{F} = m\frac{dv}{dt} = e(\overline{E} + \overline{v} \times \overline{B}) \tag{3}$$

where

$\overline{F}$ = force
$\overline{E}$ = electrostatic field
$\overline{B}$ = magnetic field
$\overline{v}$ = electron velocity
e = electronic charge

The electron must travel in a vacuum if it is not to be scattered and lose its kinetic energy by collision with relatively massive gas molecules. Nuclear particles such as protons and neutrons are each about 1837 times larger in mass than the electron.

Electrostatic Electron Lenses If in Eq. (3), $\overline{B} = 0$, then $\overline{F} = e\overline{E}$. The equation says that an electron in a field $\overline{E}$ experiences a force $\overline{F}$ in the direction of the field. Thus in the system shown in Fig. 1 where there is a voltage V_1 on cylinder 1 and V_2 on cylinder 2, and where $V_2 > V_1$, the field and the path of an electron are as shown. The electron moving from left to

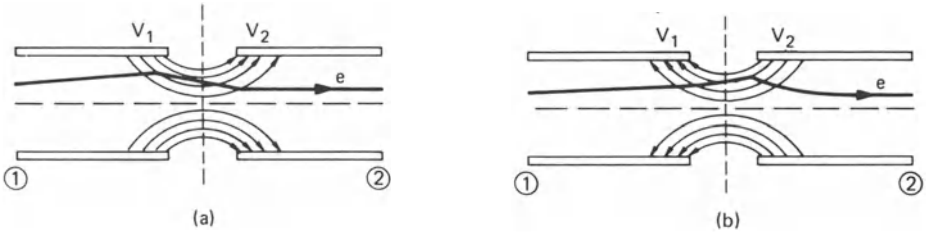

FIG. 1. Electrostatic focusing of electron beam by cylinder lenses ① and ②. (a), voltage $V_2 > V_1$; (b), voltage $V_2 < V_1$.

right increases its velocity and is deflected towards the axis. After passing the median, the force is away from the axis, but since velocity is increased, the electron spends less time in this part of the field. Therefore, deflection away from the axis is less than it was towards it, and there is a net convergence. If $V_2 < V_1$, as in Fig. 1 (b), then for an electron beam traveling from left to right the lens will still be convergent because maximum deflection will occur after the electrons have slowed down. All such lenses are convergent for $\overline{E} = 0$ on both sides of the lens.

Magnetic Electron Lenses If in Eq. (3) $\overline{E} = 0$, then $\overline{F} = e\overline{v} \times \overline{B}$. This says that the force $\overline{F} = e|\overline{v}||\overline{B}| \sin \theta\, \overline{\epsilon}$ where $|\overline{v}|$ and $|\overline{B}|$ are the numerical values of the vectors and θ is the angle between them; $\overline{\epsilon}$ is a unit vector perpendicular to both, and indicates the direction of the force. For $\overline{F}$ to be greater than 0, $\overline{v}$ must be greater than 0. The force constrains the electron to move in a circle of radius $\rho = (\overline{v} \sin \theta)/(\overline{B}\ e/m)$. At the same time it moves in a perpendicular direction with velocity $\overline{v} \cos \theta$, and therefore, it traces the path of a helix and returns to the axis in a time $T = 2\pi/(\overline{B}\ e/m)$ which is independent of both $\overline{v}$ and θ. The net effect is that all electrons are focused by $\overline{B}$ to produce an image of the source from which they diverge.

The simple magnetic lens consists of a short coil of wire contained in a surrounding shield of magnetic material. A small gap in the case material concentrates the escaping field when the coil is energized. The electron microscope (shown in Fig. 2) illustrates the use of magnetic lenses. The coils are wound in opposite sense to cancel the spiral distortion of the electron beam which is introduced by the individual lenses.

Electrostatic Deflection If in Fig. 3(a) a voltage V_d exists between the plates $x_1\ x_2$ and an electron enters along the axis with a constant velocity $v = (2\ Ve/m)^{1/2}$, then because of the field $\overline{E}_y$ caused by V_d, a transverse force $\overline{F}_y$ causes a motion in this direction to be impinged on the electron, i.e., $m\ (d^2y/dt^2) = V_d e/\mathrm{d}$, from which $dy/dt = (V_d/\mathrm{d})\ (e/m)\ t$ and $y = \frac{1}{2}\ (V_d/\mathrm{d})\ (e/m)\ t^2$. The force acts for time $t = \ell/v$; thus deflection $y = \frac{1}{2}\ (V_d/\mathrm{d})\ (e/m)\ (\ell/v)^2 = \frac{1}{4}\ (V_d/\mathrm{d})\ (\ell^2/V)$. The additional deflection, after $\overline{F}$ has ceased to act on the electron, is $y^1 = (V_d/V)\ (\ell L/2\mathrm{d})$.

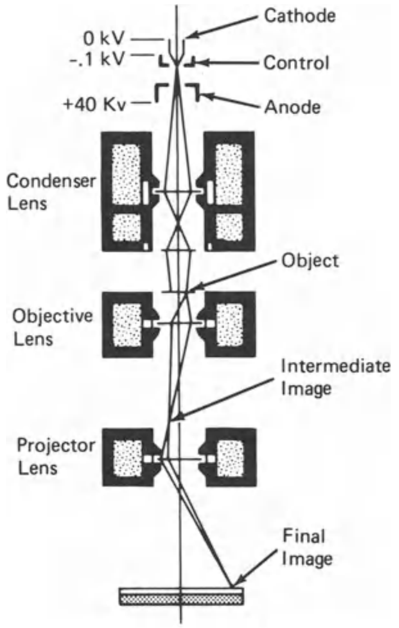

FIG. 2. Schematic diagram illustrating the general arrangement of a transmission electron microscope.

Magnetic Deflection See Fig. 3(b). If $\overline{B}$ is a sharply defined field, then the deflection on leaving the field is given by $y = \ell^2/2\rho$. Total deflection $D = L\ \tan \alpha + y$. To a good approximation

$$D = \frac{\overline{B}L\ell}{v}\frac{e}{m}\left(1 + \frac{1}{2L}\right).$$

It should be emphasized that these considerations are only approximate. In practice, factors such as the inability to sharply define a field edge in space cause added complications.

Cathode Ray Tubes A device worthy of brief consideration is the cathode ray display tube. Its basic components are as follows: an electron gun, an acceleration and focus system, a deflection, and a display system which is normally a phosphor screen. Depending on the type of tube the applied voltage causes electrostatic or magnetic deflection. In the oscilloscope tube electrostatic deflection is used while in the large display tube, such as the television

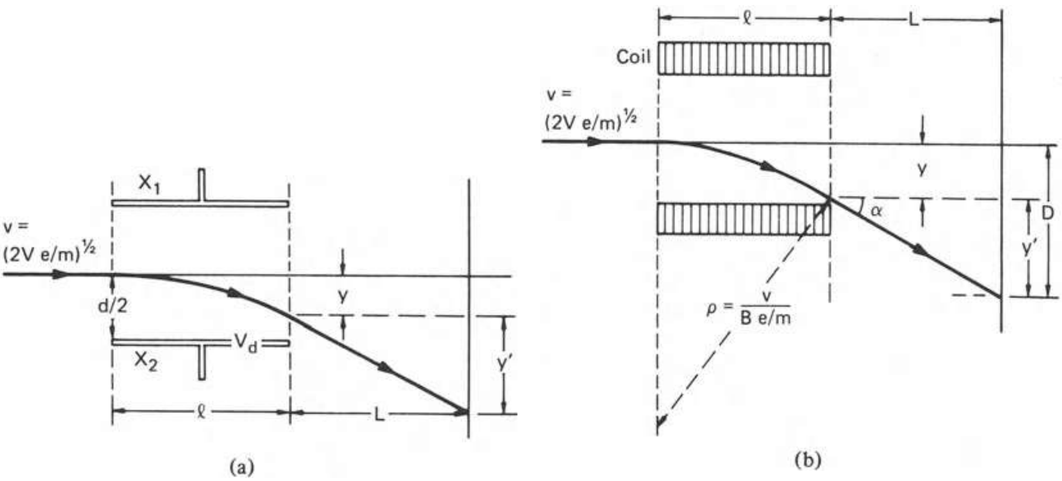

FIG. 3. (a) Deflection of electron beam by electric field between parallel plates X_1X_2. (b) Deflection of electron beam by magnetic field. Electron path is an arc of a circle only while it is influenced by field. After leaving the field the path is linear.

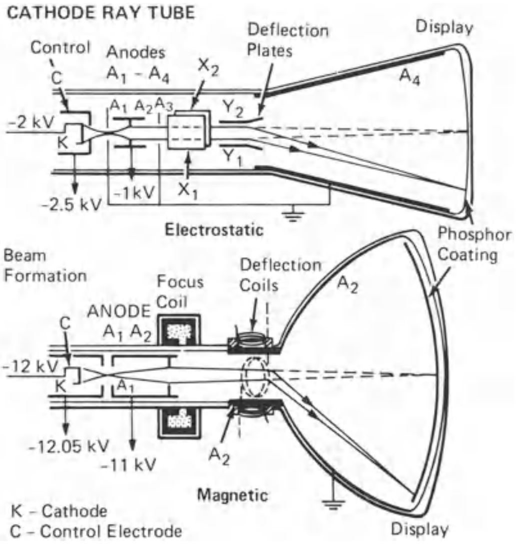

FIG. 4. Schematic diagram of cathode ray tubes.

tube, magnetic deflection is used because of the large scan angles which are required. The tubes are illustrated in Fig. 4.

Advanced Oscilloscope Tubes The instrument tube shown in Fig. 4 is of low cost and has limited frequency performance to 5 to 10 MHz. If voltage on A_4 is increased, then it becomes increasingly difficult to deflect the beam in such a tube. In recent years performance of the comparatively low-cost tube has been increased to greater than 50 MHz by the introduction of post-deflection acceleration systems, the most successful of which is shown in the tube illustrated in Fig. 5. Here a grid of fine wires placed over the end of the gun assembly shields the deflection area from the effect of the high acceleration field required for high brightness and high writing speed. The electrons pass through the grid and those which collide with it cause low energy emission of secondary electrons which can be collected readily by placing a small positive voltage on a neighbouring electrode such as A_4, and therefore they do not cause background illumination of the image produced by the primary beam.

Table 1 illustrates the operating features and performance of the tube. The display envelope is commonly rectangular and an external magnetic coil is needed to align the beam axes with those of the display face. Plate capacitances are reduced by the use of side pins. Nevertheless these capacitances and transit time phenomena contribute to the main limitations for use at higher frequencies. However, other tubes operating at frequencies greater than 500 MHz have been developed.

Color Television Tube In the television tube the beam must be deflected to trace each part of the screen in sequence while it is simultaneously intensity modulated. The resulting picture is a mosaic of dark and light elements. Three primary red, green and blue pictures must be displayed in exact registration to obtain a a high-quality color picture. Color mixing to produce the wide range of colors required is obtained subjectively and depends on the relative brightnesses of the three primary light yields at a particular point on the screen. There are numerous ways of achieving the color picture, but the "shadow mask tube" has been developed to provide the most economical method. There are three primary guns in the tube, each tilted to converge to a central point near the screen. A single de-

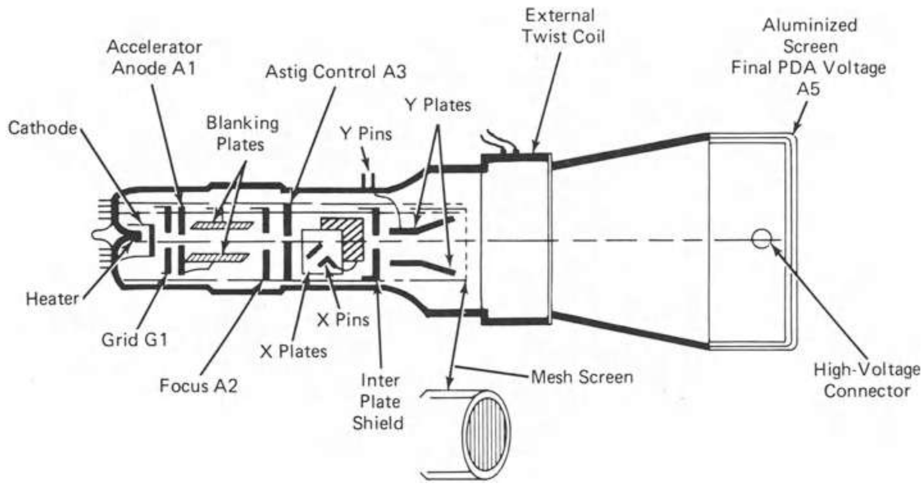

FIG. 5. Advanced Instrument Cathode Ray Tube. Mesh screen, held near mean plate potential, prevents PDA field from reducing deflection plate sensitivity. Note other features such as side pin connection to plates to reduce capacitance; also the blanking arrangement for blanking the beam during time-base flyback. (The method has advantages over using grid G1.) See Table 1 for other information.

TABLE 1. PERFORMANCE OF MESH PDA TUBE (See Reference 5)

flection coil is used to scan the beams in registration (as shown in Fig. 6. Additional deflection yokes carry currents derived from the main deflection waveform to introduce convergence corrections as needed to maintain registration over the complete screen.

The screen must emit red light when bombarded by electrons from the red gun, green from the green gun, and blue from the blue gun. To enable this to occur a perforated metal mask is positioned about 12 mm from the screen and the beams in fact converge to its central point rather than that of the screen. Electrons must pass through the mask holes to reach the screen as shown in Fig. 7. The beams appear to originate from three apparent deflection centers in the deflection field. Thus, they

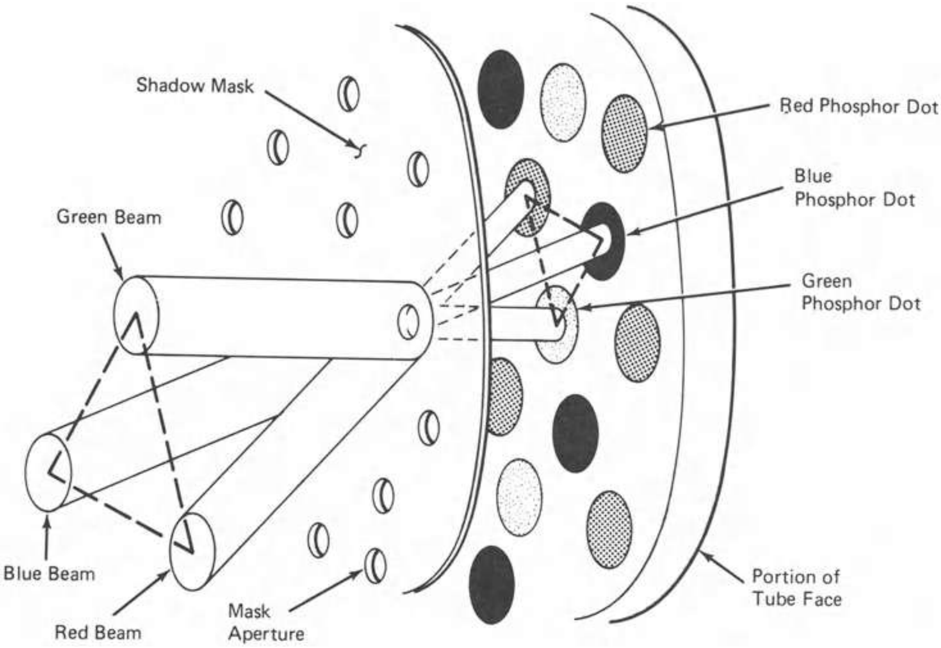

FIG. 7. Operation of shadow mask in color television tube.

will strike the face in three points of a triangle when passing through a particular hole. Red, green, or blue emitting phosphor "dots" are deposited at these points as appropriate. The plate is called a shadow mask because when one gun is switched on, the unwanted dots are not energized since they lie in its shadow. Typical mask holes are 0.5 mm in diameter and about 0.7 mm apart. The total number of holes is about 400 000 for a 25-inch tube.

During manufacture the mask itself is used to process the screen. The phosphor is deposited with a photosensitive lacquer and a UV light source is placed at the appropriate deflection center. The screen is exposed through the mask, developed, and the process repeated for the other two colors. The deflection centers move slightly towards the screen for large deflection angles, and a correction lens has to be used to compensate during exposure. The accurate positioning of the million or more phosphor dots is achieved in this way.

ELECTRON SPIN

The electron, as one of the stable fundamental particles (a lepton) of physics, has a small rest mass m and a classical unit of charge $-e$, but also possesses the attribute of spin, a strictly quantum mechanical property. Associated with this spin is an angular momentum of magnitude $\hbar/2$ ($\hbar$ is Planck's constant) and a magnetic moment given approximately by $e\hbar/2mc$, where $e\hbar/2mc = \mu_B$ is known as the *Bohr magneton* ($\mu_B = 0.9273 \times 10^{-20}$ ergs/gauss). On the other hand, orbital angular momentum, such as for electrons in atoms, is quantized in integral units of $\hbar$. Thus, the electron spin quantum number of $\frac{1}{2}$ is different than that for orbital quantum numbers. Furthermore, the *electron spin gyromagnetic ratio* (the spin magnetic moment divided by the spin angular momentum) is twice the classical value for orbital angular momentum. This feature plays an important role in the Zeeman effect of optical spectra of atoms. Electron spin and its magnetic moment are predicted by the relativistically invariant Dirac equation. Whereas quantum mechanical wave functions for orbital motion are invariant under 2π rotations, electron spin wave functions are not invariant under 2π rotations, but instead change sign. The vector components of the electron spin operator can be conveniently described in terms of the 2×2 Pauli spin matrices. These two-component quantities are termed *spinors.*

The first direct experimental evidence for quantized electron spin **S** (having a z-component $S_z = m_s\hbar$, with $m_s = \pm\frac{1}{2}$) was obtained from the Stern-Gerlach experiment in which a collimated beam of neutral silver atoms was split into just two separate beams with opposite deflections when the silver atoms passed through an inhomogeneous magnetic field. This experimental approach developed into the molecular beam approach, which was so fruitfully pursued by Rabi, Kusch, and colleagues in the study of free atoms and molecules. These workers first used the magnetic resonance technique to change atoms from one spin orientation (with respect to a space quantization axis) to another, thus altering the populations to be deflected by the inhomogeneous field. Another important ramification of electron spin was in the Zeeman effect of optical spectra of atoms in an external magnetic field. Uhlenbeck and Goudsmit in 1925 proposed the concept of spin in order to explain the spectroscopic fine structure of atoms. The different gyromagnetic ratios for orbital and spin motion produce a state-dependent Zeeman splitting ($\Delta E = g\mu_B H$), where the g-factor is given by the famous Landé result which depends on the spin (**S**), orbital (**L**), and total (**J**) angular momentum of the atom. This result explained the anomalous Zeeman effect.

Early studies of spin-dependent effects in solids and liquids were made utilizing susceptibility and magnetization techniques, techniques determining the bulk magnetic moment (including orbital contributions) of a macroscopic sample. In 1945 Zavoisky reported the first observation of *electron paramagnetic resonance* [EPR, sometimes also called *electron spin resonance* (ESR)] in a solid. *Nuclear magnetic resonance* (NMR) was reported independently a year later by two groups. These developments utilizing the magnetic resonance approach, a much more sensitive and accurate method for detecting the presence of spins, represented a natural extension of the magnetic resonance technique first used in molecular beam methods.

The detection of magnetic resonance, described in quantum mechanical terms, represents the absorption of power in a radio-frequency (RF) coil or microwave cavity in the form of photons of frequency ν and energy $2\pi\hbar\nu$ such that $2\pi\hbar\nu = g\mu_B H$. $g\mu_B H$ is the Zeeman splitting resulting from the local magnetic field H. H may contain a contribution from other sources (i.e., hyperfine and exchange interactions) besides the external field. For $H =$ 3000 gauss, $\nu \simeq 9 \times 10^9$ Hz for $g \simeq 2$, a frequency conveniently in the microwave range, suggesting microwave spectroscopy methods for EPR. A block diagram of a typical EPR microwave spectrometer is shown in Fig. 1. Rapid advances in microwave- and radio-frequency techniques before and during World War II greatly benefitted the rapid growth of both EPR and NMR.

The power of the EPR technique results not only from the enhanced sensitivity, but from the microscopic information obtained from the EPR spectra about the environment of the unpaired electron spins. This microscopic information consists of g-shifts [$\Delta g = g - g_{\text{f.e.}}$ (f.e. = free electron), $g_{\text{f.e.}} = 2(1 + \alpha/2\pi - \cdots) \simeq$ 2.0023 since the fine structure constant $\alpha \simeq$ 1/137] resulting from the spin-orbit and orbital Zeeman interactions, fine structure splittings (for spin $\mathbf{S} \geqslant 1$ only) resulting from crystalline fields, hyperfine spectra resulting from electron spin-nuclear spin interactions, line widths and shapes resulting from various spin-spin interactions, the motion and diffusion of spins, and spin-lattice relaxation (spin-phonon interactions). Pulsed EPR (the spin-echo technique) and dynamic (field swept adiabatic fast passage) measurements have yielded information on spin-spin interactions, spin diffusion, and spin-lattice relaxation. The detailed microscopic information obtained from the spin Hamiltonian parameters tells us much about the symmetry properties and spatial extent of the electron (hole) wave function of a particular paramagnetic species. Figure 2 shows the EPR spectrum of atomic hydrogen situated at a cubic interstitial site in CaF_2 for $\mathbf{H} \parallel [100]$. The principal splitting into two patterns results from the interaction of the unpaired electron with its hydrogen nucleus with spin $I = \frac{1}{2}$ (two hyperfine fields for $m_I = \pm\frac{1}{2}$). The two symmetric patterns of 9 lines each (intensity ratios 1:8:28:56:70:56:28:8:1) result from the interaction with eight equivalent ^{19}F ($I = \frac{1}{2}$) nuclei. The interaction with the eight ^{19}F neighbors is termed the superhyperfine or ligand hyperfine structure. For each ^{19}F nucleus the hyperfine interaction has axial symmetry and is characterized by tensor components $A_\parallel$ and $A_\perp$. For other external field orientations the eight ^{19}F nuclei are not all equivalent and additional splittings result. A detailed theory of the embedded H-atom wave function, taking account of orthogonalization to the core electrons of the neighboring ^{19}F ions is required to explain the hyperfine tensor components.

A vast amount of work has been done on transition metal ions and rare earth ions in a wide variety of hosts, including ionic crystals, covalent crystals, and certain metals. Here we limit our discussion to S-state ($\mathbf{L} = 0$) ions such as Fe^{3+} or Mn^{2+} [$(3d)^5$ configuration for free

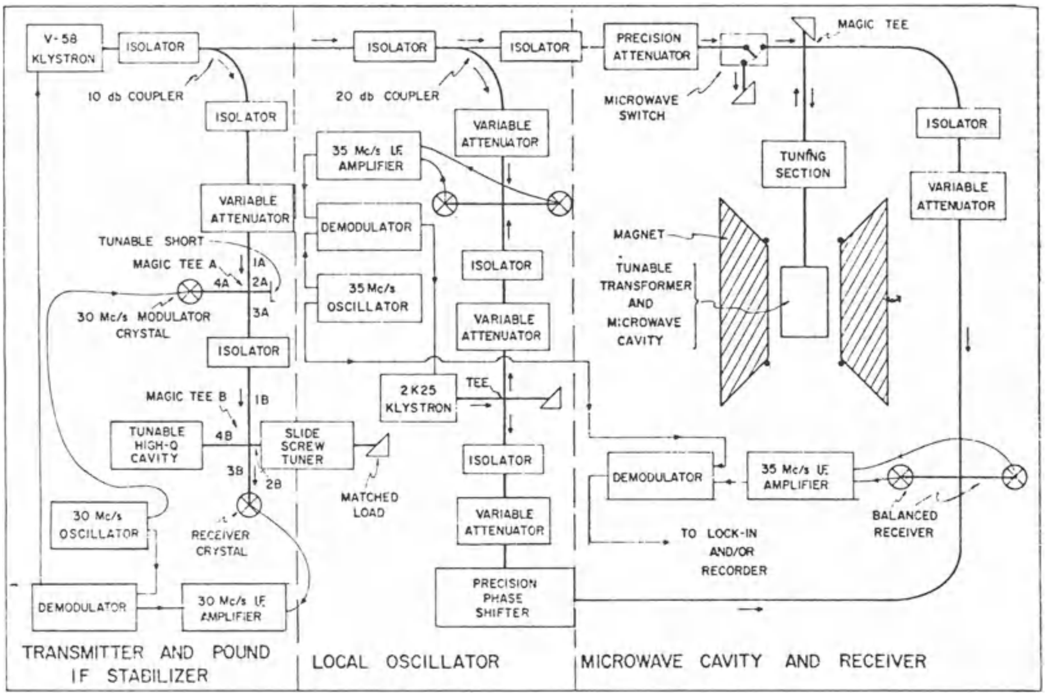

FIG. 1. Block diagram of a high-sensitivity superheterodyne X-band EPR spectrometer. [After Holton, W. C., and Blum, H., *Phys. Rev.* 125, 89 (1962).]

ion]. For the $S = \frac{5}{2}$ ground state ions the crystal field can play an important role in determining the EPR spectrum. In the strong crystal field case zero field spin splittings are larger than typical Zeeman energies. Even for an iostropic g-value and no hyperfine interaction the EPR spectrum can be very anisotropic and depends critically on the symmetry and strength of the local crystal field. Certain rare earth ions in appropriate symmetry hosts have been utilized

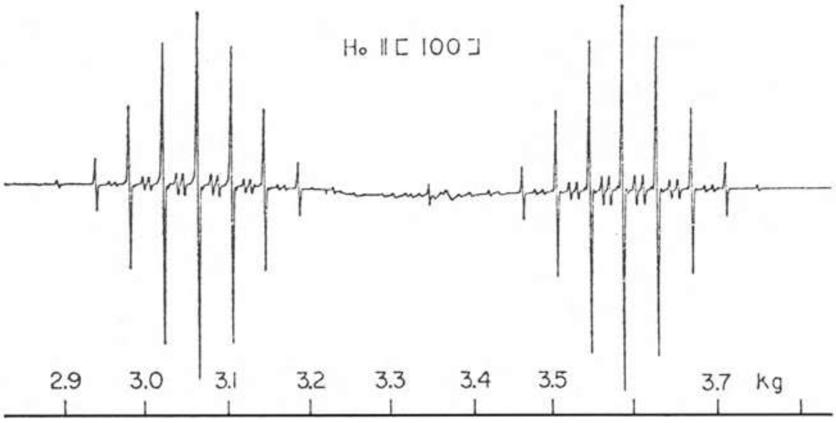

FIG. 2. EPR absorption derivative spectrum of CaF_2:H for **H**∥ [100]. The sharp line at 3.35 kG is a g-marker while the doublets between the major lines of the two g line patterns are forbidden transitions. [After Hall, J. L., and Schumacher, R. T., *Phys. Rev.* 127, 1892 (1962).]

to make a 3- or 4-level maser (microwave amplification by stimulated emission of radiation). Such solid state microwave amplifiers, first proposed by Bloembergen, have been of considerable technological importance.

It frequently happens that the paramagnetic ion of interest has an orbital degeneracy in a particular crystalline field. This leads to the interesting Jahn-Teller effect. A static or dynamic distortion (the latter represents a tunnelling between equivalent static distortions) occurs, lowering the total energy of paramagnetic ion plus environs. This distortion can have a profound effect on the EPR spectrum. Analysis of these spectra yields information on the symmetry and magnitude of the distortion.

Non-*S*-state ions or impurities frequently have large anisotropic *g*-shifts resulting from the spin-orbit interaction which depend critically on the position of excited orbital states. Analysis of the *g*-tensor thereby provides useful information on the excited state energies of an impurity ion or defect. One example is the O_2^- molecular ion, frequently observed as a substitutional impurity in ionic crystals. Consider an O_2^- ion, oriented along a [110] axis, replacing a halogen ion in an alkali halide. The axially symmetric free O_2^- would have a *g*-tensor with components $g_{\parallel}$ and $g_{\perp}$ for **H** parallel and perpendicular to the molecular axis, respectively. In the alkali halide the $2p\pi_g$ orbitals are split by both the spin-orbit interaction and the larger crystalline field producing a correction to $g_{\parallel}$ and a splitting of $g_{\perp}$ into two components $g_{[1\bar{1}0]}$ and $g_{[001]}$. The sign of $g_{[1\bar{1}0]} - g_{[001]}$ determines whether the unpaired electron in the $2p\pi_g$ orbital is along the $[1\bar{1}0]$ or [001] axes. Experimental results show the unpaired $2p\pi_g$ orbital is aligned along the $[1\bar{1}0]$ axis for potassium and rubidium halides, but is along the [001] axis in the sodium halides.

EPR line shapes in solids often are inhomogeneously broadened by residual hyperfine interactions with nearby nuclei. In these circumstances the unresolved lines observed in EPR spectra do not allow the determination of the hyperfine tensors of these residual hyperfine interactions. Feher developed an ingenious electron-nuclear double resonance technique (ENDOR) that permits the resolution of these otherwise unresolved hyperfine interactions. The idea depends on the much narrower line widths of the NMR transitions. An EPR transition is partially saturated at fixed field while a RF source is swept through the NMR transitions of the nuclei coupled through the residual hyperfine interactions with the unpaired electron (hole). Strong saturation of these NMR transitions alters the populations of the electron (hole) spin energy levels and alters the magnitude of the EPR signal. The EPR transitions are sensitive probes of weak NMR transitions from a small number of nuclei. ENDOR has been utilized to map the complicated oscillatory wave function of shallow donors in silicon and accurately determine the position in momentum space of the conduction band minima. Another interesting ENDOR example in Fig. 3 shows part of the ENDOR spectrum of the *F*-center and *M*-center (excited triplet $S = 1$ state) in KCl at $T \sim 90$ K. (a) gives the spectrum of the first shell of K-nuclei for the F-center without optical excitation. (b) shows additional ENDOR transitions from the

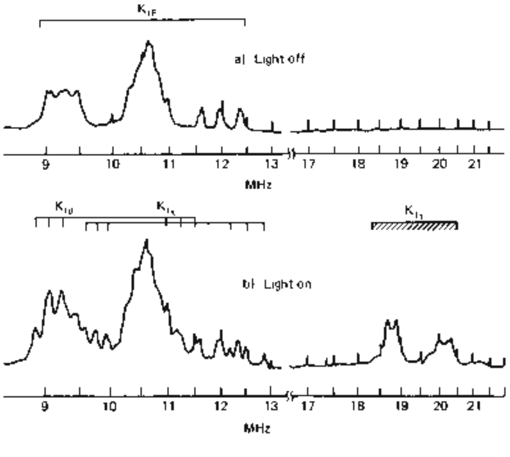

FIG. 3. ENDOR spectra of a KCl crystal containing *F*-centers and *M*-centers. $B_0 = 3345$ gauss $\parallel [100]$, $T = 90$ K. (a) Without light excitation; first shell (*K*-nuclei) of the *F*-center; (b) during 3650-Å light excitation, additional ENDOR lines of *K*-nuclei of *M*-centers in the triplet state. [After Seidel, H., *Phys. Letters* 7, 27 (1963).]

nearest neighbor shells of K-nuclei of the excited $S = 1$ state of the M-center after irradiation with 3650 Å light. The ENDOR technique provided direct experimental proof of the models of these centers—the F-center consisting of an electron trapped at a halogen ion vacancy and the M-center composed of two adjacent F-centers.

Another important type of double resonance technique is the optical detection of magnetic resonance (ODMR). The optical-RF double resonance technique, first proposed by Brossel and Kastler, was demonstrated by Brossel and Bitter and has been extensively used in studying excited states in gases. The ODMR approach is particularly useful when the excited state population is very small and direct observation of the excited state EPR spectrum would be impossible. The sensitivity is enhanced by detecting optical photons from the fluorescing excited states while the magnetic field is swept through the excited state EPR spectrum. Absorption of microwave photons induces changes in the optical photon emission spectrum. The principle is similar to the ENDOR technique in that the sensitivity is enhanced by detecting higher energy photons. Figure 4 shows the ODMR spectrum of a deep defect in silicon observed at $T = 1.7$ K for two cases—with and without the application of a compressional stress. This data is valuable in testing various theoretical models of these defects.

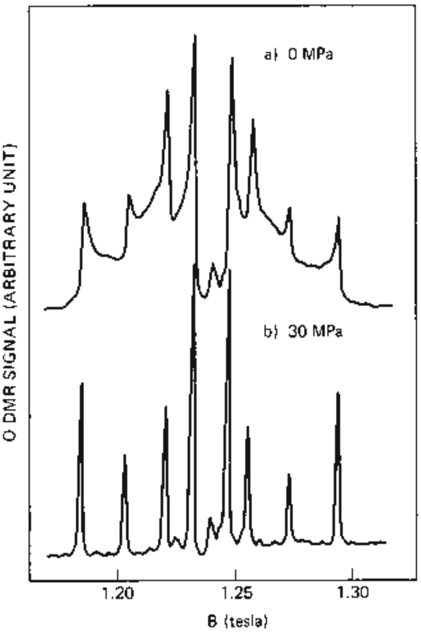

FIG. 4. ODMR spectrum the 0.97-eV luminescence in neutron-irradiated silicon. B ∥ [011], $T = 1.7$ K, $\nu_{\text{EPR}} = 35.0$ GHz. (a) Zeros stress spectrum; (b) Spectrum with 30 MPa compressional uniaxial stress, T ∥ [0$\bar{1}$1]. [After Lee, K. M., et al., *Phys. Rev. Lett.* 48, 37 (1982).]

Many other variations and applications of EPR should be mentioned. These include spin echoes, a novel, powerful technique developed by Hahn for NMR, but which has also been useful in EPR. In concentrated spin systems in crystalline solids the isotropic Heisenberg exchange interaction, in addition to smaller anisotropic exchange interactions, exist between pairs of neighboring spins. These systems frequently show spontaneous magnetization (below a critical temperature), long range spin order, and ferro-, ferri-, or antiferromagnetic behavior. The spin modes of these systems can be studied using *ferromagnetic resonance* (FMR) or *antiferromagnetic resonance* (AFMR) techniques. The *magnetic resonance of conduction electrons* (CESR) has not only been studied in certain high purity metals and heavily doped semiconductors, but also in metals containing magnetic impurities. EPR has given useful information on unpaired spins in amorphous semiconductors, on lunar samples, on low-dimensional systems (1 and 2 dimensions), on systems subjected to hydrostatic pressure or uniaxial stress, and on a wide range of unpaired spins in the form of molecular free radicals. Furthermore, spin systems have afforded an ideal system to study phenomena in nonequilibrium statistical mechanics.

For several decades EPR has been utilized as a powerful tool, which has been broadly applied to chemical and biophysical applications. While it is impossible to address the many important applications of the EPR technique to chemistry and biology, a few illustrative examples should be mentioned. Paramagnetic molecules or ions in solution undergo translation and a rotational tumbling motion. In these cases the EPR spectra, line widths, and shapes are strongly affected by the magnitude of the anisotropic terms (anisotropic g-shifts and hyperfine interactions) and the correlation times characteristic of the molecular tumbling rates. The EPR spectra, along with associated theory, yield useful information on the molecular rotational tumbling of the paramagnetic molecules. The EPR of numerous free radicals, produced as intermediates in chemical reactions or by radiation damage, is another topic studied in chemistry and biology. One most important example of EPR radiation damage studies is of the individual amino acids and the DNA helix. However, many biologically important molecules are not paramagnetic. A vast field of growing importance has arisen, termed spin labeling, in which an appropriate paramagnetic molecule is added to a given system to act as a "neutral" (noninterfering) probe of the diamagnetic biological molecule. Certain parts of important proteins, such as the heme group (with Fe^{3+}) and other porphyrins, have been extensively studied with EPR and ENDOR techniques. Figure 5 shows the ENDOR spectra of

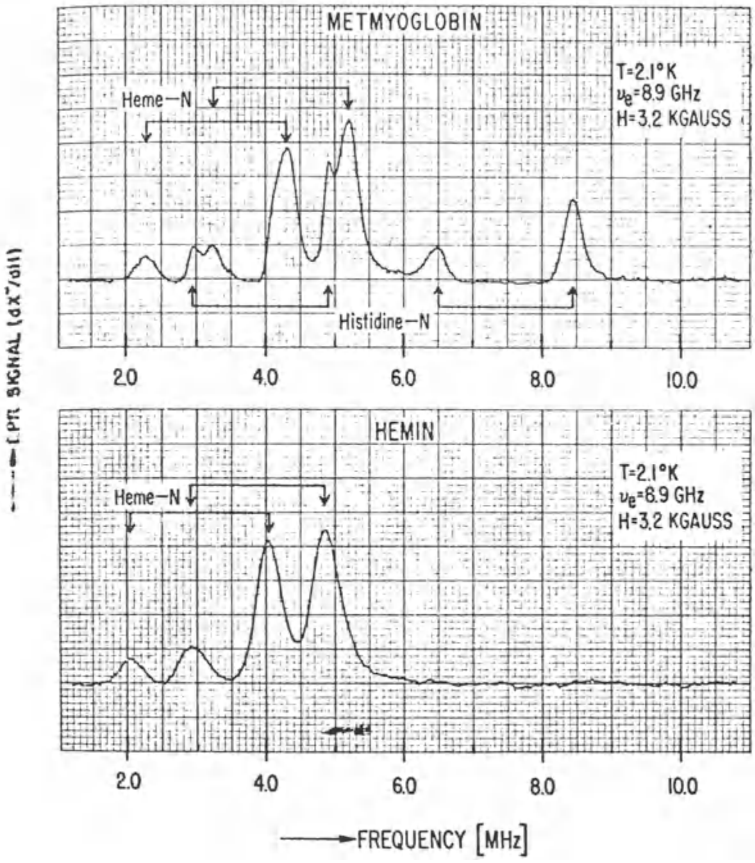

FIG. 5. ENDOR spectra due to ^{14}N interactions in hemoglobin. normal human methemoglobin A and also that of the mutant hemoglobin $M_{\text{Hyde Park}}$. The differences in the two spectra give information on the binding of histidine nitrogens to the iron and on the nature of the mutant. Along with NMR, EPR, ENDOR, and ODMR have all become valuable tools utilizing spins in the study of biological systems.

ELECTRON TUBES

Although electron tubes have been replaced with solid state electronic devices in most applications, tubes will retain their importance in applications involving high voltage, high power, high frequency, and visual display.

The basic electron tube consists of an evacuated glass envelope containing a *cathode* that emits electrons by thermionic emission and a positive *anode* that collects these electrons. The tube is evacuated so that electrons can travel without colliding with gas molecules. Other forms of electron tubes operate in a high pressure regime where gas ionization is important (i.e., thyratrons, ignitrons, voltage regulator tubes, etc.) but high pressure tubes will not be discussed. In addition, one or more transparent wire *grids* are typically inserted between the cathode and anode to control the flow of electrons.

Diodes The simplest such tube is called a *diode* (two electrodes) and is shown schematically in Fig. 1. If the anode (or *plate*) voltage is positive relative to the cathode, the electrons that boil off the cathode will be drawn to the anode and collected. Hence an electrical current flows from anode to cathode (opposite to the electron flow) in a diode. On the other hand, if the anode is negative relative to the cathode, the electrons are repelled, and no current flows.

The relationship between current and voltage in the vacuum diode is shown in Fig. 2. For small positive voltages the electric field that draws electrons away from the cathode is partially shielded by the cloud of electrons that surrounds the cathode. This is called the *space-charge-limited region*, and the current in amperes is given approximately by *Child's law:*

$$I = 2.33 \times 10^{-6} \, A V^{3/2}/d^2$$

where A is the area of the cathode in square meters, d is the separation of the cathode and anode in meters, and V is the voltage difference between the anode and cathode. For large positive voltages the electric field is strong enough to collect all the electrons emitted by the cathode, and the current is independent of voltage but depends strongly on the absolute temperature T as described by *Richardson's equation:*

$$I = 1.3 \times 10^6 \, AT^2 e^{-e\phi/kT}$$

where k is *Boltzmann's constant* (1.38×10^{-23} joules/K), ϕ is the work function of the cathode (typically a few volts depending on the material), e is the electronic charge (1.6×10^{-19} coulombs), and A is the area of the cathode in square meters. This is called the *emission-limited region*.

Triodes If one inserts a transparent conducting grid between the cathode and anode, as indicated schematically in Fig. 3, the device is called a *vacuum triode* (three electrodes). If the grid is made positive relative to the cathode, but not as positive as the plate, it will accelerate the electrons and increase the cathode current, provided the tube is operating in the space-charge-limited region. Some of the electrons are collected by the grid, but if the grid is transparent, many of the electrons will pass through the grid and will be collected by the even more positive plate. A large grid current is usually undesirable because it requires that the source connected to the grid provide power, and this power must be dissipated by the grid, which in extreme cases may overheat the grid. Consequently, the vacuum triode is normally operated with its grid negative relative to its cathode. In such a case, it is energetically impossible for electrons to reach the grid, and so the grid current is always zero. On the other hand, if the grid is sufficiently close to the cathode, and not too negative, some of the electrons feel the electric field from the positive plate and pass through the grid and are collected by the plate. In this way, a small voltage applied to the grid can be used to control the flow of current be-

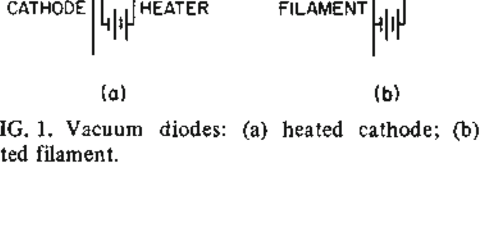

FIG. 1. Vacuum diodes: (a) heated cathode; (b) heated filament.

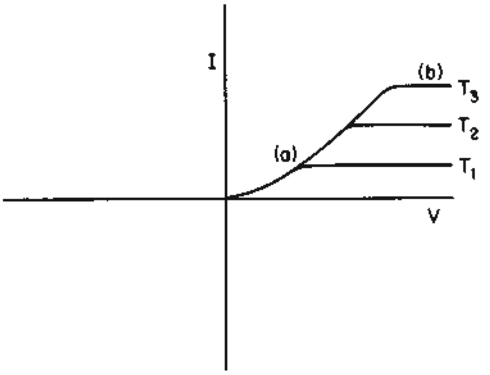

FIG. 2. I vs V characteristics of a vacuum diode for various cathode temperatures: (a) space-charge-limited region; (b) emission-limited region ($T_3 > T_2 > T_1$).

tween the plate and the cathode. The important property of the vacuum tube is that the source which controls the grid voltage supplies no power, since the grid current is zero, and yet it can significantly alter the power delivered by a source connected between the plate and cathode, and thus can be used as an amplifier.

The incremental change in plate current i_p can be calculated from the incremental change in grid-to-cathode voltage v_{GC} and plate-to-cathode voltage v_{PC} according to

$$i_p = g_m v_{GC} + v_{PC}/r_p$$

where g_m is called the *grid-plate transconductance* and r_p is called the *plate resistance*. The plate-to-cathode of a vacuum tube can thus be considered as a voltage source of value $-\mu v_{GC}$ (where $\mu = g_m r_p$) in series with a resistance r_p. The fact that the *amplification factor* μ is typically 100–1000 means that a vacuum tube can be used in a circuit to provide voltage amplification. Since the input resistance of a vacuum tube circuit usually exceeds 1 megohm whereas the plate resistance r_p is much smaller (kilohms), a vacuum tube amplifier provides a very large power gain.

Tetrodes In order to raise the amplification factor and reduce the grid-to-plate capacitance for high frequency operation, a second grid, called the *screen grid*, is often placed between the control grid and plate. This grid is usually held at a constant voltage, positive relative to the cathode, but negative relative to the plate. Such a tube is called a *tetrode* and has a plate current that is approximately independent of the plate-to-cathode voltage.

Pentodes One drawback of the tetrode is that, whenever the plate becomes negative relative to the screen, secondary electrons are knocked off the plate by the incident primary electrons. These secondary electrons are attracted to the screen. This causes an undesirably high screen current and can cause the plate current to reverse direction. To eliminate this effect, a third grid, called the *suppressor grid*, is inserted between the screen and plate. Such a tube is called a *pentode*. The suppressor grid is usually held at a constant voltage near that of the cathode and, in fact, is often connected internally to the cathode.

Cathode Ray Tubes When the electrons strike the plate of a vacuum tube, their kinetic energy is normally transferred to heat, resulting in a plate dissipation power limit that should not be exceeded without risking damage to the tube. However, it is also possible to have the electrons strike a fluorescent screen, in which case some of the electron energy is transformed to visible light. If the electrons are focused into a narrow beam by the use of apertures, and deflected in two dimensions by means of deflection plates or magnetic fields, a visible spot can be produced and moved rapidly across the face of the tube to produce a visual image. Such a tube is called a *cathode ray tube* (*CRT*) and is shown schematically in Fig. 4. Cathode ray tubes find application as visual display devices in instruments such as oscilloscopes, television receivers, and computer displays.

Klystrons Above a few hundred MHz, the plate voltage and plate current exhibit a significant phase difference generally due to electron transit time effects, and conventional tube designs become ineffective. At microwave frequencies, special tubes are used which employ velocity-modulation of an electron beam. An external magnetic field may be used to confine the electron beam. In the *klystron* the electron beam is modulated by traveling through a pair of closely spaced grids connected across a resonant cavity. The *reflex klystron* shown in Fig. 5 is used as an oscillator. It consists of a single

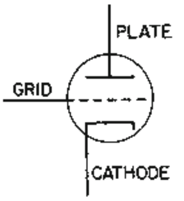

FIG. 3. Vacuum triode.

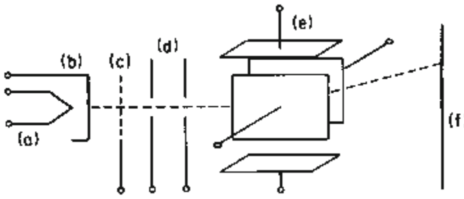

FIG. 4. Cathode ray tube: (a) filament; (b) cathode; (c) control grid; (d) focusing electrodes; (e) deflection plates; (f) fluorescent screen.

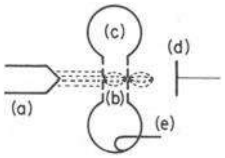

FIG. 5. Reflex klystron: (a) filament; (b) grid space showing bunched electrons; (c) resonant cavity; (d) reflector; (e) coupling loop.

cavity followed by a drift space and an electrode known as a *reflector*. The streaming bunches of electrons are reflected back into the grid/cavity area in the proper phase to sustain oscillation. The *amplifier klystron* shown in Fig. 6 consists of many cavities in series, with the input applied to the first cavity and the output taken from the last. Power is applied or extracted from these cavities usually by means of a coupling loop.

Traveling Wave Tubes In a *traveling wave tube* (*TWT*) the electron beam is focused and confined by an external solenoidal magnetic field or by a periodic permanent magnet structure in a relatively long cylindrical cavity. The electron beam is bunched by means of an rf current applied to a helical coil which surrounds the beam. An electromagnetic wave is thus produced which travels down the tube at a velocity slower than the velocity of the electrons in the beam. The electrons are thus able to transfer some of their energy to the wave, resulting in an amplified rf current in the helix. Because no resonant cavities are employed, the TWT can be used as a broadband amplifier or tunable oscillator at frequencies above about 1000 MHz.

Magnetrons In the *magnetron*-type tube, electrons are emitted from a filament and move radially outward in two dimensions toward a coaxial anode as shown in Fig. 7. However, an external magnetic field along the axis of the cylinder causes the electrons to move in roughly circular orbits around the cathode. The anode consists of a periodic sequence of resonant cavities. The electrons are bunched by the electric field across the entrance to these cavities and thus give up energy to the cavity field at the resonant frequency. This energy is extracted from the cavities by coupling loops or a waveguide. Magnetrons are used as fixed-frequency oscillators in high power cw service (such as microwave ovens) and short pulse radars.

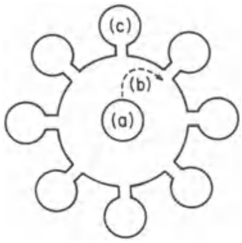

FIG. 7. Magnetron: (a) cathode; (b) path of electron in magnetic field; (c) resonant structure.

Light-Sensitive Tubes Electron tubes can also be used as sensitive detectors of light and other electromagnetic radiation in the near infrared and ultraviolet. A common form of such a detector is the *photomultiplier* (*PM*) tube. As shown in Fig. 8, such a device is a vacuum tube consisting of a cold, photosensitive cathode that emits electrons when struck by light. The electrons are attracted to a nearby positive electrode (called a *dynode*), where they typically release 3–6 secondary electrons which are attracted to the next, even more positive dynode, and the whole process repeats through many stages, producing a large current at the anode. Such a device is so sensitive that it can detect a single photon of light, in which case the output consists of a negative voltage pulse with a size determined by the capacitance of the measuring instrument.

An alternative and more compact configuration is the *channeltron electron multiplier* (*CEM*) in which a long, thin, evacuated glass tube is coated on the inside with a low-work-function conducting material that takes the

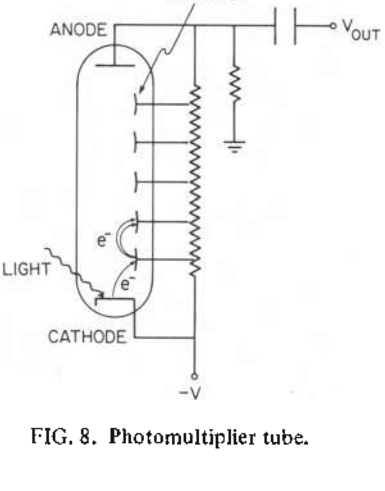

FIG. 8. Photomultiplier tube.

place of the individual dynodes in the PM tube. A high voltage is applied between the ends of the tube, and an avalanche of electrons is formed whenever light is incident on the more negative end of the coating. By combining many of the characteristics of the photomultiplier tube and the cathode ray tube, various types of image-sensitive tubes, such as the *image orthicon* and *vidicon* tube have been created. These tubes are used in television cameras.

ELECTRONICS

The field of electronics comprises the design, analysis, and application of electric circuits and the devices which control electric currents in such circuits. Since electric currents arise from the flow of electrons in conductors and the properties of control devices depend upon the motion of electrons in them, electric circuits, electronic devices, and their combinations depend upon the properties of the fundamental unit of electric charge, the electron. The age of electronics is reckoned from the discovery that the electron current in a vacuum triode can be controlled by electric signals applied to one of the triode's three terminals, the grid. Invention of the transistor in 1948 expanded the possibilities of electronic circuits to such an extent that semiconductor devices have to a large extent supplanted vacuum tubes, except for special applications. The expansion of semiconductor technology to integrated circuits now extends electronic techniques to nearly all aspects of contemporary society, ranging from communications and entertainment to information processing for business and military, and to measurement and control in manufacturing and science.

Understanding of electronic circuits implies knowledge of the currents in all parts of the circuit. An electric current accompanies the drift motion of free electrons in a conductor in response to an electric field, and the energy required to effect successive electron accelerations between collisions within the solid is called the electric potential difference, or *voltage* (in honor of the early Italian worker in electricity, Alessandro Volta). The *resistance* of a conductor to electron flow involves both material parameters and geometrical factors so that, for example, the resistance of a long thin wire is larger than that of a short thick wire of the same material. An electric circuit component having a specific value of resistance is called a *resistor*; according to *Ohm's Law* (after Georg Simon Ohm), the constant of proportionality between the current I, carried by a resistor, and the potential difference V is just the resistance:

$$V = RI.$$

This relation is a fundamental to all electronic circuit analysis and design.

The energy source that sustains steady currents in circuits is often a chemical battery. Calculating the currents in various branches of a network of resistors and batteries can be achieved by successive applications of Ohm's Law, but is greatly facilitated by *Kirchhoff's Rules* (after Gustav Kirchhoff). These are: (1) the algebraic sum of all currents at every junction in a network is equal to zero; and (2) the sum of voltages around any complete loop of a network is equal to zero. The first rule is essentially a statement of the conservation of electric charge, and the second is a consequence of the conservation of energy. It often proves possible to replace all or a portion of a network by an equivalent circuit in order to simplify the analysis. Thus, for example, the *Thévenin equivalent circuit* (named after M. L. Thévenin) which can represent the properties of an entire network is simply a single voltage source in series with a single resistor. Thus, very complicated systems can be analyzed and designed.

The currents in practical electronic circuits are time dependent, and the simplest time-varying current alternates direction sinusoidally. Since even the most complex current or voltage waveforms may be represented by a Fourier series consisting of harmonically related sine waves, ac circuit analysis is reduced to simple sinusoidal currents and voltages. Capacitors and inductors impede the varying currents in ac circuits basically because of the energy that must be stored and dissipated in the electric field between the electrodes of a capacitor and in the magnetic field associated with the current in an inductor. This effect is conveniently expressed in complex number notation by writing Ohm's Law describing, for example, an ac circuit consisting of a resistor, capacitor and inductor in series as follows:

$$V = [R + j(\omega L - 1/\omega C)]I$$

where $j = \sqrt{-1}$, ω is the angular frequency, and the current and voltage are sinusoidal. The quantity in brackets is called the *complex impedance* of the circuit, and its imaginary part is termed the *reactance*. If the frequency is such that the inductive reactance equals the capacitative reactance ($\omega L = 1/\omega C$) the circuit is said to be *in resonance*; the current is a maximum and is in phase with the voltage. An important and familiar application of resonance is to select different channels in radio and TV receivers by adjusting the circuit to resonance at the given channel frequency with a variable capacitor.

The key elements in all electronic circuits are the active devices which can control strong currents between two terminals of the device in response to weak electric signals applied to a third, thus amplifying input signals almost without bound. Semiconductor devices, most notably the *bipolar transistor* and the *field effect transistor*, are the principal active components in modern electronic systems, but the great versatility of semiconductor materials, principally silicon, has spawned an amazing variety of other semiconductor devices. Of particular significance is the field effect transistor design which is fabricated with a metal control electrode deposited upon the insulating oxide layer of a small silicon crystal carrying the two output terminals; the descriptive terminology of this metal-oxide-silicon structure is MOSFET. Voltage signals applied to the metal electrode change the conductivity of the underlying silicon and thus the current between the output terminals, leading to amplification of the input signal. Ingenious fabrication techniques can produce such structures having dimensions of the order of 10 micrometers, so that many hundreds or thousands of transistors can be placed on the same single crystal. Suitable metallic interconnections between devices yield an entire electronic circuit completely contained within one solid wafer of silicon. Extensions of this integrated circuit technology lead to VLSI, very large-scale integration, in which networks of several hundred thousand transistors are included in a silicon chip a few millimeters square and less than a millimeter thick. Thus, an extremely complex electronic circuit can be produced in a practical size, and, because of the extreme miniaturization, require minimal electric power. Integrated circuit designs based upon complementary symmetry, that is, which use transistors that employ electronic conduction in combination with those that employ hole conduction, so-called CMOS technology, are particularly appropriate because of very low power consumption. On the other hand, bipolar integrated circuits tend to have high operating speeds, which is important in extensive systems.

Electronic circuits, be they composed of discrete transistors or integrated circuits, operate in two distinct modes. In one case, the output signal is a linear function of the input signal and covers the range from zero to a saturation value determined by device or circuit parameters. Digital circuits, on the other hand, operate such that the output is either zero or some finite voltage and no intermediate values are important. These two techniques are complimentary, but, although linear circuits take precedence historically, the world of electronics is becoming ever more digital. Turning first to linear amplifiers, the gain a of the two types of single transistor amplifier is given by

$$a = \frac{V_o}{V_i} = \begin{cases} -G_m R_L & \text{(FET)} \\ -\dfrac{h_{fe}}{h_{ie}} R_L & \text{(Bipolar)} \end{cases}$$

where V_o is the output signal, V_i is the input signal, G_m, h_{fe}, h_{ie} are device parameters, and R_L is a resistor carrying the output current. Clearly, the output is a linear function of the input; the minus sign indicates that the output signal polarity is inverted with respect to the input. Gains exceeding 100 are easily possible in a single stage and greater values are attained simply by cascading several stages. Practical amplifiers can be designed to amplify minute dc signals and others, particularly those employing resonant circuits, to amplify high frequency signals up to 50 gigahertz.

The performance of amplifiers is enhanced in several respects by returning a fraction βV_o, of the output voltage to the input, a process called *feedback*. The output signal of a feedback amplifier is then $V_o = a(V_i + \beta V_o)$, or

$$V_o = \frac{aV_i}{1 - a\beta} \cong \frac{1}{\beta} V_i \quad \text{if} \quad -a\beta \gg 1.$$

The inequality means that the polarity of the feedback signal is negative. It does not prove difficult to achieve sufficient gain for the inequality to hold, so that, as this expression shows, the amplifier gain depends only upon the feedback network and not at all upon transistor parameters. This achieves greater stability and linearity. If, on the other hand, β is some nonlinear factor, the output signal can be a complicated function of the input. In this case, the feedback amplifier may be looked upon as operating upon the input to produce a modified output signal. Such operational feedback amplifiers were first used in analog computers to add, multiply, integrate or differentiate input signals. Opamps have subsequently found broad application and in integrated circuit form are widely used as complete amplifiers in preference to systems built of discrete transistors.

Positive feedback in an amplifier, together with the condition

$$\alpha\beta = 1$$

suggests an infinite output signal, according to the above expression, which in practice means that an output is obtained in the absence of an input signal, that is, the circuit oscillates. A resonant circuit feedback network assures that the equality is satisfied only at the resonant frequency, and such oscillators are secondary time standards as well as generators of high frequency signals for radio and TV broadcasting, microwave transmission, satellite communications, etc. In this connection, the high frequency carrier signal radiated from the sending to the receiving station is modulated with the audio, video, or data signal by varying the carrier amplitude, frequency, or amplitude and frequency in combination. At the receiving end, the signal is amplified and demodulated to recover the initial signal. Widespread radio and television communication networks represented the first major application of electronics and have subsequently been joined by many diverse control and processing applications. In fact, the versatility of electronics is so great that it is common practice to develop electric signals analogous to phenomena of interest so that all processing may be carried out electronically.

Very strong positive feedback may cause an amplifier to oscillate between zero output and a finite saturation value, becoming, in effect, a digital oscillator. One form of such a multivibrator circuit can be caused to remain in one or the other state until triggered into the opposite state by an appropriate external signal. That is, the circuit remembers. Very large arrays of such binary circuits make up the memory devices needed in digital computers. The integrated circuit form of a semiconductor random-access memory, or RAM, can store as many as 262,144 bits (see below) of information in a single silicon chip.

In digital electronics, voltage signals are used to represent quantities in the binary number system. Since the binary number system has only two digits, 0 and 1, these can be represented by signal waveforms which have only two values, zero and some finite saturation value set by circuit or transistor parameters. Digital circuits are, therefore, inherently more reliable than linear circuits, which must handle a continuous range of signals. Furthermore, digital signals can be amplified indefinitely and stored accurately. The advantages of reliability and accuracy of digital circuits were first realized in digital computers but now find application in all fields of electronics. Digital circuits tend to be much more complex than linear circuits, however, so it remained for the advent of integrated circuit technology to make digital electronics viable.

Notation and logic in the binary number system are analogous to the more familiar decimal system. The binary number 10110, for example, stands for increasing powers of two, or

$$\begin{array}{rl} 10110 & : \; 1 \times (2^4) + 0 \times (2^3) + 1 \times (2^2) + 1 \times (2^1) + 0 \times (2^0) \\ & : \; 16 \; + \; 0 \; + \; 4 \; + \; 2 \; + \; 0 \\ & : \; 22 \end{array}$$

That is, the binary number 10110 represents the same quantity as the decimal number 22. Voltage pulses in digital electronics represent digital numbers in two ways. The series representation has regularly spaced voltage pulses corresponding to increasing powers of 2 appearing in time sequence beginning with 2^0. In the alternative method, parallel representation, voltage pulses for the increasing powers of 2^0 appear simultaneously on separate transmission paths. In either case, each digit, be it a 0 or a 1, is termed a *bit*, a contraction for *b*inary dig*it*. Parallel representation is extensively used in digital circuits because all bits of a number are available in a time equal to the voltage pulse for one bit. Conversely, a time equal to the number of bits in the number is needed for serial representation, but, since only one signal path is required, this method is conventionally used for long-distance transmission. Digital transistor circuits are considered to operate upon the pulse waveforms representing digital numbers according to the logic of Boolean algebra. Thus, for example, a single transistor amplifier with two inputs, A and B, performs the logical NOT-AND, or NAND, operation, since only when both A and B inputs are present is the output equal to zero (note the signal inversion in a single-stage amplifier). A NOT-OR, or NOR, logic gate is equally possible, and it is interesting to note that, according to Boolean algebra, all possible logic operations (among the simpler are addition and multiplication) can be achieved by suitable arrays of NAND gates alone, or NOR gates alone. This is important for design and maintenance of extensive logic arrays.

The synergism of digital electronics and integrated circuits reaches its ultimate in sophistication in the microprocessor, which is essentially an entire digital computer contained in a single silicon chip. The microprocessor combines small size and low cost with sophisticated logic processing that permits a seemingly unending parade of important and ingenious applications. A digital computer is a complex array of logic gates organized into five main parts: input, output, memory, arithmetic, and control units. The digital circuits are designed to carry out logic calculations of all kinds and, therefore, the computer is furnished a set of specific instructions, or a *program*, pertaining to any desired calculation or process. The input and output units present digital numbers and the digital words of the program to the computer and subsequently retrieve results. The memory stores each data number and program word at a specific address in memory until it is needed during execution of the program. The arithmetic unit contains the logic gates that perform the logic operations called for by the program, and the function of the control unit is to interpret each instruction and set the circuits of the computer accordingly. The control unit also regulates the basic speed at which the computer operates. Because the functions of the arithmetic unit and the control unit are central to performance of a microprocessor, they are often referred to as the *central processing unit*, or CPU, and fabricated together on one silicon chip. In this case, peripheral chips for memory and input/output operations must be associated with the microprocessor CPU chip. This permits flexibility in design, but complete 5-unit, single-chip microcomputers are also widely used.

After the program and data are placed in memory and the microprocessor started, the control unit reads the first instruction, prepares the circuits accordingly and causes the appropriate number to be read from memory as specified by the address in the instruction. After completion of the indicated operation, the result is returned to memory and the control unit passes on to the next instruction. The CPU proceeds sequentially through the program until the last instruction is reached and the end result transferred to the output unit. It proves possible to write programs in such a way that at a certain instruction the CPU can jump to one or the other of two different program continuations, depending upon the value of an intermediate result. In this fashion, the microprocessor adapts to its activity in a way that cannot be predicted by the human programmer. Note also that by simply changing the program, a microprocessor can undertake any task, which is an extremely powerful feature. On the other hand, often a dedicated microprocessor has a specific program for its one task embodied in a read-only-memory, or ROM, which is fixed during fabrication of the integrated circuit. In either case, the digital words of the program are various arrays of the digits 0 and 1 and this makes it extremely difficult to prepare a program in machine language. Many ingenious schemes have been devised which permit programming in stylized algebra or rudimentary English (or other human language, of course); in this case, a special, previously prepared program translates the high-level language program into machine language.

The power and flexibility of microprocessors is engendering an electronic revolution equivalent to that in communications permitted by linear circuits decades ago. In manufacturing and process control, the logic adapts to the job at hand and may respond by driving a robot to a given task. The business office of the present, and future, contains word processors that correct spelling, type at hundreds of words per minute, and edit text effortlessly; data storage and retrieval systems to describe the instantaneous state of the business; and electronic mail that eliminates memos and filing. Personal computers balance bank accounts, will soon permit electronic banking, and also play intelligent games. Smart home appliances talk and listen, and automobiles are made more fuel efficient and less polluting through adaptive microprocessor control. Even communication is revolutionized as computers communicate and digital techniques replace linear circuits. This extends to phonograph and TV records as well. Truly it may be said that electronics supplements human intellectual activities not unlike the way the steam engine supplemented human muscle.

There is also a branch of electronics, more properly termed *physical electronics*, which studies physical phenomena of electrons per se. Very often this focuses on the motion and control of electrons in a vacuum and from such studies have developed the familiar cathode ray tube used in TVs and computer terminals; the electron microscope and its several derivatives which provide enormous visual magnifications; photomultiplier tubes and image intensifiers which detect and display nuclear particles, star images, and TV shows. Another aspect treats features of electrons in solids, particularly semiconductors, transistors, and the host of other useful semiconductor devices such as solar batteries, photocells, and light emitting diodes. Even the large nuclear particle accelerators, kilometers in circumference, can be considered part of this branch of science.

ELECTROWEAK THEORY*

By electroweak theory is meant the unified field theory that describes both weak and electromagnetic interactions. The development of a unified electroweak theory is certainly the most dramatic achievement in theoretical physics to occur in the second half of this century. It puts weak interactions on the same sound theoretical footing as quantum electrodynamics. Many theorists have contributed to this development, which culminated in the works of Glashow, Weinberg and Salam,[1] who were jointly awarded the 1979 Nobel Prize in physics. Some of the important ideas that contributed to this development are the theory of beta decay formulated by Fermi and parity violation suggested by Lee and Yang and incorporated into the immensely successful V-A theory of weak interactions by Sudarshan and Marshak. At the same time ideas of gauge invariance were applied[2] to weak interaction by Schwinger, Bludman, and Glashow. Weinberg and Salam then went one step further and wrote a theory that is renormalizable, i.e., all higher order corrections are finite, no mean feat for a quantum field theory! The theory had to await the development of the quark model of hadrons for its completion.

To understand the basic content of the theory, a simple beta decay of neutron into proton, electron and antineutrino can be expressed by the reaction $n \rightarrow p + e^- + \bar{\nu}$. The theory is much better behaved if this reaction is divided into two reactions

$$n \rightarrow p + W^-, \qquad W^- \rightarrow e^- + \bar{\nu}. \qquad (1)$$

The W particle is called an *intermediate W boson* because it is an intermediary in this weak process. The W particle is very heavy, and reactions in Eq. (1) occur only "virtually." The strength of the W interaction (or the coupling constant) is comparable to the electromagnetic interactions, but the large mass of the W makes the effective strength of the interaction both short ranged and weak. (The effective strength is approximately (coupling constant)^2/mass of $W)^2$). We now know that neutron and proton are respectively made of (udd) and (uud) quarks, where the u quark has charge $\frac{2}{3}$ e and the d quark has charge $-\frac{1}{3}$ e. The transitions in Eq. (1) then arise at the quark level from the process

$$d \rightarrow u + W^-, \qquad W^- \rightarrow e^- + \nu. \qquad (2)$$

Reactions in Eq. (2) can be viewed as transitions between two doublets (u, d) and (ν, e^-). These doublets are referred to as *weak isospin doublets*. The crucial idea on how to construct a gauge theory for objects that are doublets (or higher multiplets of some group) was provided by Yang and Mills.[3] It is a generalization of the field concept that underlies quantum electrodynamics. In the latter, particles have scalar charges and do not transform to new states in an interaction; the carrier of the force, the electromagnetic field, is itself neutral. In this generalization the carriers of the force (like $W^\pm$) themselves can carry this more complicated charge and can have self-interactions. The field carriers would be massless like photons in the symmetry limit, so a new mechanism to make some of them massive had to be discovered. We begin the discussion of the theory in the so-called *symmetry limit*, a limit that could be realized at very high energies (energy larger than 100 GeV). In this limit the gauge group is $SU(2) \times U(1)$. The group $SU(2)$ is similar to the isospin group and the left-handed quarks and leptons form doublets under this group. $U(1)$ is like electromagnetic interactions, and the charge associated with this group is called *hypercharge* (Y). There is a fundamental relation between the charge Q, the third component of weak isospin I_3, and hypercharge Y:

$$Q = I_3 + Y \qquad (3)$$

The assignment of quantum numbers for quarks and leptons are:

$$\begin{array}{ll} \text{Left-handed doublets} & \left\{ \begin{array}{lll} u & \nu_e & I_3 = \frac{1}{2} \\ d & e & I_3 = -\frac{1}{2} \end{array} \right. \\ \text{Hypercharge} & Y = \frac{1}{6} \quad -\frac{1}{2} \end{array} \qquad (4)$$

There are interaction strengths g and g' associated with the groups $SU(2)$ and $U(1)$ respectively. If a and b are members of any isodoublet in Eq. (4), the basic processes that occur with strength g are

$$\begin{aligned} a &\rightleftarrows b + W^+ \\ b &\rightleftarrows a + W^- \\ a &\rightleftarrows a + W^0 \\ b &\rightleftarrows b + W^0 \end{aligned} \qquad (5)$$

and those with strength g' are

$$\begin{aligned} a &\rightleftarrows a + B^0 \\ b &\rightleftarrows b + B^0 \end{aligned} \qquad (6)$$

where $W^\pm$, W^0 form a triplet and are carriers of the weak $SU(2)$ force, while B^0 is the carrier of the $U(1)$ force. Former process occur with the strength g, and the latter with g' times the hypercharge.

This picture needs modification at low energies. The mass of the W should show up, and the photon should remain massless and inter-

*This work is supported in part by a grant from the Department of Energy under contract No. DE-AT06-76ER70004.

act with matter in the usual manner. How is this accomplished? This is where Weinberg and Salam introduced the idea of *spontaneous breaking of symmetry*. It is caused by a new isodoublet—The *Higgs field*. It has the following remarkable property: its minimum of energy occurs not when the field strength is zero, but when it takes some finite value. This in turn implies a preferred direction in weak isospace, and this breaks symmetry. The effect of the destruction of symmetry is as follows:

(1) The hypercharge field B and the third component of the W triplet, W^0, mix to form new states

$$A = \cos\theta_W\, B - \sin\theta_W\, W^0$$

$$Z = \sin\theta_W\, B + \cos\theta_W\, W^0. \tag{7}$$

Here A is the usual photon, and Z a new massive state.

(2) The Higgs fields interact with $W^\pm$ and Z, making them massive. A prediction of the theory is that

$$M_Z{}^2 = M_W{}^2 \sec^2\theta_W \tag{8}$$

where M_Z and M_W are masses of the Z and W boson, respectively.

(3) The coupling of the field A to quarks and leptons is identical to the coupling in quantum electrodynamics.

(4) The bosons $W^\pm$ carry charge, and their interactions lead to V-A theory of beta decay. (The name V-A derives from *Vector-Axial vector* structure of currents in this theory.)

(5) The gauge boson Z leads to new interactions that involve "neutral currents" (i.e., processes like $u \to u + Z$, with $Z \to \nu + \bar{\nu}$). This is a new, completely unexpected prediction. The test of this prediction had to await the experimental development of high energy neutrino beams. This prediction has now been verified and found to yield agreement with the experiment to the level of 5–10%. The Z boson interactions depend on the value of the mixing angle θ_W. Several different experiments lead to the value $\sin^2\theta_W = 0.23 \pm 0.02$.

So much for the description of electroweak theory. The most important experimental verification, the observations of $W^\pm$ and Z bosons has been announced. Their masses were predicted to be $M_W \approx 80$ GeV and $M_Z \approx 90$ GeV. In the summer of 1983 the discovery of both W^+ and Z bosons was reported by C. Rubia using the proton-antiproton collider at CERN. The masses are in excellent agreement with the theoretical prediction. The observation of the Higgs particle is much more difficult to carry out experimentally, but is nonetheless an important test of the theory.

Where do new quarks and leptons fit into the scheme? They have to enter as doublets. Two more lepton doublets have been identified (μ^-, ν_μ) and (τ^-, ν_τ), while two quark doublets are also expected to occur, (c, s) and (t, b). Except for the t quark, the others have been seen. No one has the slightest idea of why these additional doublets occur in nature. This problem is referred to as the *Generation Puzzle*. A refinement of the theory suggests that the actual doublets involve d', s' and b' which are mixtures of d, s, and b. This mixing, called *Cabibbo mixing*, permits decays that alter strangeness like $s \to u + W^-$ to occur with a small probability.

Is the theory complete? Most researchers suspect that strong, weak and electromagnetic forces should ultimately be united into one unified theory (called *grand unified theory*). Many attempts to do so have been made, leading to new predictions which would signal this kind of theoretical structure. Some theories predict the decay of the proton[4] although with a large but measurable lifetime, and others predict additional Z bosons.[5] The next few years should prove an exciting period in physics where many of these new ideas will be tested.

ELEMENTARY PARTICLES

The search for the elementary constituents of matter is as old as physics itself, but any quantitative attempt at such a theory had to await the experimental discoveries of this century. Such a search is prompted by two considerations: the identification of the basic building blocks of nature and the hope that their laws of interaction would be essentially simple.

The atom had to yield its claim to indivisibility when it was found that electrons were constituents of all atoms; moreover, the electrons from various species of atoms were identical. Light, with its particle properties, seemed another universal entity connected with matter, since the photons (light quanta) which were emitted in atomic transitions appeared identical apart from their momenta. The *electron* and the *photon* were the first two elementary particles to be discovered, and a quantitative theory of the emission and absorption of photons by the electrons in an atom was possible only after the invention of quantum mechanics. The corresponding picture of the atom regarded the electrons in an atom as being subject to electrostatic attraction of the positively charged nucleus (and the mutual repulsion of other electrons), the photons having only a transistory existence being either emitted or absorbed in the transitions between the atomic states. The search for the structure of matter now became a search for the constituents of the nucleus.

A quantum theory of the nucleus (or rather nuclei) was made possible by the discovery of the *proton* and the *neutron*. The nuclear interaction which was responsible for holding the nucleus together (against the disruptive electrostatic repulsion of the protons) was found to be of an entirely new kind, much stronger than the electric interaction at short distances but decreasing very much more rapidly with distance. The various complex nuclei differ in the number of protons and neutrons they contain.

By that time, the theory of the interaction between electrons and photons had developed to the point where the electrostatic repulsion or attraction between electrically charged particles could be understood in terms of the exchange of photons between them. In the lowest nontrivial approximation, it gave the Coulomb law for small velocities. The basic interaction was the emission and absorption of "virtual" photons by charged particles. A similar mechanism could be invoked to explain the short-range nuclear interaction, and to picture the nuclear interaction as due to the exchange of particles which have nonzero masses which are a fraction of nuclear mass. (The approximation procedure used for deducing the static Coulomb force from the electron-photon interaction is no longer valid here; and the nuclear force has a rather complicated form. However, these theoretical considerations did predict the existence of a set of three particles called *pions*, which have since been discovered.)

Another kind of particle and another kind of interaction were discovered from a detailed study of beta radioactivity in which electrons with a continuous spectrum of energies are emitted by an unstable nucleus. The corresponding interactions could be viewed as due to the virtual transmutation of a neutron into a proton, an electron, and a new neutral particle of vanishing mass called the *neutrino*. The theory provided such a successful systematization of beta decay data for several nuclei that the existence of the neutrino was "well established" more than twenty years before its experimental discovery. The beta decay interaction was very weak even compared to the electron-photon interaction.

Meanwhile, the electron was found to have a positively charged counterpart called the *positron;* the electron and positron could annihilate each other, with the emission of light quanta. The theory of the electron did in fact "predict" the existence of such a particle. It has, since then, been found that the existence of such "opposite" particles (*antiparticles*) is a much more general phenomenon (see below and also see ANTIPARTICLES).

Our present catalog of elementary particles and decay modes contains many more entries. These particles fall into families: the *photon family*, the *lepton family*, and *meson family*, and the *baryon family*, as well as a number of postulated particles like *quarks* and *gluons.* Most of these particles are unstable and decay within a time which is often very small by normal standards but which is many orders of magnitude larger than the time required for any of these particles to traverse a typical nuclear dimension. There is a wide variety of reactions between them, but they could be understood in terms of three basic interactions—the *strong* (or *nuclear) interactions*, the *electromagnetic interactions*, and the *weak interactions.* The nuclear forces and the interaction between pions and nucleons belong to the first type; the electron-electron and electron-photon interactions to the second; and the beta decay interaction to the third. The present theoretical framework enables us to handle more or less quantitatively the electromagnetic and weak interactions and certain aspects of all interactions. Despite this, it is possible to understand many aspects of strong (as well as the other) interactions in terms of conservation laws and invariance principles (see CONSERVATION LAWS AND SYMMETRY).

The classical conservation laws of energy, momentum, and angular momentum are valid in the relativistic quantum theory of elementary particles also. The particles may possess intrinsic angular momentum or *spin*, which, expressed in natural units $h/2\pi$ of angular momentum, is restricted to an integer or a half-odd integer. Angular momentum conservation holds only when this spin angular momentum is included. But one finds that to every particle there corresponds an antiparticle with the same mass, same spin, and same lifetime. (In the case of the photon and the neutral pion, they are their own antiparticles; they are strictly neutral particles.) The particle and antiparticle have equal and opposite electric charges, and the antiparticle of the antiparticle is the original particle. *Conservation of electric charge* is another familiar (although nonclassical) conservation law satisfied by all known interactions.

In addition to additive conservation laws which arise from continuous symmetries, there is a set of "multiplicative" conservation laws which are associated with discrete symmetries. It is possible to examine the invariance of the physical laws under space inversion, i.e., using a left-handed coordinate system or vice versa; if the statement of the law is unaffected by this interchange, it is possible to show that a quantum number having the two values ±1 can be assigned to classify the quantum-mechanical states so that a state with the label +1 will not change to one with the label −1 due to any interaction. This quantum number is called *parity*. Just as particles may possess intrinsic angular momentum (spin), particles may also have intrinsic parity. Table 1 lists the particles (and their corresponding antiparticles) with their respective additive quantum numbers, intrinsic parities, and lifetimes. General principles of relativistic quantum theory imply that antiparticles of integral spin particles have the same parity as the particles; for half-odd-integral spin particles the antiparticle has the parity opposite that of the particle. All experimental checks are in accordance with this prediction.

In addition to invariance under space inversion, we may consider *particle conjugation* (replacement of particles by antiparticles) *invariance* and *time reversal invariance*, or combinations of these transformations. It turns out that strong and electromagnetic interactions are invariant under each of these three transformations (and hence any product of these), but weak interactions are invariant only under combined inversion (product of particle conjugation and space inversion) and under time reversal. It can be shown that all interactions are invariant under the product of the three transformations of space inversion, particle conjugation, and time reversal if some very general principles of the relativistic quantum theory of these particles are valid.

Even the statement that weak interactions are invariant under combined inversion has turned out not to be strictly true. In the decay of the neutral K meson we should have expected a short-lived particle (even under combined inversion) called $K_1{}^0$ and a longer-lived particle (odd under combined inversion) called $K_2{}^0$, provided combined inversion were strictly valid. We do observe such short- and long-lived components, but we also expect that the long-lived component $K_2{}^0$ cannot decay into two pions. Yet experimentally we find a small amount of decay into two pions. This violation of combined inversion (and, hence, of time reversal invariance) is only two-tenths of a percent, but it is definitely present. Thus, none of the discrete symmetries (except the product of the three) seems to be strictly valid.

One notices that the various particles belonging to a family have the same spin and the same values of the additive quantum numbers except the electric charge. The *photon* has a universal interaction with all charged particles; it has been found possible to connect the conservation of electric charge and this universal interaction structure, on the one hand, to the vanishing mass and unit spin of the photon, on the other. The electron and muon partake of both electromagnetic and weak interactions, but do not exhibit any strong interaction. In fact the muon family appears to be simply a duplicate of the electron family except for a change in the unit of mass. These light particles are collectively known as *leptons*. This fascinating puzzle has now been made more intriguing by the discovery of the τ-lepton with possibly its own neutrino. Why the repetition of this pattern, this recurrence?

For a long time people had assumed that "the" *neutrino* had zero mass like the photon. In weak interaction physics since the left-handed and right-handed fermions behave differently (see V-A chiral interactions, below) it is not necessary that the mass be zero. Contemporary thinking puts neutrino masses not necessarily zero, not even diagonal in the species: so that we could have neutrino oscillations in which one species slowly transmutes itself into another in a reversible manner very much like the oscillations of a pair of weakly coupled pendulums. No definite conclusions can be stated about neutrino masses at the present time except for certain numerical limits.

The *meson family* consists of eight members which fall into a triplet of *pions*, a singlet *eta*, a doublet of *kaons*, and a doublet of *antikaons*. They are all pseudoscalar (spin zero and odd parity) and exhibit strong interactions. The charged particles are of course coupled to the photon, but even the neutral members can participate in electromagnetic interaction by virtue of the large probability of virtual dissociation into charged particles. They participate in a variety of weak interactions including the nuclear beta decay interaction.

It is found that the kaons, the *hyperons* (baryons other than the neutron and proton), and their antiparticles, collectively known as *strange particles*, can decay by weak interactions not involving leptons or photons with a lifetime which is large compared to the natural periods appropriate to strong interactions. On the other hand, these particles are produced copiously in high-energy nuclear collisions. These two circumstances can be understood in terms of the existence of another additive quantum number, called *hypercharge*, which is conserved in strong and electromagnetic interactions but violated in weak interactions.

The meson-baryon system exhibits further regularities as far as strong interactions are concerned. The neutron and the proton have

TABLE 1. CATALOG OF ELEMENTARY PARTICLES

Particle	Family[a]	Spin	Mass (MeV)	Lifetime[b] (sec)	Antiparticle	Parity[c]	Charge	Hyper-charge	Baryon Number	Lepton Number	Charm
Photon, γ	Photon	1	0	Stable	Photon, γ	-	0	0	0	0	0
Electron neutrino, ν_e	Lepton	$\frac{1}{2}$	0	Stable	Antielectron neutrino, $\bar{\nu}_e$	Undefined	0	0	0	1	0
Electron, e^-		$\frac{1}{2}$	0.51100	Stable	Positron, e^+	+	-1	0	0	1	0
Muon neutrino, ν_μ		$\frac{1}{2}$	0	Stable	Antimuon neutrino, $\bar{\nu}_\mu$	Undefined	0	0	0	1	0
Muon, μ^-		$\frac{1}{2}$	105.659	2.20×10^{-6}	Positive muon, μ^+	+	-1	0	0	1	0
Tau, τ^-		$\frac{1}{2}$	1784	$< 2.3 \times 10^{-12}$	Positive tau, τ^+	+	-1	0	0	1	0
Neutral pion, π^0	Meson	0	134.96	0.83×10^{-16}	Neutral pion, $\bar{\pi}^0$	-	0	0	0	0	0
Positive pion, π^+		0	135.56	2.60×10^{-8}	Negative pion, π^-	-	+1	0	0	0	0
Eta, η		0	549	7×10^{-19}	Eta	-	0	0	0	0	0
Neutral kaon, K^0		0	497.7	0.86×10^{-10}	Neutral antikaon, $\bar{K}^0$	-	0	+1	0	0	0
Positive kaon, K^+		0	493.67	1.24×10^{-8}	Negative antikaon, $\bar{K}^-$	-	+1	+1	0	0	0
Charmed D^+		0	1868	2.5×10^{-13}	Charmed D^-	-	+1	0	0	0	+1
Charmed D^0		0	1863	3.5×10^{-13}	Charmed $\bar{D}^0$	-	0	0	0	0	+1
Proton, p	Bayron	$\frac{1}{2}$	938.28	Stable	Antiproton, $\bar{p}$	+	+1	+1	1	0	0
Neutron, n		$\frac{1}{2}$	939.57	$0.93 \times 10^{+3}$	Antineutron, $\bar{n}$	+	0	+1	1	0	0
Lambda, Λ		$\frac{1}{2}$	1115.6	2.6×10^{-10}	Antilambda, $\bar{\Lambda}$	+	0	0	1	0	0
Positive sigma, Σ^+		$\frac{1}{2}$	1189.4	0.8×10^{-10}	Negative antisigma, $\bar{\Sigma}^-$	+	+1	0	1	0	0
Neutral sigma, Σ^0		$\frac{1}{2}$	1192.5	5.8×10^{-20}	Neutral antisigma, $\bar{\Sigma}^0$	+	0	0	1	0	0
Negative sigma, Σ^-		$\frac{1}{2}$	1197.3	1.48×10^{-10}	Positive antisigma, $\bar{\Sigma}^+$	+	-1	0	1	0	0
Neutral xi, Ξ^0		$\frac{1}{2}$	1315	2.9×10^{-10}	Neutral antixi, $\bar{\Xi}^0$	+	0	-1	1	0	0
Negative xi, Ξ^-		$\frac{1}{2}$	1321	1.6×10^{-10}	Positive antixi, $\bar{\Xi}^+$	+	-1	-1	1	0	0
Omega, Ω^-		$\frac{1}{2}$	1672	0.8×10^{-10}	Antiomega, $\bar{\Omega}^+$	+	-1	-2	1	0	0

[a] Electron, muon, and tau families are collectively known as the *lepton family.* The proton and neutron are both nucleons; other members of the baryon family are the hyperons.

[b] The neutral kaon has a long-lived component $K_2{}^0$ and a short-lived component, which are quantum mechanical superpositions of the neutral kaon and the neutral anitkaon.

[c] Electron, muon, tau, proton, neutron, and lambda parities are defined by convention. Antifermions have opposite parity from fermions, Antibosons have same parity as bosons.

very nearly the same mass and similar nuclear interactions, although their electromagnetic properties are quite different. The three pions have different electric charges, but again they have approximately equal masses and similar nuclear interactions. This kind of multiplet structure is evident for other strongly interacting particles: the *kaons* form a doublet, the *sigma hyperons* form a triplet, the *xi hyperons* form a doublet, and the *lambda hyperon* remains a singlet. In view of the relative weakness of the electromagnetic interaction, it is tempting to ascribe all deviations from exact equality of the masses to the indirect action of the electromagnetic interaction. In this framework, it is possible to consider the members of a multiplet to be different states of the same particle corresponding to the values of a new quantum number. What is remarkable is that if one takes this point of view, it is possible to show that the strong interactions exhibit a remarkable invariance under a group of continuous transformations which may be viewed as the group of rotations in a fictitious three-dimensional space (or more correctly as the special unitary group $SU(2)$ of transformations on two variables). The transformations act as follows: the singlet is unchanged, the doublet components transform like the components of a spinor, and the triplet components transform like the components of a vector. This property of strong interactions is called *charge independence*, and the corresponding conserved dynamical variable (with three components) is called the *isotopic spin*. It then turns out that hypercharge conservation is a consequence of isotopic spin conservation and electric charge conservation. While the conservation of isotopic spin is violated by the electromagnetic (and weak) interactions, the charge independence of nuclear interactions is still expected to be satisfied to within a few per cent and experimental tests confirm this. Since the symmetry associated with invariance under isospin transformations is not directly related to space-time properties, one often refers to it as an *internal symmetry*.

One might now raise the question: Which of these particles are basic constituents of matter? For the case of the atom, say the simplest of them all, the hydrogen atom, it seems easy to say that it is a composite system made up of an electron and proton bound together by an electrostatic force. However, this answer is not completely satisfactory, since the electrostatic force itself is due to the exchange of light quanta, and in the process of atomic transitions photons are emitted or absorbed. Yet we do not include them as constituents of the atom. In beta radioactivity, electrons and neutrinos emerge from the nucleus, yet the nucleus is not pictured as containing either of these varieties of particles but rather as made up of protons and neutrons. The beta electron and neutrino are rather assumed to be created at the moment of emission. With the mesons taking part in strong interactions, however, such distinctions are no longer obvious, and the question of whether a particle is elementary or is composed of several other particles cannot be answered except perhaps within the context of a more quantitative but limited model. A point of view that has gained some acceptance is that *none* of these particles are elementary and that each is a composite of several particles.

This view, while by no means inevitable or even well-established, is a possible picture, because in the realm of elementary particles we can not only add particles together to construct a composite system, we can also "subtract" particles by adding antiparticles. The claim that particles A and B go to make up the particle C is different to distinguish from the claim that particles $\bar{B}$ (antiparticle to B) and C go to make up the particle A. Further, particles play a dual role. On the one hand, they are constituents of a composite system; on the other hand, they are the objects which are exchanged to generate forces between the constituents. In any case, in view of the very large number of entries in Table 1, it is not desirable to accept all of them as the ultimate constituents of matter.

This is even more forcefully brought to our attention by the recent discovery of a very large number of ultra-short-lived particles. They appear as sharp resonances in multiparticle systems. Since these "resonances" disintegrate within a short time (even on the nuclear scale!), it is difficult to view them as elementary particles, but they seem to play an important role in interaction phenomena and are produced as often as the more stable (and familiar) mesons and baryons included in Table 1. It appears at the present time that they ought to be included on more or less the same footing. A list of the better established resonances is given in Table 2 along with the mesons and baryons from Table 1. Since an unstable particle lives only for a very short time its energy and consequently its mass cannot be sharp, and from elementary quantum mechanical considerations we should expect this "width" in the mass of a resonance to be inversely proportional to its lifetime. Since the width is what is measured experimentally the width (rather than the lifetime) is usually quoted in connection with resonances.

Since these particles are coupled in the strong interactions, one would expect them to occur in isospin multiplets. This is in fact observed. It turns out that since strong interactions are invariant under particle conjugation and are charge independent, we could define a multiplicative quantum number called *G-parity* which has definite values ±1 for mesons and meson resonances. These values are also included in Table 2.

With these resonances included among the "elementary particles" we have a situation

TABLE 2. SOME STRONGLY INTERACTING PARTICLES AND RESONANCES

Particle or Resonance	Spin	Mass (MeV)[a]	Width (MeV)[b]	Parity	Electric Charge	Hyper-charge	Isotopic Spin	G-parity
Pion, π	0	138.5	0	−	0, +1, −1	0	1	−
Kaon, K	0	495.8	0	−	0, +1	+1	$\frac{1}{2}$	Undefined
Antikaon, $\bar{K}$	0	495.8	0	−	0, −1	−1	$\frac{1}{2}$	Undefined
Eta, η	0	548.8	0	−	0	0	0	+
Rho resonance, ρ	1	776	158	−	0, +1, −1	0	1	+
Kaon resonance, K^*	1	893	50	−	0, +1	+1	$\frac{1}{2}$	Undefined
Antikaon resonance, $\bar{K}^*$	1	893	50	−	0, −1	−1	$\frac{1}{2}$	Undefined
Phi resonance, ϕ	1	1020	4	−	0	0	0	Undefined
Omega resonance, ω	1	782	10	−	0	0	0	−
J/ψ	1	3097	0.063	−	0	0	0	−
Nucleon, N	$\frac{1}{2}$	938.9	0	+	0, +1	+1	$\frac{1}{2}$	Undefined
Lambda, Λ	$\frac{1}{2}$	1115.6	0	+	0	0	0	Undefined
Sigma, Σ	$\frac{1}{2}$	1193.4	0	+	0, +1, −1	0	1	Undefined
Xi, Ξ	$\frac{1}{2}$	1318.4	0	+	0, −1	−1	$\frac{1}{2}$	Undefined
Nucleon resonance, N^*	$\frac{3}{2}$	1236	120	+	0, +2, +1, −1	+1	$\frac{3}{2}$	Undefined
Y resonance, Y^*	$\frac{3}{2}$	1385	36	+	0, +1, −1	0	1	Undefined
Xi resonance, Ξ^*	$\frac{3}{2}$	1530	7	+	0, −1	−1	$\frac{1}{2}$	Undefined
Omega minus resonance, Ω	$\frac{3}{2}$	1672	0		−1	−2	0	Undefined

[a] The average mass of the members of the isotopic multiplet is tabulated.

[b] Since the unstable particles of Table 1 live "practically forever" on the nuclear time scale, the corresponding widths are several orders of magnitude smaller than 1 MeV; these are quoted here as 0.

somewhat parallel to atomic spectroscopy *before* the discovery of quantum mechanics. The catalogue of the strongly interacting particles (collectively known as *hadrons*) now contains well over a hundred entries, and it would be difficult to consider a hundred plus "elementary" constituents. Yet how are we to select the genuine subset of elementary constituents? We have already remarked about the picture in which *every* hadron is a composite system. We should then look for regularities among them, including groupings into families, multiplets, etc., as well as for systematic relations between masses, spins, multiplet sizes, etc.

There are also practical questions regarding the identification and interpretation of resonances. When a number of reaction channels are open a resonance may not be easily visible as a pronounced peaking in crosssection or mass plot. Fortunately resonances like the ground-state hadrons seem to fall into multiplets, and this together with other systematics aid us in identifying resonances: observation is intimately tied in to the theoretical framework employed.

One notes also that the meson and baryon multiplets seem to fall into further super-multiplets. Following the analogy of the isospin group, we may now ask what internal symmetry group is responsible for this interaction. We must also remember that whatever is responsible for the violation of this higher symmetry must itself be a part of the strong interaction. A scheme in which invariance under the special unitary group on three variables $SU(3)$ holds approximately has been successfull in correlating and predicting the spectrum of particles and their interactions. The isospin group $SU(2)$ is a subgroup of this unitary group. Just as for charge independence, no *basic* reason has been found for the origin of this "unitary symmetry." Still other symmetry groups, even wider than $SU(3)$ and generally incorporating it, and which are even more significantly violated, are being studied. It appears that the complete understanding of these higher internal symmetries would involve not only their origin, but also the origin of their violation.

The hadron multiplets appear to have other regularities. We can discern, by analogy with atomic physics, subfamilies consisting of a lowest-spin "excited states." The states listed in Table 2 may be viewed as the ground states. If we plot the masses squared versus the spin for several of these subfamilies, we find them to lie approximately on straight lines with a universal slope of about 1 $(\mathrm{GeV})^{-2}$. These may be thought of as the generalization of the bound state energy versus spin relation for potentials to the domain of resonances, and thus, as orbital excitations; and in this context they are known as *Regge families.*

The ground states themselves may be understood in terms of a generalization of the "internal symmetry" to include a spin aspect also, so that instead of $SU(3)$ we consider $SU(6)$. The spin $\frac{1}{2}$ even-parity baryon octet and spin $\frac{3}{2}$ even-parity baryon decuplet resonances together then form a single 56-dimensional representation of $SU(6)$. The nine spin 0 odd-parity mesons and the nine spin 1 odd-parity vector meson resonances form a mixture of the 35-dimensional and the 1-dimensional representation of $SU(6)$. We can combine this $SU(6)$ structure together with the orbital excitations mentioned above to bring about a phenomenological $SU(6) \times O(3)$ classification for hadrons.

It is very tempting to think of this $SU(6) \times O(3)$ structure as pointing to a substructure of the hadrons in terms of 3 hypothetical entities with spin $\frac{1}{2}$ and even parity which transform as a 3×2-dimensional representation of this group called *quarks.* The simplest baryon resonances are then to be viewed as three-quark compounds and the meson resonances as quark-antiquark compounds. The spin, parity, and $SU(3)$ quantum numbers of most hadrons are consistent with this picture and some quantitative understanding of the resonance masses and decay parameters can be obtained within this framework. sometimes referred to as the *quark model.* It should be pointed out that so far no quarks have been discovered and physicists are not sure if they even expect them to exist as ordinary particles.

The baryons and baryon resonances identified as three-quark compounds correspond to a completely symmetric spin-internal symmetry wave function. The spin $\frac{1}{2}$ and spin $\frac{3}{2}$ baryons may be viewed as realizing a third rank symmetric tensor realization. But quarks, being spinorial entities, should behave as Fermions and hence should furnish a totally antisymmetric third rank tensor. It is therefore appropriate to endow quarks with an as yet unidentified property called *color* with *at least* three linearly independent states. If for economy we use only three colors, all known hadrons are color singlets: one may require "color confinement" as an essential ingredient of hadron structure.

What about the binding of the quarks and more generally of the quark-quark and quark-anti-quark forces? We can expect them to be quite strong since at low energies and momentum transfers the hadrons act as indissoluble. But we need a special feature for these forces: unlike usual forces in atomic and nuclear physics these forces must be "confining," and hence *increase, with distance.* In contrast, in many high momentum transfer reactions which probe small distances these quark binding forces are relatively weak. It turns out that these features result from an interaction structure invented by Yang and Mills on the basis of gauge invariance generalizing the electromagnetic coupling to charged particle fields to more general non-commutative groups. Identifying the color of quarks as the realization of an $SU(3)$ color group leads to the introduction of an eightfold vector meson field of zero mass coupled to the quarks as well as self-coupled, which leads to forces with precisely the properties required. The quanta of these octets of fields are called *gluons.* They are neutral with regard to isospin and its generalization, which in contrast to color is called *flavor.* The fundamental strong interaction is then the gluon interaction. The hadron-hadron interaction by contrast is the residual interaction between quark compounds, somewhat analogous to the van der Waal's forces between atoms. No wonder nuclear forces are so complicated!

At the present time most experts seem to believe that the quantum theory of coupled colored quarks and their Yang-Mills gluons is the theory of strong interactions. It is called *quantum chromodynamics* (QCD). The difficulties of principle that plagued the theory of photons and electrons, *quantum electrodynamics* (QED), are still there; but in addition we have new difficulties in calculation. As if in compensation we have many more phenomena to which QCD can be applied. Nonperturbative methods and semiphenomenological methods have been developed to cope with these difficulties. Particularly important have been the observation that the effective coupling strength is energy dependent and in QCD it *decreases* as the momentum transfer increases, leading to "asymptotic freedom." The precise manner in which this takes place is described by the renormalization group equations.

The elementary particle scene has been livened by the discovery of extremely narrow resonances and their identification as quark-antiquark bound states. This has led to the identification of a new flavor quantum number called *charm.* Together with charge and strangeness this suggests that the internal symmetry (flavor) group is $SU(4)$ rather than $SU(3)$ or $SU(2)$. It is only the breaking of the symmetry by the large mass differences between the various quarks that tended to hide these symmetries. The discovery of charm has also provided a means for accounting for the absence of strangeness-changing neutral hadronic currents in weak interactions.

Strong interactions are thus described in terms of a color triplet of four flavors of quarks which are called u, d, s, c (for *up, down, strange,* and *charm*). It is a question of some interest whether this is the end. It is generally accepted that one of the very narrow resonances should be identified as a new quark pair. If this is called b (for *beauty* or *bottom*) and a sixth called t (for *truth* or *top*) is also postulated, we would have these pairs: $u, d; s, c; t, b$. This would be then very similar to the leptons, where we seem to have $e, \nu_e; \mu, \nu_\mu; \tau, \nu_\tau$: three families of quark pairs and three of lepton pairs. This family recurrence suggests even more strongly that the leptons and quarks are intimately connected; and that we have not exhausted levels of possible unification. What was an electron-muon puzzle is now a full-fledged "family" affair!

As particles get organized into multiplets, so do interactions exhibit systematic properties. During the last century Maxwell unified electric and magnetic interactions into the electromagnetic theory. With the reinterpretation of the coupling of the charge flow to the electromagnetic field to be implemented by a gauge invariant interaction in quantum field theory we got quantum electrodynamics (QED). In the middle of this century, Sudarshan and Marshak started from Fermi's theory of beta decay of the neutron to unify weak interactions into a chiral ("handed") V-A interaction. In this theory for the first time we identified the left-handed fermions to be the only ones coupled; in contrast to electromagnetism, in which the left and right chiral components were both coupled but the neutrino was not. The adaptation of this theory to strange and charmed particles has now been carried out satisfactorily.

Is it possible to weld together the Maxwell theory of electromagnetism and the Sudarshan-Marshak theory of chiral weak interactions into a unified electroweak theory? Clearly the weak interactions are weak and if seen as due to charged counterparts to the photon these intermediate vector mesons should be about 40 times the proton mass. It turns out that Glashow, Weinberg, and Salam constructed precisely such a theory by starting with a Yang-Mills theory of a group $SU(2) \times U(1)$ involving the left-handed doublet comprising the electron and neutrino on the one hand and the right-handed electron on the other. This symmetry must break spontaneously and in the process generate substantial masses for the vector mesons. Such a theory is "renormalizable," so that higher order field theory corrections can be calculated in an unambiguous manner. It is not fully unified since there are two distinct coupling constants which can be related to the ratio of the charged to neutral vector bosons. It predicts a level of neutral current interactions in agreement with experiments. The mechanism of generation of masses involves the use of certain auxiliary Higgs fields which also serve to give the electron its mass. Once the electron-neutrino interactions are formulated we could use it for the two other lepton pairs and the three quark pairs.

The existence of *three* families rather than two throws some light on the puzzling small time reversal violation as "natural," in that the complex phases appearing in a mass matrix coupling left- and right-handed objects cannot all be "defined away" as soon as three families appear.

If we really pursue the goal of unification and are emboldened by the close similarity between quarks and leptons attempt to put them together as a grand multiplet, we would be led to a *grand unified theory* (GUT), or rather several theories. Symmetry is broken in these theories so that at ordinary energies they do not appear.

Particularly simple forms of GUT are based on the groups $SU(5)$ and $O(10)$; these theories do predict a quark-lepton transition induced by a very heavy boson. This would lead to the decay of the proton, possibly into a positron and neutral pion or other such modes. The lifetime for such a decay would depend on the heavy boson mass, varying roughly as the fourth power of the mass. Using renormalization group equations and the observed ratio of the couplings one can estimate the mass and hence the proton lifetime. This yields a lifetime on the order $10^{31\pm2}$ years. While this means an extremely small transition rate there are a great number of protons in the world, and detection, if they decay, is imminent.

We should also remark that the particles so far discovered all have either finite mass (Class I particles or *bradyons*), or zero mass (Class II particles or *luxons*). It is an interesting question to ask if particles of imaginary mass (Class III particles or *tachyons*) can and do exist. It used to be thought that such particles could not exist, since their existence would violate the principle of relativity, but now we know that such is not the case. If hadronic tachyons exist, the quantum theory of tachyons predicts that they will show up as fixed resonances in momentum transfer. Leptonic tachyons (and photonlike tachyons) could probably be best detected in astronomical phenomena. If they exist they would provide for a substantial pressure in the interior of hot stars and thus provide a balancing force to alleviate gravitational collapse. Whether the concept of particles of imaginary mass, which is the relativistic counterpart of geometric size used in simpler nonrelativistic physics, is useful in elementary particle physics is not yet clear.

One of the remarkable new developments is the close relationship between cosmology and elementary particle physics. This goes beyond the application of standard methods of nuclear synthesis and stellar astrophysics in dealing with the change in physical laws under cosmological conditions. The spontaneous symmetry breaking that makes weak interactions weaker than electromagnetism no longer operates when energy density and temperatures are very high. Similarly, masses and thresholds are dependent on the presence of radiation and other particles in high concentration. Finally the baryon to photon abundance ratio can be related to the violation of time reversal invariance.

Despite the breathtaking unifications we are still short of two unifications. One is the unification of gravitation with particles interactions. While the emphasis on geometry characteristic of general relativistic gravitation theory is now permeating particle physics via gauge theories, the combination of gravitation with particle theories is still far from satisfactorily envisaged, much less carried out.

The other unification is of bosons and fermions by a supersymmetry. Such theories are now being actively pursued, since they seem to have some effect of diluting the infinities in quantum field theory. Supersymmetry is reluctant to "break" in a simple manner, yet break it must if experiment is our guide: bosons and fermions are not degenerate in their masses.

To sum up: we have a large number of "elementary" particles which are not so elementary. We have a number of theories which aid us in understanding the regularities observed in their spectrum and in their interactions. We have discovered a large number of invariance groups and the extent to which they break. And we have found that coupling to the flow of electric charge and its noncommutative generalizations as well as the flow of energy and momentum lead to a class of gauge theories which may underlie all the physical interactions. However, we still do not understand the multiplicity of particles and interactions. The past decade has been a time of great discoveries. Particle physics promise to be a rich area of physics in the foreseeable future. Perhaps yet another level of discovery awaits us in our search for the constitution of matter.

ELEMENTS, CHEMICAL

The idea of a basic simplicity underlying the bewildering complexity of nature has always been a conceptual thread woven into man's view of the world. The Greek philosophers of antiquity were among the first to record their speculations, and we are to this day influenced in an unconscious way by their thoughts, concerning the elements, which they supposed to be the ultimate components of matter and chemical change. Thus we speak of "man's battle with the elements" and "the raging elements" in unconscious reflection of the ideas of Thales, Anaximenes, Heraclitus and Empedocles of the fifth century B.C. who believed that all matter was made of one or more of the elemental substances: earth, air, fire and water. These ideas did not prove particularly fruitful in advancing our understanding of the nature of matter and chemical change. Nevertheless, it was not until van Helmont (1648) that they were challenged on a rational basis.

In 1662, Robert Boyle, in the *Sceptical Chymist* gave a reasonably clear definition of a chemical element with an operational basis which we can accept today. "I mean by elements, . . . certain Primitive and Simple, or perfectly unmingled bodies; which not being made of any other bodies, or mingled bodies, are the Ingredients of which all those called perfectly mixt bodies are immediately compounded, and into which they are ultimately resolved." He gave no list of elements, however, this being left to Lavoisier who published a naturally incomplete, but remarkably accurate list in 1789, in his justly famous, *Traité de Chimie*.

The Definition of "Element" In modern language, Boyle can be paraphrased in the following way: an *element* is a chemical species that cannot, by ordinary chemical manipulation be decomposed into a number of simpler chemical species. It is the entity that survives intact the infinite variety of transformations that a sample of matter can be caused to undergo. Every *compound* is composed of two or more of these species and can be decomposed into them by suitable chemical procedures. This definition provides an operational means of identifying an element in terms of laboratory procedure, and by it, any species that defies decompositional efforts must be classified as an element. Such an assignment must of course be somewhat tentative, since in a number of cases, substances that have stubbornly resisted decomposition and therefore carried the classification, have ultimately yielded as new techniques developed.

With the recent growth in detailed knowledge of atomic structure, it became possible to define an element in terms of the submicroscopic structure of matter. Such a definition is relieved of the ambiguities mentioned above. Thus an element is a sample of matter that consists of only one kind of atom, the atoms being identified in terms of their atomic number, or nuclear charge. Each element is composed of atoms having characteristic nuclear charge and an equivalent number of electrons. This nuclear charge can be determined by the charged-particle scattering technique first employed by Rutherford or by the simpler and more precise method of Moseley which relates the frequency of the characteristic x-rays produced by the element upon electron bombardment to the nuclear charge z by means of the equation

$$w = R(z - b)^2$$

where w is the wave number of the x-ray, z is the nuclear charge, and b and R are constants.

This definition removes the ambiguities created by such observations as the decomposition of elemental molecular hydrogen or nitrogen by high temperatures into atomic species, or the decomposition of the rare gases into charged species in an electric discharge. This type of decomposition, which does not effect the underlying nuclear structure is thus excluded from the operational definition originating with Boyle.

Numbers and Kinds of Elements The number of substances recognized as chemical elements has steadily increased since the publication of Lavoisier's list which included about thirty of the true elements. Today it is recognized that there are some 90 naturally occuring elements, the exact number depending upon the level of abundance considered limiting. There are also about 15 artificial ones with this latter number possibly increasing as the techniques of nuclear science improve. The artificial elements include those with atomic numbers above 92 as well as promethium and technetium. Technetium is also observed in stars, and in that sense is naturally occuring. (See table in the article ISOTOPES).

The 105 presently known elements represent distinct chemical species differing by integral units of positive charge (corresponding to the charge of the proton) beginning with element number 1, hydrogen, and progressing through element number 105. Species having nuclear charges between 1 and 105 have all been identified, so it can be said that the list of elements is complete, except for the possibility of adding new ones with atomic numbers greater than 105. Considerable effort, both experimental and theoretical, is currently being expended in the effort to find super-heavy elements of unusual stability. With the discovery of element 103, the actinide series was completed. Both 104 and 105 are quite unstable; however, islands of stability are predicted to occur between atomic numbers 114 and 126 and again between 164 and 194.

Most of the elements exhibit variations in mass, due to the varying numbers of neutrons present in their nuclei. Atoms having the same nuclear charge but differing in mass number or atomic weight are referred to as ISOTOPES. If all of these are considered, then there are approximately 1000 different atomic species represented in the list of chemical elements. Only 18 of the elements existing in nature exhibit a single mass number, and some, tin being a good example, have as many as ten naturally occurring stable species differing only in their neutron number or mass. All of the elements exhibit a variety of mass modifications which are artificially produced, but these are unstable or radioactive. These artificially produced species, of course, make up the bulk of the previously mentioned 1000 different entities. The *naturally occuring* radioactive isotopes, in addition to those beyond bismuth, include carbon 14, chlorine 36, vanadium 50, potassium 40, rubidium 87, indium 115, lanthanum 138, neodymium 144, samarium 147, lutetium 176, tantalum 180, rhenium 187, and platinum 190.

The Natural Distribution of Elements The relative abundance of the elements is quite different for the earth's crust from what it is thought to be for the universe as a whole. These terrestrial abundances are listed in Table 1 from which it can be seen that only thirteen elements comprise over 98 per cent of the earth's crust, the oceans and the atmosphere. It will be noted that many of the common and important elements of commerce are not included in this list, but rather belong to the remaining 2 per cent of the earth's crust. Copper, lead, and nitrogen are especially conspicuous by their absence.

If we turn our attention now to cosmic abundances, the list has quite a different make up (see Table 2). This list of course is known with considerably less accuracy since it is our attempt to guess at the relative abundance of the chemical elements in the entire universe: our galaxy, all the other galaxies, and the vast, but

TABLE 1. THE THIRTEEN MOST ABUNDANT ELEMENTS ON THE EARTH'S SURFACE

Element	Abundance (%)
Oxygen	49.52
Silicon	25.75
Aluminum	7.51
Iron	4.70
Calcium	3.39
Sodium	2.64
Potassium	2.40
Magnesium	1.94
Chlorine	1.88
Hydrogen	0.88
Titanium	0.58
Phosphorus	0.120
Carbon	0.087

TABLE 2. THE THIRTEEN MOST ABUNDANT ELEMENTS IN THE UNIVERSE

Element	Relative Abundance[a]
Hydrogen	3.5 × 10^8
Helium	3.5 × 10^7
Oxygen	2.2 × 10^5
Nitrogen	1.6 × 10^5
Carbon	8 × 10^4
Neon	2.4 × 10^4
Iron	1.8 × 10^4
Silicon	1 × 10^4
Magnesium	9 × 10^3
Sulfur	3.5 × 10^3
Nickel	1.3 × 10^3
Aluminum	8.8 × 10^2
Calcium	6.7 × 10^2

[a] These abundances are relative to silicon taken as 1 × 10^4.

not entirely empty spaces in between. This information has largely been gathered by spectroscopic studies of the light emitted by the luminous bodies in these galaxies and by careful analysis of the samples of off-planet material (meteorites) that constantly shower the earth, as well as lunar-samples.

It can readily be seen that this list is quite different from the terrestrial abundance list. For the universe as a whole, the elements hydrogen and helium far outrank all others, while on the earth, hydrogen is only tenth in abundance and helium doesn't even appear on the list. Oxygen remains high, and nitrogen, absent from the terrestrial list, is the fourth most abundant element when cosmic abundances are considered. In Fig. 1, some of the interesting variations in abundance are displayed. The relative abundance is plotted against mass number.

It will be noted that elements with atomic weights that are multiples of four and two are

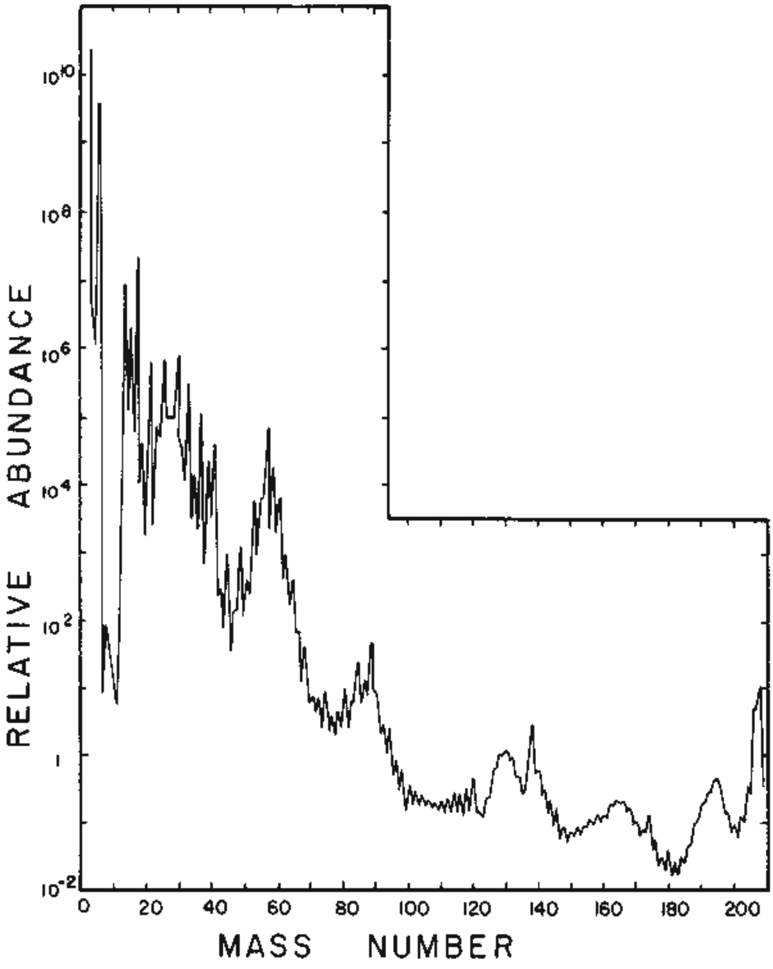

FIG. 1. [From Cameron, A. G. W., *Sky and Telescope*, 254 (May, 1963).]

more abundant than nearby elements with relatively similar atomic weights. Examination shows that those elements having *proton or neutron* numbers 8, 50, 82, and 126 also exhibit maxima. These numbers are so-called magic numbers confering an especially high degree of nuclear stability.

The Origins of the Elements The origin of the elements and their eventual appearance in the observed abundances in the earth has been the subject of intense research and speculation for many years. The currently accepted ideas involve a series of events, some dating back to the "beginning" and others continuing to occur in appropriate locations throughout the universe even today, which result ultimately in the production of all the known naturally occuring elements.

The first part of the story, one of remarkably short duration, involves a modified "big bang" of the type postulated by Gamow. At the beginning of our universe all matter was thought to exist in a highly condensed sphere of neutrons (the *ylem*). This giant nucleus underwent a cataclysmic explosion and with a half-life of around eleven minutes the neutrons were converted to protons and electrons. Because of the very high photon density in the ylem about 25% of the resulting expanding cloud was converted into helium by condensation of the hydrogen nuclei, concomitantly filling the universe with black body radiation as the cloud cooled. The existence of such radiation, corresponding to a temperature of 2.7°K has been confirmed experimentally.

The remainder of the story is spread over a period of from 10 to 15 billions of years and involves the cycle of stellar evolution familiar to the astronomer. The original cloud of interstellar matter suffered local condensation into billions of stars. As these stars consume their hydrogen by a fusion process they undergo a series of changes in internal conditions acting as the factories of the chemical elements. At first only helium is formed, but as the hydrogen is consumed and helium formed the temperature of the core falls, allowing it to contract by gravitational attraction. This contraction offsets the cooling trend and the core becomes even hotter—heating the outer hydrogen mantle and causing it to expand and cool, producing the so-called *red giant* star. Continued contraction of the core raises its temperature until helium fusion is possible, producing the lighter elements such as carbon, oxygen, neon, magnesium, and silicon. Essential to the production of these lighter elements is the possibility of utilizing the extremely short-lived product of the first condensation of two helium nuclei, ^{8}Be, ($t_{1/2} = 2 \times 10^{-16}$ s). Fortunately the density of matter in the red giant cores is so great that the probability of subsequent reaction of beryllium with helium to produce the lighter elements is very high.

The heavier elements, up to and including iron, are generally the result of carbon fusion in very massive stars with interior temperatures of the order of one billion degrees. This produces a "soup" of nuclei, nucleons, alpha-particles, and photons in which reaction between the lighter particles and heavier nuclei leads to elements as heavy as iron.

To form elements up to the mass of bismuth the s- (or slow) process is invoked. This involves the equilibrium addition of neutrons to the intermediate nuclei with intervening beta-decay. This growth of heavier and heavier nuclides is arrested by the intervention of a number of very short-lived species. The trans-bismuth elements require an environment of even higher pressure and neutron abundance, as found in the cores of supernovae.

Eventually stars eject matter containing this array of elements into interstellar space. The Earth, the Sun, and other planets are presumably the result of accretion of this cosmic dust, in a whirling cloud which centrifuges the heavier nuclides outward, leaving the helium and hydrogen to coalesce to form our central star.

Synthetic Elements The first of the synthetic elements was made in 1937 by the bombardment of molybdenum with deuterons. This produced technetium, filling a long recognized gap in the periodic table for element number 43. The other gap, at number 61, promethium, was filled in 1947 when ^{149}Pm was isolated in small yield from the products of fission of ^{235}U.

Since that time 13 additional synthetic elements have been made, all lying beyond uranium in the periodic table. These are formed by a variety of processes involving neutron capture or bombardment with heavy ions.

ENERGY LEVELS, ATOMIC

The term "energy level" is used in referring to discrete amounts of energy which atoms and molecules can have with respect to their electron or nuclear structure. The concept of permissible discrete energy levels was first introduced by Planck in explaining the physical basis for the spectral distribution of blackbody radiation. A second related principle due to Planck was that the emission and absorption of radiation are associated with transitions between these energy levels, the energy thereby lost or gained being equal to the energy, $h\nu$, of the quantum of radiation. Here h is Planck's constant and ν is the frequency of the radiation.

The first application of energy levels in the electron structure of atoms to explain optical spectra was made by Bohr. The original Bohr atom had as its basis that the only allowable states of an atom were those in which the electronic angular momentum was an integral multiple of $h/2\pi$. Circular orbits suggested by Bohr were extended by Sommerfeld to include the quantization of momentum in elliptic orbits, and to provide an improved explanation of optical spectra.

These early concepts were modified by the development of the theory of wave mechanics, in which it was shown that the allowable "stationary" states for the electrons in an atom must represent solutions of the Schrödinger wave equation. These solutions are conveniently represented by a set of "quantum numbers" for each electron. On this basis the electron structure of an atom containing any number of electrons can be built up. Two further concepts that are essential to this picture, however, are electron spin proposed by Uhlenbeck and Goudsmit, and the exclusion principle due to Pauli. In addition to the angular momentum of the electron in its orbit, each electron possesses angular momentum due to spin about an axis. The Pauli exclusion principle specifies that no two electrons in an atom can exist in the same quantum state, corresponding to the same set of quantum numbers.

Each electron in an atom can be characterized by four quantum numbers, n, l, m_l, m_s. The energy of an electron depends principally upon the positive integer n, and larger values of n correspond to larger electronic orbits. The quantum number l possesses physical significance in terms of angular momentum in the orbit, and is constrained to have the values of zero or positive integers less than n. The number, m_l, represents the component of l along a given axis, and must take on the values of zero or positive and negative integers whose absolute values are less than or equal to the value of l. The quantum number, m_s, can be $+\frac{1}{2}$ or $-\frac{1}{2}$, and represents the component of the spin along the axis.

Within a given atom, electrons having the same value of the principal quantum number, n, form a definite group or "shell." Those electrons possessing the same value of l for a given value of n are in the same subgroup or "subshell." The possible number of electrons in a shell or subshell depends upon the possible values of m_l and m_s. Whenever a subshell is filled, the total angular momentum of the electrons involved is zero. Electrons outside of filled subshells contribute additional angular momentum which is summed vectorially and assigned the numbers J, L and S. Here J is representative of the total angular momentum, L the orbital angular momentum, and S the spin angular momentum.

An atom is stable only when it exists in the state for which the quantum numbers of its electrons give the lowest total energy. The energy of the atom may be increased to a higher level by having an electron "excited" to another state represented by a different set of allowed quantum numbers. Transitions back again to the "ground" state will be accompanied by the emission of radiation. Wave mechanics indicates, however, that only certain transitions from one quantum state to another can be probable. These "selection rules" specify that $\Delta L = \pm 1$ and that $\Delta J = 0$ or ± 1.

Following the principles just given, an electron energy-level diagram can be constructed for the excited states of the atoms of any particular isotope. Discrete energy levels will exist for the allowed quantum states of excited electrons. The spectrum of radiation which can be emitted from the isotope will be determined by the energy differences between these states, where the transitions involved are allowed by selection rules. Figure 1 illustrates such an energy-level diagram for sodium.

This diagram indicates that very little difference in energy level results from changes in the electron spin orientation. These orientations correspond to different values of J for the same value of L. No attempt is made to show a separation in the diagram for the cases of $L = 2$ and $L = 3$. Such closely spaced energy levels due to the effect of the coupling of the electron spin give rise to "fine structure" in spectra.

Many spectral lines, when examined with high resolving power instruments, are found to exhibit a still finer structure of several lines very close together. This is termed "hyperfine structure" and has been found to be due to two causes. One is the isotope effect in which atoms

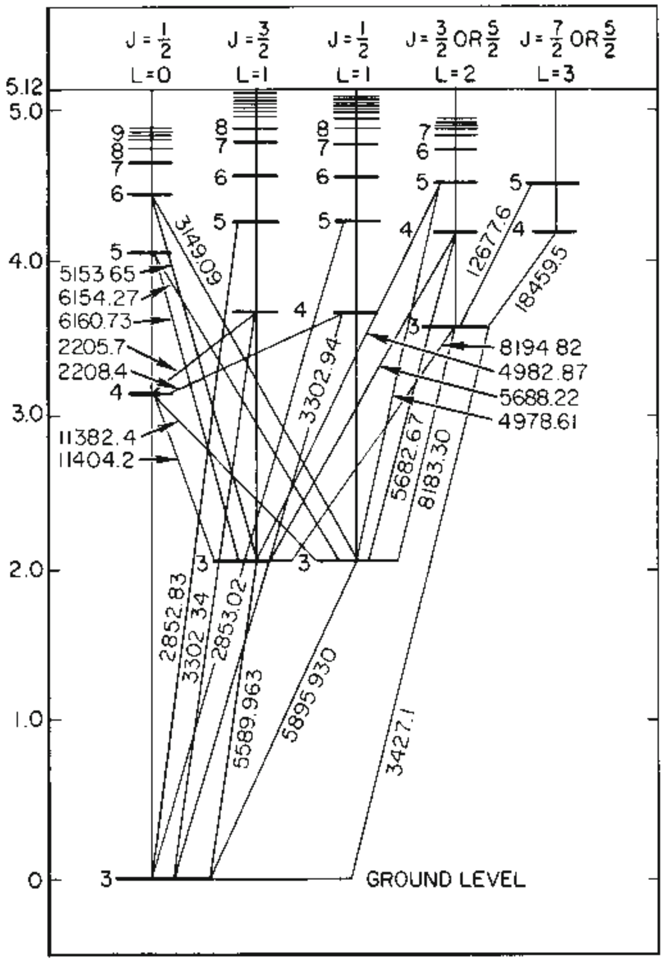

FIG. 1. Energy-level diagram for sodium. The large numbers are wave lengths in A of radiation emitted or absorbed during the indicated transitions. Principal quantum numbers are shown as integers.

of different isotopes of the same element possess slightly different excited electron energy levels. The other cause of hyperfine structure has been determined to be due to the fact that the atomic nucleus also possesses angular momentum, which is vectorially added to the electronic angular momentum and quantitized. Differences in the resultant states of the atom correspond to very small differences in the energy levels and hence in the observed spectrum.

Another source of structure in spectra results when the atoms emitting or absorbing the radiation are in a magnetic or an electric field. In a field, space quantization in the direction of the field takes place. The values of the magnetic moment or electric moment of the atom associated with the various possible components of angular momentum as quantitized in the field direction result in different energy levels. This splitting of levels is referred to as the Zeeman effect in the case of an applied magnetic field, and the Stark effect in the case of an applied electric field (see ZEEMAN AND STARK EFFECTS). The amount of splitting increases with the intensity of the superposed field. In addition, the spectral structure can vary due to a tendency for the orbital momentum, *L*, and the spin momentum, *S*, to become uncoupled and undergo space quantization independently in high fields. In weak fields, the space quantization is determined from the total angular momentum *J*.

The splitting of energy levels in electric or magnetic fields has become much more important in another type of phenomenon referred to as magnetic resonance (see MAGNETIC RESONANCE). Two examples are electron spin resonance (esr) and nuclear magnetic resonance (nmr). If a single level is split into its Zeeman components by a magnetic field H, electromagnetic radiation of frequency ν will induce transitions between the Zeeman levels if the following condition is satisfied:

$$h\nu = g\mu H$$

Here g is energy level "splitting factor" and μ is the appropriate "magneton" (Bohr magneton μ_B for esr and nuclear magneton μ_N for nmr). (See reference 1.) For magnetic field strengths conveniently available in the laboratory, the resonance frequencies are in the short radio or microwave regions.

Any electron of an atom may be excited to some higher allowed energy level by absorption of the amount of energy specified by the difference in the energy levels involved. By absorption of a sufficient amount of energy, any electron can be removed from an atom, resulting in ionization. It is not necessary to consider only the outermost loosely bound electrons. When electrons from inner shells are excited or removed, the process of returning to the "ground" or lowest energy state involves the emission of "characteristic" x-rays. They are "characteristic" in that the x-ray spectrum produced is typical of the particular atom producing the radiation. Atoms of higher atomic number and transitions involving electrons in innermost shells produce higher-energy radiation. Absorption, as well as emission, of characteristic x-ray radiation is observed between allowed electronic energy levels. For further information on atomic spectra and energy levels, see reference 2.

In addition to the energy levels associated with particular types of atoms, wave mechanics shows that discrete quantum states and energy levels are associated with molecular structure. New energy levels arise from vibration and rotation of molecules. To illustrate the allowable vibrational states for a diatomic molecule, consider Fig. 2, which shows the mutual force, F, and the potential energy, V, plotted as a function of the separation, r, between the two atoms. Possible energy levels are indicated by the dotted lines. Even the lowest state corresponds to an energy greater than V_0, where the force between the atoms would be zero, and hence has some associated kinetic energy.

The rotation of a molecule has a quantitized angular momentum which can be vectorially combined with that of the electrons. Transitions from one level to another usually involve a change in the electronic state as well as in the rotational state. Since energy differences due to allowed changes in rotational motion are very small compared to the energy differences in electronic states or vibrational states, the effect of transitions in rotational states is to produce bands of very closely spaced frequencies in the emission and absorption spectra. Such "rotational" bands are observed in molecular spectroscopy, depending upon what other transitions may be simultaneously involved, in the ultraviolet region, the visible, the infrared, and even the microwave region. See reference 3 for further details on molecular energy levels and associated spectra.

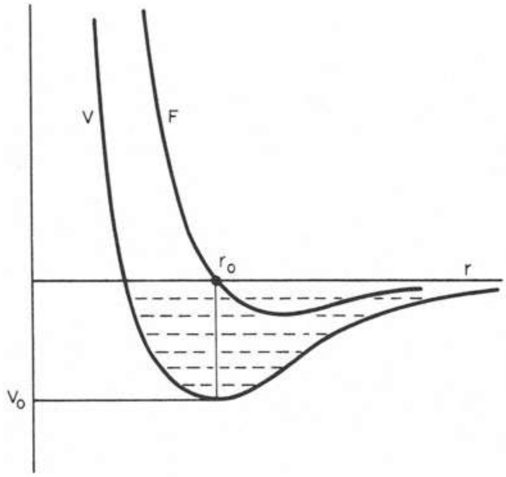

FIG. 2. Mutual potential energy V and force F as a function of atomic separation in a diatomic molecule. F is repulsive when positive and attractive when negative.

An atom may not only combine with others to form a molecule, but may be one of a large

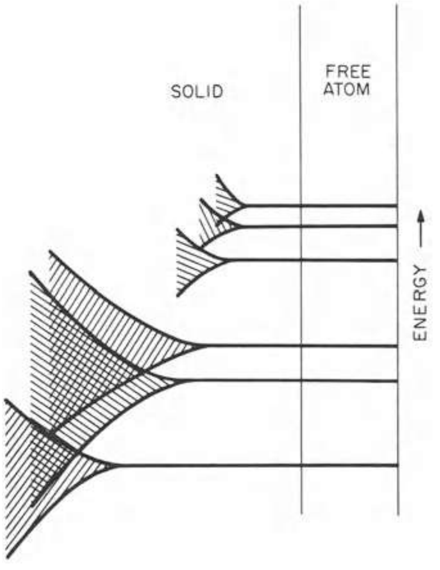

FIG. 3. The electron levels of a free atom split into bands when the atom enters a solid.

number of atoms forming a crystal. Here solutions to the wave equation show that within the solid, the individual energy levels of the free atom broaden into bands of overlapping levels. This is illustrated in Fig. 3. The bulk electrical and optical properties of solids are determined by the nature of these energy-level bands. Metals have the highest occupied energy band unfilled, while satisfying the exclusion principle that no two electrons occupy the same state. This permits electrons to gain energy under the application of an electric field and flow freely through the solid. Insulating crystals have the highest occupied energy band filled and appreciably separated from the next higher band. Semiconductors represent an intermediate situation where electrons can be injected into an unfilled band to contribute to conduction.

If the solid crystal is not completely regular but contains imperfections or impurity atoms, specific electron energy levels will be associated with these sites. This condition is responsible for luminescence and phosphorescence in certain solids. Additional information on energy bands in solids is given in reference 1.

ENERGY STORAGE, ELECTROCHEMICAL

Introduction Energy storage is important in alleviating discrepancies between energy supply and energy demand. These discrepancies may be either temporal or spatial or both. Energy storage is already being used in many applications, varying in size from a few milliwatt-hours (e.g., electric watches and calculators) to many gigawatt-hours (pumped hydroelectric storage). Energy may be stored in many ways, including storage as potential energy in the earth's gravitational field (raising a weight), kinetic energy (a spinning flywheel), thermal energy (heating a substance), chemical energy (carrying out a reversible chemical reaction), or electrochemical energy (carrying out a reversible electrochemical reaction). This article deals with the storage of energy by means of electrochemical reactions which can be carried out in both forward and reverse directions. The devices which provide this capability are called rechargeable (or secondary*) electrochemical cells. Cells may be connected to series and/or parallel to form arrays called batteries.†,‡

There are many current applications for electrochemical energy storage devices, varying from aerospace (batteries for satellites' onboard power, recharged by solar cells; starting batteries for aircraft) to military (communications equipment, torpedoes, submarines) to industrial (electric forklift trucks, other electric vehicles) to consumer (battery-powered appliances, automobile batteries). Future applications that are providing incentive for current research and development include energy storage for electric utility systems (megawatt hours), for solar and wind-powered electric systems (kilowatt hours to megawatt hours), and for electric vehicles (tens of kilowatt hours).

The characteristics of rechargeable batteries that are important in many applications include the specific energy (energy stored per unit battery mass, Wh/kg), the specific power (power delivered per unit battery mass, W/kg), the cycle life (number of discharge-charge cycles before failure), the lifetime (time to failure), and the cost (usually expressed as \$/kWh of energy storage capability). Of course, it is desirable to have batteries of high performance, long life, and low cost. The scientific implications of these goals are shown in Table 1.

There are a number of fundamental characteristics that enable the achievement of the goals of Table 1. The desired characteristics for each of the three essential parts of a cell (the negative electrode, the positive electrode, and electrolyte) are listed in Table 2. A large electronegativity difference between the reactants, and small equivalent weights yield a high theoretical specific energy for a cell:

$$\text{Theoretical specific energy} = \frac{-\Delta G}{\sum \gamma_i M_i}$$

*Primary electrochemical cells are based upon reactions that cannot be reversed; the cells are discarded after a single discharge.

†Often the term battery is misused in place of cell.

‡See ENERGY STORAGE, THERMAL-MECHANICAL for other types of energy storage systems.

TABLE 1. GENERAL GOALS FOR BATTERIES.

Goal	Implication
High specific energy	High cell voltage Low equivalent weight High utilization of active material
High specific power	High cell voltage Rapid reactions Rapid mass transport Low internal resistance
Long life	Reversible reactions Low corrosion rates Negligible rates of side reactions
Low cost	Inexpensive, plentiful materials Simple manufacturing processes High efficiency Little or no maintenance

where γ_i is the number of moles of reactant i, M_i is the molecular weight of reactant i, and ΔG is the Gibbs free energy change for the overall cell reaction. The theoretical specific energy is a useful guide in the selection of cells for applications in which high specific energy is important (e.g., mobile uses). For cells with solid reactants, it can be expected that 20–25% of the theoretical specific energy will be obtained from well-designed cells. A plot of the theoretical specific energy for a number of cells is shown in Fig. 1.

A careful examination of Fig. 1 reveals that the cells with the highest theoretical specific energy generally involve reactants that are not stable in contact with an aqueous electrolyte (Li, Na), whereas those of lower specific energy are compatible with aqueous electrolytes (Pb, Cd, Fe, NiOOH, etc.). This feature results in the subdivision of rechargeable cells into two major categories: those with aqueous electrolytes, which operate at ambient temperature, and those with nonaqueous electrolytes, most of which operate at high temperatures (for reasons given below).

Ambient-Temperature Rechargeable Cells Rechargeable cells that operate at ambient temperature in almost all cases make use of aqueous electrolytes. The use of aqueous electrolytes limits the choice of electrode materials to those that do not react with the water in the electrolyte at an unacceptably high rate. This consideration eliminates the alkali metals (e.g., Li, Na, K) and the alkaline earth metals (e.g., Mg, Ca, Ba) from consideration, even though they have low electronegativities and low equivalent weights, and other desirable properties called for in Table 2. Materials that are sufficiently stable with aqueous electrolytes, have acceptably low electronegativities, take part in electrochemical reactions that can be reversed, and have other desirable properties as negative electrodes include Pb, Cd, Fe, and Zn. Elements that have high electronegativities are found in groups V, VI, and VII of the periodic chart of the elements. These have been used both as elements (e.g., Cl_2, Br_2) and in compounds (e.g., metal oxides such as PbO_2, NiOOH, AgO) in positive electrodes.

The lists of negative and positive electrode reactants given above can be used to select pairs of electrodes to make cells, along with suitable electrolytes. Aqueous electrolytes are usually strongly acidic (e.g., H_2SO_4) or strongly alkaline (e.g., KOH) in order to maximize the electrolytic conductivity, which contributes to achieving a low cell resistance and therefore a high specific power capability. The cells that are currently available, or are under development include $Pb/H_2SO_4/PbO_2$, Cd/KOH/NiOOH, Fe/KOH/NiOOH, Zn/KOH/NiOOH, Cd/KOH/AgO, Zn/KOH/AgO, $Zn/ZnBr_2\text{-}KCl/Br_2$, $Zn/ZnCl_2/Cl_2$.

The Pb/PbO_2 cell is the most widespread and least expensive of all those currently available. Its most common use is for starting, lighting, and ignition purposes in automobiles. The automobile battery stores about 1 kWh. With about 10^8 automobiles in the U.S., nearly 10^8 kWh of energy is stored in these batteries. For electric

TABLE 2. DESIRABLE CHARACTERISTICS OF SYSTEMS FOR HIGH-PERFORMANCE ELECTROCHEMICAL CELLS.

Characteristic·	Negative Electrode Reactant	Positive Electrode Reactant	Electrolyte

*A more important criterion for the electrolyte is low density.

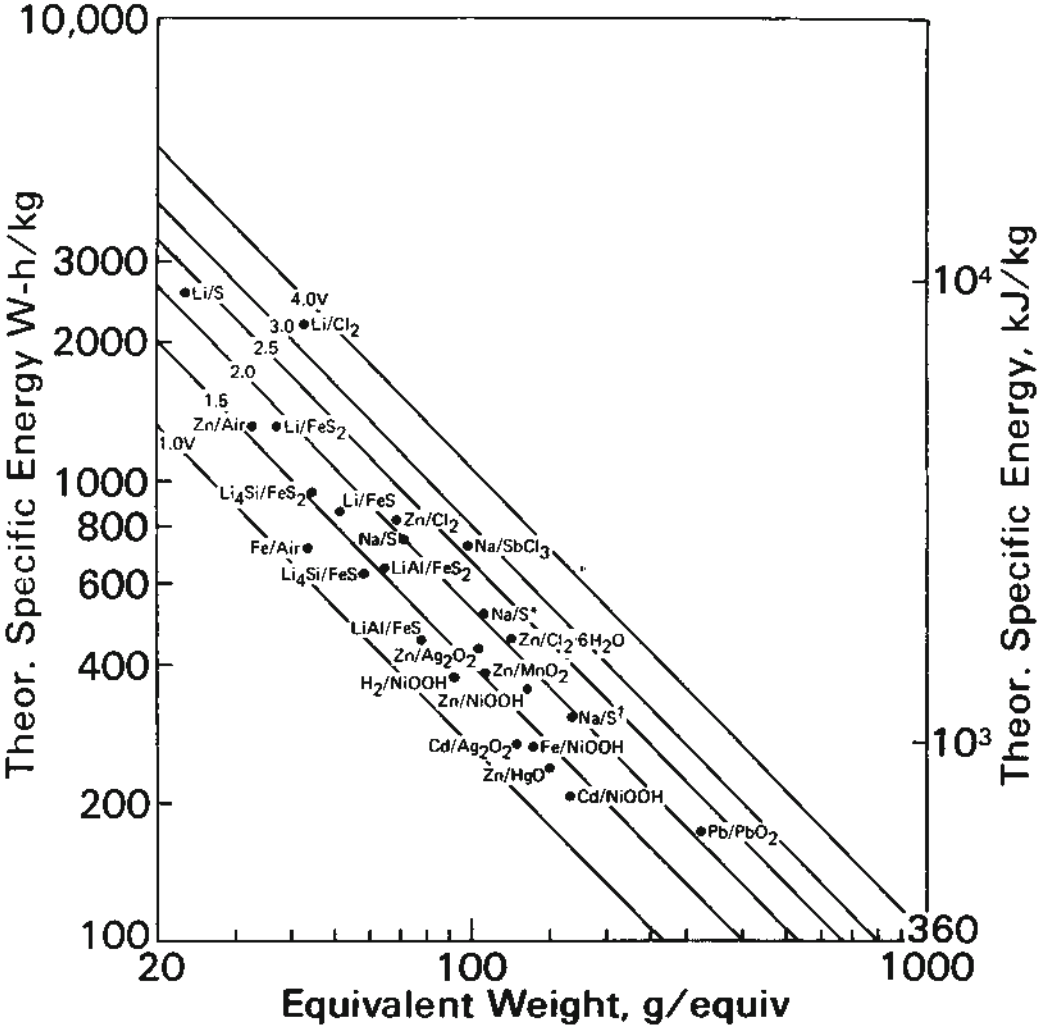

FIG. 1. Theoretical specific energy of candidate cells. Lines are for cell voltages from 1 volt to 4 volts, as labeled.

vehicle applications, the specific energy of Pb/PbO_2 at 25–40 Wh/kg is too low–70 Wh/kg is needed for an urban driving range of 150 km (a common goal). For electric utility energy storage, the cost of Pb/PbO_2 (~$100/kWh) is too high, and the cycle life is too low.

The Cd/NiOOH cell, with its very long cycle life and ruggedness has found various military and aerospace applications that do not require storage of much energy (there is a limited supply of Cd, and it has a high cost). A significant consumer market for use in small battery-powered appliances has also developed.

The Fe/NiOOH cell, also known as the Edison cell, has disappeared from the marketplace, largely because of its high cost. There are now efforts to develop a lighter-weight, lower-cost Fe/NiOOH cell for electric vehicle propulsion, but its modest specific energy of 40–50 Wh/kg, and its low efficiency (~60%) limit its applicability for electric automobiles or stationary energy storage.

The Zn/NiOOH cell has a very attractive specific energy of 70–75 Wh/kg, but the short cycle life of the Zn electrode (<300 cycles) has prevented it from achieving wide application. Research and development efforts aimed at improving the Zn electrode continue.

The Cd/AgO and Zn/AgO cells offer higher specific energy than their NiOOH counterparts, but the high cost of Ag limits them to military, aerospace, and specialty applications usually requiring the storage of small amounts of energy.

In recent years, Zn/halogen systems with flowing electrolyte-plus-reactant streams have been under development. These systems may be of acceptably low cost (less than \$100/kWh) because they rely heavily on such inexpensive materials as carbon and polymers. The specific energies are in an intermediate range (about 60 Wh/kg for Zn/Br_2 and 70 Wh/kg for Zn/Cl_2). The safe storage of halogens is an important issue for these systems. Chlorine is stored as an icelike material $Cl_2 \cdot 8H_2O$ at temperatures below 9°C. Bromine is stored as a chemical complex formed from quaternary ammonium organic salts. This complex is a dense, oil-like liquid which spontaneously separates from the electrolyte. These Zn/halogen flow batteries are more complex than other batteries, and probably will not be acceptable for mobile applications if alternative batteries of similar specific energy are available. Stationary applications are good possibilities, especially if efficiencies above 70% are achieved.

There has been a great deal of research devoted to nonaqueous ambient-temperature rechargeable cells, especially those using Li electrodes, with the hope of achieving 100–200 Wh/kg. This has been a difficult research area because all the electrolytes investigated have been thermodynamically unstable in contact with lithium. Consequently, the lithium electrode has not been capable of being recharged very many times before failure, and there have been some explosions resulting from rapid reactions of lithium with the electrolyte. In addition, only a few candidate positive-electrode materials have shown the ability to be recharged repeatedly. One of these is TiS_2, a layered crystal that permits the entry of Li atoms between its crystal planes. Research continues on rechargeable ambient-temperature lithium cells, but none are available yet.

High-Temperature Systems It has been found that the alkali metals, which promise high specific energy, can be used more readily at elevated temperatures than at ambient temperature. This is the case because elevated-temperature operation permits the use of stable molten-salt or ceramic electrolytes which have high conductivities for alkali metal cations. For various chemical reasons, molten salt electrolytes are used with the lithium electrode, and ceramic electrolytes are used with the sodium electrode. The positive electrodes are sulfur or compounds containing sulfur. These cells operate at 350–475°C, and large batteries would be kept at operating temperature by means of efficient thermal insulation to contain the heat produced by the battery in its normal operation.

An example of the molten-salt cells is the $Li_4Si/LiCl\text{-}KCl/FeS_2$ cell. The compound Li_4Si is used instead of lithium because it is a lightweight solid, whereas Li is liquid at temperatures above 180°C, and is therefore difficult to control in the cell. The same is true for solid FeS_2 as compared to sulfur, which melts at 118°C. The LiCl-KCl eutectic electrolyte melts at 352°C, and the cell is operated at about 450°C. The theoretical specific energy of this cell is 960 Wh/kg, as shown in Fig. 1. Practical values as high as 180 Wh/kg have been reported for single laboratory cells. Only a few small laboratory batteries have been built, many large cells and some multi-kWh batteries of LiAl/LiCl-KCl/FeS cells have been demonstrated. This system is quite similar to $Li_4Si/LiCl\text{-}KCl/FeS_2$, but it has a much lower specific energy (about 100 Wh/kg vs. 180–200 Wh/kg).

Molten-salt cells may find application for stationary energy storage, and for electric vehicles with high duty cycles, so that thermal cycling to ambient temperature is only infrequently required. In addition to high specific energy, these cells have inexpensive reactants. If the high-temperature corrosion problems can be overcome, molten-salt cells may be attractive.

The ceramic-electrolyte cells are best exemplified by the $Na/Na_2O \cdot 8Al_2O_3/S$ cell. The electrolyte is called beta alumina, and can conduct sodium ions in the crystallographic planes perpendicular to the *C*-axis. The purity and crystal size of the electrolyte are critical to achieving long life and high performance. This cell operates at 350°C, and uses liquid Na and liquid S as the reactants. A graphite felt material serves to collect the current in the nonconductive sulfur. The electrolyte is used in tube form, with one reactant inside, the other outside.

The ceramic electrolyte is made from materials which are basically inexpensive, but purity, quality control, and manufacturing conditions have made the process extremely expensive, and a major topic for continued development. The electrolyte should be strong, very dense ($>97\%$ of theoretical), of low resistivity (<10 Ω-cm), have controlled crystal size and structure and be highly pure.

Thousands of single cells of various sizes up to 100–200 Ah have been tested, as well as several multi-kWh batteries, and one 75–100 kWh battery. With additional development of the electrolyte, work on sulfur corrosion, and cost reduction, the Na/S cell could find applications similar to those mentioned above for Li_4Si/FeS_2.

Summary and Outlook The several rechargeable cells discussed above are listed with some of their important characteristics in Table 3. It is clear from this table that none of the systems at present meets the goals for the major energy storage applications of electric automobiles ($>$70 Wh/kg, $>$100 W/kg, $>$300 cycles, $<$\$100/kWh), or energy storage for electric utilities ($>$70% efficiency, 80 kWh/m^2 floor space, $>$2000 cycles, 10 years life, $<$\$50/kWh). There are other applications that may be filled by the

ENERGY STORAGE, THERMAL-MECHANICAL

Introduction* Energy storage systems serve to lower the cost of delivering energy in a suitable form to a user at the required time. For example, in electric utility systems the cost to produce energy can change by as much as a factor of five over a twenty-four hour period. By storing relatively cheap nighttime energy, the cost for supplying daytime energy can thus be significantly reduced.

Thermal energy storage systems rely on storing energy in the form of heat; whereas mechanical energy storage systems rely on storing energy in the form of potential and/or kinetic energy. Other forms of energy storage systems use chemical energy (e.g., batteries), electrical energy (e.g., capacitors) and electromagnetic energy (e.g., superconducting electromagnets).

Physical Principles—Mechanical Energy Storage Mechanical energy may be stored in a number of forms:

- Potential energy
- Kinetic energy
- Elastic (or strain) energy
- Compressed gas energy

The international system of units (SI) denotes the (J) as the unit to be used for energy. It is equivalent to $m^2 \cdot kg \cdot s^{-2}$ or $N \cdot m$, where m is

*See also ENERGY STORAGE, ELECTROCHEMICAL.

meters, kg is kilograms, s is seconds, and N is Newtons.

Potential energy is the energy associated with the position of an object in a gravitational field and is equal to $Mg\Delta h$, where M is the mass of the object in kg, g is the gravitational constant (at the earth's surface $g = 9.8 \text{ ms}^{-2}$), and Δh is the vertical distance (m) between two points within the gravitation field.

Kinetic energy can be stored in an object moving in a straight line where the stored energy equals $MV^2/2$ and V is the object's velocity (m s^{-1}). Kinetic energy can also be stored in a rotating object, with stored energy being equal to $I\omega^2/2$, where I is the object's *moment of inertia* (kg · m^2) about its axis of rotation and ω is it's angular velocity (s^{-1}). A wheel-shaped object in the form of a flat disc or radius R (m), thickness T (m), and density ρ (kg/m^3) has a moment of inertia about its center of $I = T\pi\rho R^4/2$, which equals $MR^2/2$.

Elastic (or strain) energy can be stored in the stretching or compressing of a solid object, where the stored energy equals $K(\Delta X)^2/2$. K is the object's spring constant (kg s^{-2}) and ΔX is the change of the object's length (m). The above can be generalized to two or three dimensions for solids and liquids.

Compressional gas energy can be stored in a gas that has been transformed from one pressure (p) and volume (V) to another pressure and volume. The expression for this stored energy is $\int_{V_2}^{V_1} p\, dV$, which represents the mathematical integral (or continuous summation) of the parameter p from volume V_1 to volume V_2. Pressure is represented by Newtons per square meter (N m^{-2}) and volume is represented by cubic meters (m^3).

Physical Principles—Thermal Energy Storage Thermal energy may be stored in two forms:

- Sensible energy
- Latent energy

Sensible energy is stored when a substance at one physical state (e.g., the solid state) undergoes a temperature change. The expression for this stored energy is $CV(T_2 - T_1)$, where C is the *specific heat capacity* of a unit volume of the substance in J/kg · °C, where °C is temperature in degrees Centigrade; V is the volume of the substance (m^3); and T is temperature (°C).

Latent energy is stored when a substance undergoes a change in physical state at constant temperature (e.g., from liquid state to gaseous state). The amount of stored energy depends on the type of substance, its mass, and the type of state change it undergoes. If the change of state occurs at the substance's melting point, the *heat of fusion* (J/kg) is the stored energy. If the change of state occurs at the substance's boiling point, the *heat of vaporization* (J/kg) is the stored energy.

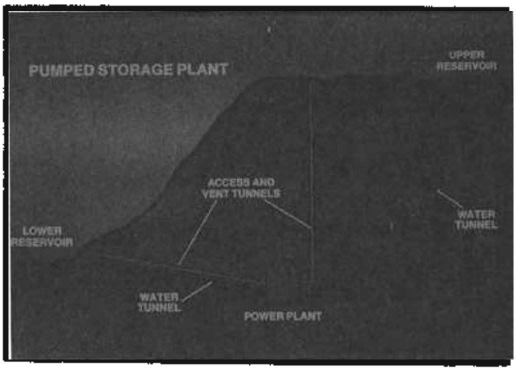

FIG. 1. Schematic diagram of pumped hydroelectric energy storage power plant.

Pumped Hydroelectric Energy Storage Pumped hydroelectric plants (see Fig. 1) rely on the principle of potential energy storage and have been in use for over 50 years. The total power capacity (energy delivered per unit of time) all of such plants in the United States is currently approximately 13,000 megawatts (MW). A typical plant is rated at 1000 MW. The plant power rating is determined by the potential energy of the water stored in an upper reservoir (in relation to the vertical distance to the lower reservoir) divided by the time it takes for the water to flow through the water piping and pump-turbine generator separating the two reservoirs. These power plants have proved to be an economically attractive way for electric utilities to store inexpensive evening energy (used to pump the water into the upper reservoir) and thus provide daytime energy at a lower cost by allowing the stored upper reservoir water to flow through a turbine generator into the lower reservoir. Although these types of power plants are very efficient (approximately 72%), future construction efforts have been hampered by their large cost, diminished topographical opportunities, and their possibly negative environmental impact as perceived by nearby citizenry.

A good example of a pumped storage plant is the Northfield Mountain (Massachusetts) facility (1000 MW). The water stored in the upper reservoir can produce power for a nominal six hours; thus the stored energy is 6000 MWh which is equal to 2.16×10^{13} J. For comparison purposes the amount of energy stored in this one facility is approximately 20% of the storage capacity of all the automotive batteries in the United States.

Flywheel Energy Storage Flywheel energy storage devices rely on the principle of kinetic energy storage and have likely been used by man longer than any other type of energy storage device. They have smoothed or leveled man's energy sources in such historic applications as the potter's wheel, the grain mill, and the water wheel. More recently, flywheel technology has been applied in the design of the steam engine, automobile, pile driver, and gyroscope. The use of the potter's wheel permitting a craftsman with a heavy wheel to make uniformly shaped pots while he supplied leg energy in unequal amounts and at irregular times, probably dates back 5,000 years.

As the flywheel spins, a tensile stress or load is created in its structural material. The amount of stress increases as the square of the flywheel angular velocity. The ultimate strength of the flywheel material to withstand this stress limits the amount of energy that can be stored. The relationship between the strength σ (N/m^2) of the material, the stored energy E, the material mass M, and the density ρ (kg/m^3) is $\sigma = KE\rho/M$, where K is a constant that is greater than or equal to 1 and is determined from the geometry of the flywheel. The energy stored in a flywheel per unit volume V is $E/V = E\rho/M = \sigma/K$. For a flywheel with $K = 2$ (associated with a non-tapered wheel rim) and $\sigma = 2 \times 10^8$ N/m^2 (a value corresponding to steel), the energy storage per unit volume is 10^8 N/m^2 = 10^8 J/m^3.

Compressed Air Energy Storage Compressed air energy storage (CAES) devices have recently become commercialized for electric utility applications. They incorporate modified state-of-the-art combustion turbines and site-specific underground reservoirs to store off-peak energy for later use during peak demand periods (see Fig. 2). The CAES power plants operate in different modes during different time periods. During an off-peak period, relatively inexpensive energy from coal-fired and/or nuclear base-load units powers the motor to compress air, which is then stored in an underground reservoir. During the subsequent peak period, the compressed air is withdrawn from storage and mixed with fuel. The combustion gases created by burning this mixture are expanded through turbines connected to the generator motor to produce electric power. Because the turbine is not required to drive a compressor during the peak time period (which it must do in a conventional combustion turbine system) a CAES plant reduces the use of petroleum- or gas-based fuels by more than 60%.

The underground caverns used to store the compressed air can be excavated in three types of geologic formations: salt domes, hard rock, and aquifers. Approximately three-fourths of the continental United States has suitable geology for compressed air caverns.

A 290 MW compressed air plant using underground salt-dome caverns is the first such plant in the world and is currently operating in Huntorf, Federal Republic of Germany, providing peak-leveling duty for the German utility Nordwestdeutsche Kraftwerke Ag. (Fig. 3). This power plant was commissioned in 1978 and has a storage capacity lasting 4 hours. The first USA application of this storage technology is currently under consideration by a number of USA utilities.

TABLE 1. EXAMPLES OF SENSIBLE HEAT AND LATENT HEAT MATERIALS.

Material	Sensible Heat,* Specific Heat Capacity (J/kg°C)	Latent Heat	
		Heat of Fusion (J/kg)	Heat of Vaporization (J/kg)
Water, H_2O	4.18	3.34×10^5	2.26×10^6
Mercury	1.39×10^2	1.18×10^4	2.95×10^5
Lead	1.28×10^2	2.29×10^4	–
Glauber's salt	1.93×10^3	2.51×10^5	–

*At 1 atm., 20°C

Sensible Heat Energy Storage Sensible heat thermal energy systems have been used by man for thousands of years to keep dwellings at relatively constant temperature. Thick adobe walls on a dwelling store heat during the day and keep the inhabitants warm at night. This and other ways to store solar energy utilizing sensible heat systems have recently been rediscovered because of increased interest in reducing both fuel consumption and associated heating and cooling costs.

Other ways to store heat often used in the past include the use of large stones, ceramic bricks, and even cast iron blocks near an early evening fire, which transmit their heat as radiant energy to warm the user after the fire goes out. More recently, in steam-electric power plants, the principle of sensible heat has been used to store energy from steam made available during low electricity demand periods. The steam is used to raise the temperature and pressure of water contained in tanks. When steam is needed during high electricity demand periods, a valve is opened on the upper portion of the tank to allow the pressure to decrease and produce the needed steam, which then lowers the temperature of the water. Although the input and output of this process is steam, the storage of the input energy is accomplished by the sensible heat of the water. The specific heat capacity of water as well as some other substances is provided in Table 1.

Latent Heat Energy Storage Latent heat thermal energy storage systems have not been as widely used as sensible heat storage systems, although latent heat systems usually have a greater energy storage potential than sensible heat systems. This is due to the high energy storage density per unit volume which can theoretically be achieved with latent heat systems, as shown in Table 1. Latent heat systems also have the advantage of operating over a narrow temperature range, which limits the design specification requirements to be met by the storage device materials,energy input, energy output, and control system components.

However, other technical issues have proved to be severe enough to hamper the widespread use of latent heat storage systems. These include the low thermal conductivity of candidate materials and their volumetric decrease during solidification, both of which inhibit the rate of heat transport during the energy input and output time periods. Also, many candidate materials do not completely solidify at their freezing point; rather, portions of the materials

TABLE 2. ENERGY STORAGE DENSITIES.

Energy Storage Technology	Energy Per Unit Mass (J/kg)	Energy Per Unit Volume (J/m^3)	Comments
Pumped hydroelectric	3×10^3	3×10^6	300 m hydraulic head
Flywheel	2×10^5	2×10^8	Fiber-epoxy composite material
Compressed air	6×10^5	10^7	Plant similar to Huntorf
Sensible head			
magnesite brick	4×10^5	2×10^8	
oil	10^5	10^8	
water	4×10^5	4×10^8	In liquid phase at 1 atm, 100°C
Latent heat, salts	10^5	3×10^8	

stay in a supercooled liquid state below their theoretical freezing point. This is due to the slow nature of the propagation of solid crystals in a liquid at its freezing point.

One of the more promising materials which exhibits the above problems to a lesser extent than other materials is sodium sulfate decahydrate (Glauber salt, $Na_2SO_4 \cdot 10H_2O$). It has been successfully tested in two solar homes and has been used in heat pumps and air conditioning systems.

Summary A comparison of some of the thermal-mechanical energy storage systems available today is presented in Table 2. Each of the storage systems described above has inherent characteristics that determine its size, weight, and associated cost. Taking these factors together with user needs and the commercial maturity of the technology, each storage system has its preferred application. Some operate in a mode where the form of the input and output energy is the same as that which is stored (e.g., ceramic brick thermal storage systems) whereas others operate in a mode where the input and output energy is different from that which is stored (e.g., pumped hydroelectric energy storage systems). Thus, the comparison shown in Table 1 only gives a portion of the many factors that need to be considered when choosing the "best" storage device for a particular energy leveling or smoothing application.

ENTROPY

The word "entropy" was coined from the Greek by Rudolf Clausius in 1865 to mean "transformation." He defined the differential change in entropy dS by:

$$dS = dQ/T \quad \text{(reversible)} \qquad (1)$$

where dQ is the element of heat added reversibly to a system at absolute temperature T. Since the values of dQ and T may be defined *operationally*, there is no need, in the classical view of thermodynamics, to explain entropy in molecular terms. As Lewis and Randall have written: "Thermodynamics exhibits no curiosity; certain things are poured into its hopper, certain others emerge according to the well known laws of the machine; no cognizance being taken of the mechanism of the process or the nature and character of the various molecular species concerned."

In 1948, Claude Shannon[3] demonstrated that the change in the function defined by

$$S_I = -k \sum_i p_i \log p_i \qquad (2)$$

uniquely measures the amount of information in any message (p_i = probability that the receiver assigns to the receipt of the ith possible). The sum is over all possible messages. Here is a simple example of the meaning of entropy. Suppose you are asked to guess which number from 1 to 100 has been secretly written on a piece of paper. Taking each p_i equal to 1/100, it is found that in the above equation, $S_I = k \log (100)$. Letting k equal 1 and taking the logarithm to the base 2 gives $S = 6.67$ "bits." This means if each question has only two possible answers (i.e., "yes" or "no"), it will take between 6 and 7 questions to find the number. The questioner begins by asking, "Is the number between 1 and 50?" Depending on the answer, he continues by reducing the possible numbers by a factor of 2 with each question. Since $2^6 = 64$ and $2^7 = 128$, the questioner will surely find the number in 7 questions and 1/3 of the time he will find it in 6 questions. Entropy may therefore be said to measure the state of ignorance of a person relative to a well-defined question, if the person only knows a probability distribution. It measures the expected number of questions he will have to ask in order to go from his state of partial knowledge to a state in which he knows everything about the well-defined question. According to the Shannon derivation,[3] S_I represents the amount of information in a message telling the actual number written on the paper (for someone for whom $p_i = 1/100$). The interpretation of entropy is used in information theory in the design of codes and in the analysis of information transmission systems.

These two entropies would seem to be different and to be connected only through having the same name. However, they have been shown to be identical when applied to the analysis of how to interpret the messages an observer obtains from instruments which only can measure the average properties of quantum systems.[1] Consider the question: "In what quantum state is this system?" Of course one can never say in which quantum state a system resides but rather can only give a probability for the system being in a particular state. The probability distribution for the states must be consistent with the observer's knowledge. The information theory principle of maximum entropy says to choose a set of probabilities which agrees with the available data and maximizes the entropy, for, in accordance with the meaning of entropy, this is the most noncommittal view. A state of equilibrium is, by the definition given by Gibbs,[4] a state of maximum entropy. From the information theory point of view, it is a state in which all of the random motions which can take place are, in fact, taking place so that the observer knows as little about the systems as it is possible to know beyond his knowledge of the "constants of the motion." If we describe a system by giving only the pressure, temperature and volume (or other gross properties), we omit many details. Entropy measures how much more there is to be said before the quantum state is specified.

As an illustration, consider a closed system of particles. From quantum mechanics, we know the system is in some state, i, with energy ϵ_i. If we make an observation of ϵ, the best we can do is infer that it represents the expectation energy, $\langle\epsilon\rangle$, for this is a repeatable quantity associated with the motion. To generate the appropriate probability distribution, we maximize S_I defined in Eq. (2), with the following constraints on the p_i:

$$\sum p_i = 1 \text{ (the system is in some state)} \qquad (3)$$

$$\sum p_i\epsilon_i = \langle\epsilon\rangle \text{ (the system has an expectation energy)} \qquad (4)$$

Maximization of the entropy subject to the two equations given leads to the probability distribution

$$p_i = e^{-\psi-\beta\epsilon_i} \qquad (5)$$

The resultant entropy, $S_{I,\max}$, is, by Gibbs[1] definition, the equilibrium entropy. The probability distribution is known as the Boltzmann distribution. It is easy to demonstrate that the parameter β is equal to $1/kT$ where k is the Boltzmann constant and T is the absolute temperature. If the observer is limited to macroscopic observations concerned with the energy of a body, the above derivation leads to laws which connect the observations to one another. That is, the quantities ψ, β, $\langle\epsilon\rangle$, S and various combinations are related to one another by equations from which p_i and ϵ_i have been eliminated. These relations are known as the "Laws of Classical Thermostatics".

For example, since, from Eq. (4)

$$d\langle\epsilon\rangle = \sum_i \epsilon_i dp_i + \sum_i p_i d\epsilon_i$$

it is clear that the changes in the energy of a body may be divided into two classes: (a) those of the type $\sum \epsilon_i dp_i$ which *necessarily* change the probabilities and therefore the entropy (non-isentropic) and (b) those in which $\sum_i \epsilon_i dp_i = 0$ (i.e., isentropic). This division into two classes of energy exchange gives rise to the concepts of "heat" and "work." For a detailed account of the derivation see reference 2.

The information theory definition of entropy thus is shown to contain, as a special case, the entropy of Clausius. The two ways of approaching entropy are seen to be consistent with one another. In the classical case concepts such as heat, work, equilibrium, temperature and state are taken as "operationally defined." From the information theory perspective, these concepts are *derived* as necessary constructs in any consistent theory of molecular phenomena. As demonstrated in (1), (2) and (5) the concept of heat has to be invented to describe energy exchanges which take place on a scale too fine to be observed directly whereas the work concept describes energy transfers which are associated with changes in macroscopic, observable coordinates.

Entropy, as a logical device for generating probability distributions, has been applied in reliability engineering, decision theory, and the theory of steady-state irreversible processes. (See list of references with reference 5.) The generalized approach to entropy usage was initiated by Jaynes.[6] Applications of the entropy principle in engineering are given in reference 7. A comprehensive review of the method of entropy maximization in many fields is given in reference 8.

EQUILIBRIUM

In the elementary sense of the macroscopic (visible to the naked eye) system, equilibrium is obtained if the system does not tend to undergo any further change of its own accord. Any further change must be produced by external means.

Mechanical and Electromagnetic Systems Equilibrium in mechanical and/or electromagnetic systems is reached when the vectorial summation of generalized forces applied to the system is equal to zero. In any potential field, that is, gravitational or electric potential or magnetic vector potential, force can be expressed as gradient of potential (magnetic force however, is a curl of a vector potential). The potential energy therefore has an extremum at the equilibrium configuration. For example, a system such as a mass suspended by a string against the gravitational force (or its weight) is at mechanical equilibrium if the tensile force in the string is equal to the weight of the mass it supports. The d'Alembert principle further states that the condition for equilibrium of a system is that the virtual work of the applied forces vanishes.

Thermodynamic Systems When a hot body and a cold body are brought into physical contact, they tend to achieve the same warmth after a long time. These two bodies are then said to be at thermal equilibrium with each other. The zeroth law of thermodynamics (R. H. Fowler) states that two bodies individually at equilibrium with a third are at equilibrium with each other. This led to the comparison of the states of thermal equilibrium of two bodies in terms of a third body called a thermometer. The temperature scale is a measure of state of thermal equilibrium, and two systems at thermal equilibrium must have the same temperature (see THERMODYNAMICS).

Generalization of equilibrium consideration by the second law of thermodynamics specifies that the state of thermodynamic equilibrium of a system is characterized by the attainment of the maximum of its ENTROPY. Thermodynamic coordinates are defined in terms of equilibrium states.

Equilibrium between two phases of a system is reached when there is no net transfer of mass or energy between the phases. Phase equilibrium is determined by the equality of the Gibbs functions (also called free enthalpy, free energy, or chemical potential) of the phases in addition to equality of their temperatures and stresses (such as pressure and/or field intensities—intensive properties). Equilibrium of first-order phase change requires continuity of slope or first derivative of the Gibbs function with respect to an intensive property and is generalized as the Clapeyron relation. Second- and higher-order phase changes are given by the condition of continuity of curvature or second derivative of the Gibbs function and so on.

Chemical or nuclear equilibrium of a reactive system is reached when there is no net transfer of mass and/or energy between the components of a system. At chemical or nuclear equilibrium, the Gibbs function of the reactants and the products must be equal according to stoichiometric proportions, in addition to uniformity in temperature and stresses. Chemical equilibrium is summarized in the form of the Law of Mass Action. The trend for the displacement from an equilibrium state is specified by Le Châtelier's principle.

Thermodynamic equilibrium is reached when the condition of mechanical, electromagnetic, thermal, phase, and chemical and nuclear equilibrium is reached.

Stability of Equilibrium A process or change of state carried out on a system such that it is always near a state of equilibrium is called a quasi-stationary equilibrium process. This requires that the process be carried out slowly. If a mechanical system is initially at the equilibrium position with zero initial velocity, then the system will continue at equilibrium indefinitely. An equilibrium position is said to be stable if a small disturbance of the system from equilibrium results only in small, bounded motion about the rest position. The equilibrium is unstable if an infinitesimal displacement produces unbounded motion. In the gravitational field, a marble at rest in the bottom of a bowl is in stable equilibrium, but an egg standing on its end is in unstable equilibrium. When motion can occur about an equilibrium position without disturbing the equilibrium, the system is in neutral (or labile, or indifferent) equilibrium, an example being a marble resting on a perfectly flat plane normal to the direction of gravity. It is readily seen that stable equilibrium is the case when the extremum of potential is a minimum.

When dealing with general thermodynamic systems, the fact that entropy tends to a maximum in the trend toward equilibrium of a natural process generalizes the above mechanical consideration with respect to stability. An equilibrium state can be characterized as a stable equilibrium when the entropy is a maximum; neutral equilibrium when displacement from one equilibrium state to another does not involve changing entropy; and unstable equilibrium when entropy is a minimum. Any slight disturbance from an unstable equilibrium state of a system will lead to transition to another state of equilibrium.

Statistical Equilibrium In the microscopic sense, that is, treating systems in terms of elemental particles such as molecules, atoms, and other material or quasi-particles (such as photons in radiation, phonons in solids and liquids, rotons in liquids), equilibrium states are recognized as the most probable states. An equilibrium state of a system is therefore defined in terms of most probable distributions of its elements among microscopic states which may be defined in terms of energy states. In this sense, statistical equilibrium is a condition for macroscopic equilibrium and an equilibrium state of a system is one of its extremal states. In the methods of STATISTICAL MECHANICS, the probability of distribution is expressed in terms of the density of distributions in the phase space. Based on the Liouville theorem, if a system is in statistical equilibrium, the number of the elements in a given state must be constant in time; which is to say that the density of distribution at a given location in phase space does not change with time. For an isolated system, the distribution is represented by a microcanonical ensemble. At equilibrium, no phase point can cross over a surface of constant energy, and the density of distribution is preserved. In this case individual molecules of a system can be represented by phase points. Any part of an isolated system in statistical equilibrium can be represented by a canonical ensemble. A subsystem of a large system in thermal equilibrium also behaves like the average system of a canonical ensemble. A system and a constant temperature bath together can be considered as an isolated system. A phase point in a canonical ensemble can represent a large number of molecules, thus accounting for strong interactions. A canonical ensemble is characterized by its temperature and is therefore pertinent to the concept of thermal equilibrium. When applied to equilibrium of systems involving mass exchange, such as a chemical system, we have a "particle bath" in addition to a constant temperature bath. The pertinent representation for equilibrium including mass exchange as well as energy exchange is known as a grand canonical ensemble, which accounts for the chemical potentials of its elements.

When applied to a system with a large number of elements, the distributions are measured by thermodynamic probability (W); the most probable distribution is such that W is a maximum. This optimal principle is consistent with the condition of maximum entropy (S) given in the above. The Boltzmann hypothesis states that $S = k \ln W$, where k is the Boltzmann constant.

Depending on the specifications of W, namely, those of Maxwell-Boltzmann (for low concentration of distinguishable particles, weak interaction and high temperature, such as a dilute perfect gas), Fermi-Dirac (for elemental particles with antisymmetric wave functions at high concentrations of indistinguishable particles and low temperatures, such as electrons in metal), or Einstein-Bose (for elemental particles with symmetric wave functions, such as He^4 at high concentration of indistinguishable particles and low temperature), equilibrium distributions take different forms (see BOSE-EINSTEIN STATISTICS and FERMI-DIRAC STATISTICS). The Maxwellian speed distribution in a dilute perfect gas is a distribution based on Maxwell-Boltzman statistics.

As a consequence of molecular considerations, when two systems are connected for transfer of mass without significant transfer of energy, such as two containers at different temperatures connected by a capillary tube, we have the relation of thermal transpiration.

Trend toward Equilibrium The mechanism by which equilibrium is attained can only be visualized in terms of microscopic theories. In the kinetic sense, equilibrium is reached in a gas when collisions among molecules redistribute the velocities (or kinetic energies) of each molecule until a Maxwellian distribution is reached for the whole bulk. In the case of the trend toward equilibrium for two solid bodies brought into physical contact, we visualize the transfer of energy by means of free electrons and phonons (lattice vibrations).

The Boltzmann H-theorem generalizes the condition that with a state of a system represented by its distribution function f, a quantity H, defined as the statistical average of $\ln f$, approaches a minimum when equilibrium is reached. This conforms with the Boltzmann hypothesis of distribution in the above in that $S = -kH$ accounts for equilibrium as a consequence of collisions which change the distribution toward that of equilibrium conditions. In terms of quantum states and their probabilities, it is also readily shown that any value of S below the equilibrium value will increase in time. Recursion of an original state for a fraction of one gmol of molecules may take a time period much longer than the estimated life of the universe of 10^{10} years.

Consideration of perturbation from an equilibrium state leads to methods for dealing with rate processes and methods of irreversible thermodynamics in general.

Fluctuation from Equilibrium A necessary consequence of the random nature of elemental particles in a body is that the property of such a body is not at every instant equal to its average value but fluctuates about this average. A precise meaning of equilibrium can only be attained from consideration of the nature of such fluctuations. In the above, we have repeatedly considered a "large" number of particles. It is important to know how large a number is "large." When considering fluctuation of energy from an average value in an isolated system, the ratio of the two is given to be proportional to $1/\sqrt{N}$, where N is the total number of elements in the system. This is also the magnitude of the fluctuation of number of particles in a system involving transformation of phases and chemical and nuclear species. An equilibrium state is one at which the longtime mean magnitude of fluctuation from the average state is independent of time and this magnitude has reached a minimum value.

Large perturbation from a given state of fluctuation leads to a relaxation process toward a state of equilibrium. The relaxation time, for instance, measures the deviation from quasi-stationary equilibrium of a process which is carried out at a finite rate.

EXCITONS

Intrinsic Excitons The exciton is a quantum of electronic excitation produced in a periodic structure such as an insulating or semiconducting solid. This quantum of energy has motion and the motion is characterized by a wave vector. Frenkel[1] was the first to treat the theory of optical absorption in a solid as a quantum process consisting of atomic excitations. The excitation process implies that the excited electron does not leave the cell from which it was excited. In his attempt to gain insight into the transformation of light into heat in solids he was able to explain the transformation by first-order perturbation theory of a system of N atoms having one valence electron per atom with the following properties:

1. The coupling between different atoms in a crystal is small compared with the forces holding the electron within the separate atoms.
2. The Born-Oppenheimer approximation is valid.
3. The total wave function is a product of one-electron functions.

The Frenkel exciton is a tight-binding description of an electron and hole bound at a single site such that their separate identities are not lost. This model is applicable to insulating crystals. In the case of semiconductors, nonequilibrium electrons and holes are bound in excitons at low temperatures by Coulomb attraction. Semiconducting crystals are characterized by large dielectric constants and small effective masses, therefore the electrons and holes may be treated in a good approximation as completely independent particles, despite the Coulomb interaction. This results from the fact that the dielectric constant reduces the Coulomb interaction between the hole and electron to the extent that it produces a weakly bound pair of particles which still retain much of their free character. The exciton forms because it represents a state of slightly lower energy than the unbound hole-electron. The effective mass theory used to describe such weakly bound particles was developed by Wannier.[2] These weakly bound excitons are most appropriately described when the band structure of the solid is considered. The intrinsic fundamental-gap exciton in semiconductors is a hydrogenically bound hole-electron pair, the hole being derived from the upper valence band and the electron from the lowest conduction band. It is a normal mode of the crystal created by an optical excitation wave, and its wave functions are analogous to those of the Block wave states of free electrons and holes. When most semiconductors are optically excited at low temperatures, it is the intrinsic excitons that are excited. The energies of the ground and excited states of the exciton lie below the band-gap energy of the semiconductor. Hence, the exciton structure must first be determined in order to determine the band-gap energy. The exciton binding energy can be determined from spectral analysis of its hydrogenic ground and excited state transitions (this also gives central-cell corrections). Precise band-gap energies can be determined by adding the exciton energy to the experimentally measured photon energy of the ground state transition.

Both direct and indirect exciton formation occurs in semiconductors, depending on the band structure. The former is characterstic of many of the II-VI and III-V compounds, and the latter is characteristic of germanium and silicon. For indirect optical transitions, momentum is conserved by the emission or absorption of phonons. The detailed nature of the band structure of semiconductors with degenerate or simple valence bands is elucidated by understanding the intrinsic-exciton structure of these semiconductors.

High Density Electron-Hole Pairs Exciton complexes analogous to H_2, H_2^+ and H^- were first described by Lampert.[3] The exciton in real crystals may be considered as a boson since it consists of an electron and a hole, each being a fermion, bound together by Coulomb interaction. Two single excitons exhibit an attractive covalent interaction which results in the formation of an excitonic molecule if the electron and hole spins are antiparallel. The binding energy of such a molecule has been calculated by Akimoto, et al.[4] They showed that exciton molecules should be stable for any electron-to-hole mass ratio. Therefore, at high excitation intensities and if the mean time for the formation of exciton molecules is less than the radiative lifetime of single excitons, then the exciton molecule system is produced.

At high excitation intensities two states of the excited system have been proposed: (1) the excitonic-molecule gas, (2) the electron-hole droplet. Calculations of the ground state energies of the excitonic-molecule system and the electron-hole droplet system have been successful in determining which system is active in the particular material being studied. It was recognized that the band structure of the material would have a major impact on the ground state of the system.

With high exciting intensities the density of hole-electron pairs is increased and excitons are formed at a higher rate. At high concentrations the interaction among excitons becomes important, and when a certain threshold density of excitons is reached liquid droplets are formed. These collective droplets consist of nonequilibrium electrons and holes and, when electron-hole recombination occurs specific radiation is emitted. A luminescence line appears at a slightly lower energy than that of the free exciton in both Si and Ge which has been identified as light from an electron-hole liquid.

Motion of Excitons The motion of excitons has been dramatically demonstrated by Gourley et al.[5] in stressed Si. The crystal was stressed along the ⟨100⟩ direction by a rounded ($R \approx 5$ cm) steel plunger. The indirect band edge is lowered in energy by strain, as a result the droplets, free excitons, and excitonic molecules are accelerated in a strain gradient toward the point of maximum shear stress. The image of the photoluminescence at 15 K, produced by laser excitation at the side of the crystal was displayed by vidicon detection and is shown in Fig. 1. The parabolic strain well provides both spatial confinement and reduced electron-hole liquid binding energy. This experimental arrangement allowed them to achieve large concentrations of free excitons with low-level steady state excitation. The high density of free excitons allowed the production of excitonic molecules in appreciable numbers. In examining the spatial extent of the excitonic gas in a parabolic potential well, they treated the exciton gas as an ideal gas. The equipartition theorem $\langle V \rangle = \alpha \langle r^2 \rangle = \frac{3}{2} KT$ predicts that the radial extent of the gas is $\approx T^{1/2}$. They examined the spatial profile by slowly scanning a sharply focused image of the crystal across a narrow slit masking the Ge photodetector. In the temperature range 5–22 K, the $T^{1/2}$ radial profile was reasonably well obeyed.

Spatial Resonance Dispersion For those states in a crystal where the photon wave vector and the exciton wave vector are essentially equal, the energy denominator for exciton photon mixing is small and the mixing becomes large. These states are not to be considered as pure photon states or pure exciton states but rather mixed states. Such a mixed state has been called a *polariton*. When there is a dispersion of the dielectric constant, spatial dispersion has been invoked to explain certain optical effects of crystals. It was originally thought that it would introduce only small corrections to such things as the index of refraction until Pekar[6] demonstrated that, if there was more than one energy transport mechanism, as in the case of excitons, this was not true. Spatial dispersion addresses the possibility that two different kinds of waves of the same energy and same polarization can exist in a crystal differing only in wave vector. The one with an anomalously large wave vector is an anomalous wave. In the treatment of dispersion by exciton theory, Pekar showed that if the normal modes of the system were allowed to depend on the wave vector, a much higher order equation for the index of refraction would result. The new solutions occur whenever there is any curvature of the ordinary exciton band in the region of large exciton-photon coupling. These results apply to the Lorentz model as well as to quantum-mechanical models whenever there is a dependence of frequency on wave number.

Bound Excitons The intrinsic exciton may bind to various impurities, defects, and complexes and the subsequent decay from the bound state yields information concerning the center to which it was bound. Bound exciton complexes are extrinsic properties of materials. These complexes are observed as sharp-line optical transitions in both photoluminescence and absorption. The binding energy of the exciton to the impurity or defect is generally weak compared to the free exciton binding energy. The resulting complex is molecular-like (analogous to the hydrogen molecule or molecule-ion) and has spectral properties which are analogous to those of simple diatomic molecules. The emission or absorption energies of these bound exciton transitions are always below those of the corresponding free exciton transitions, due to the molecular binding energy.

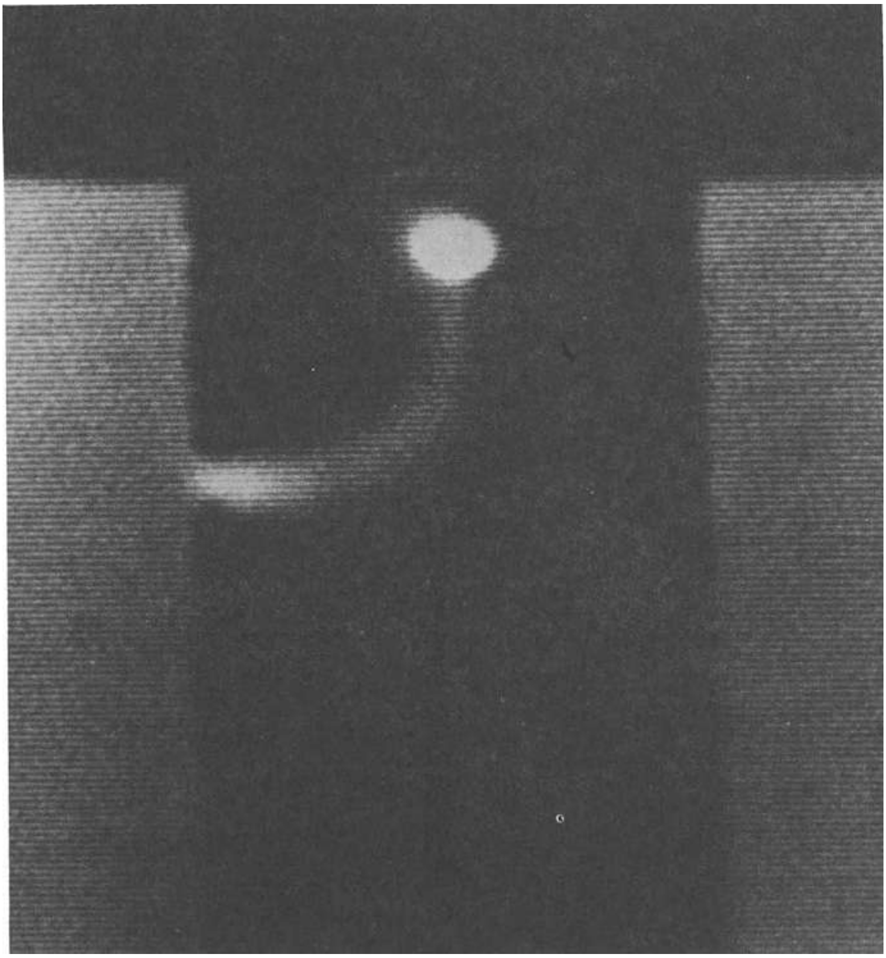

FIG. 1. Exciton luminescence emanating from a 1.5 × 1.5 × 4 mm crystal of ultrapure Si at $T \approx 10$ K. The top crystal surface, accurately flattened and polished, is pressed with a spherical contacting surface of a steel plunger cut from a ball bearing with radius $R = 3.8$ cm. Excitons produced at the left crystal surface by a CW Ar laser are drawn into a parabolic potential well corresponding to a shear strain maximum beneath the plunger (Gourley et al., Ref. 5).

Bound excitons were first reported by Haynes[7] in the indirect semiconductor silicon. He found that when group V elements were added to silicon sharp photoluminescent lines were produced and these lines were displaced in energy in a regular way. The binding energies of exciton complexes produced by adding different group V donors were described by the linear relation:

$$E = 0.1 E_i$$

where E is the binding energy of the exciton and E_i is the ionization energy of the donor. The small differences in ionization energies for different effective mass chemical donors result from central cell corrections. A similar relationship was found when the group III acceptors were added to silicon. A modified linear relationship has been found for donors and acceptors in compound semiconductors.

The sharp spectral lines of bound exciton complexes can be very intense (large oscillator strength). The line intensities will, in general, depend on the concentrations of impurities and/or defects present in the sample.

The theory of "impurity" or defect absorption intensities in semiconductors has been studied by Rashba.[8] He found that, if the absorption transition occurs at $k = 0$ and if the discrete level associated with the impurity approaches the conduction band, the intensity of the absorption line increases. The explanation offered for this intensity behavior is that the optical excitation is not localized in the impurity but encompasses a number of neighboring lattice points of the host crystal. Hence, in the absorption process, light is absorbed by the entire region of the crystal consisting of the impurity and its surroundings.

In an attack on the particular problem of excitons which are weakly bound to localized "impurities," Rashba and Gurgenishvili[9] derived the following relation between the oscillator strength of the bound exciton F_d and the oscillator strength of the intrinsic excitons f_{ex}, using the effective-mass approximation

$$F_d = (E_0/|E|)^{3/2} f_{ex},$$

where $E_0 = (2\hbar^2/m)(\pi/\Omega_0)^{2/3}$. E is the binding energy of the exciton to the impurity, m is the effective mass of the intrinsic exciton and Ω_0 is the volume of the unit cell.

It has been shown in some materials that F_d exceeds f_{ex} by more than four orders of magnitude. An inspection of the above relation reveals that, as the intrinsic exciton becomes more tightly bound to the associated center, the oscillator strength, and hence the intensity of the exciton complex line, should decrease as $(1/|E|)^{3/2}$.

In magnetic fields bound excitons have unique Zeeman spectral characteristics, from which it is possible to identify the types of centers to which the free excitons are bound. Bound exciton spectroscopy is a very powerful analytical tool for the study and identification of impurities and defects in semiconductor materials. It has been employed rather extensively over the last few years for the characterization of materials.

Multibound Excitons Sharp photoluminescent lines have been observed at energies less than the energy of the line associated with an exciton bound to a neutral donor in silicon, germanium and silicon carbide. Similar lines have also been observed which are associated with acceptors in silicon and gallium arsenide. The energies and widths of these lines were such that they could not be explained in terms of any recombination mechanism involving just a single exciton bound to a neutral shallow impurity center. A model involving a multiexciton complex bound to a donor (acceptor) was invoked in which each line was associated with radiative recombinations of an exciton in the bound multiexciton complex. The behavior of these lines in the presence of magnetic and stress fields helped to establish the viability of the bound multiexciton complex model.

Interaction of Excitons with Other Systems The interaction of excitons with phonons to form Stokes and anti-Stokes transitions are commonly observed in crystals. Interaction with the L_0 phonon is strong in most crystals. The exciton-bound-phonon quasiparticle is one form of interaction that has been observed in several materials. In the case of the quasiparticle the energy separating the parent transition and its L_0-phonon sideband is less than the L_0-phonon energy $h\omega_0$ by as much as 30% in some materials. The quasiparticle consists of the exciton-phonon bound state, having impurity modes associated with dielectric effects of the center rather than local modes associated with the mass defects of the substituents.

Resonant Raman scattering occurs with excitons as intermediate states, spin-flip scattering from bound excitons is observed and the production of excitons by two photon processes provides added information about a specific material. Exciton mechanisms are active in lasing transitions in many materials.

The study of free and bound excitons has contributed appreciably to the understanding of the basic intrinsic and extrinsic properties of many materials.

EXPANSION, THERMAL

Definition and General Remarks All substances change their shapes as a consequence of undergoing changes in temperature. A measure of this change is the thermal coefficient of expansion. In most cases the result is an increase in the length, area, or volume of a sample. The effect is by no means negligible but for moderate changes in the temperature a first-order correction suffices. The prevention of thermal expansion requires very large mechanical stresses. For example, a compressive stress of order 5 X 10^8 dynes/cm^2 is necessary to prevent a steel bar from expanding when the temperature is increased by 20°C. For solids in the form of a thin rod or cable, this change is confined (to first order) to a change in length, and a linear coefficient of expansion is thus defined by

$$\alpha_0 = \frac{1}{L_0}\left(\frac{\partial L}{\partial t}\right)_P \qquad (1)$$

where L_0 is the length of the specimen at 0°C and the subscript P implies that the pressure is kept constant. Correspondingly, for fluids and for solids of arbitrary shape, one defines a cubical or volume coefficient of expansion, β_0, by the relation

$$\beta_0 = \frac{1}{V_0}\left(\frac{\partial V}{\partial t}\right)_P \qquad (2)$$

with V_0 being the volume at the reference temperature (usually chosen to be 0°C). It may readily be shown that $\beta_0 = 3\alpha_0$. Thus for solids one usually tabulates values of α_0 while, of course, only β has meaning for fluids. Whereas β_0 is simply 1/273 for all ideal gases (this follows from the equation $PV = nRT$), there exists a wide variation for β values among liquids. Table 1 gives α and β values for several substances. The negative value of β for water below 4°C is anomalous and is caused by the comparatively open lattice structure of ice. In the case of nonisotropic crystals, the coefficient of linear expansion differs for different directions in the crystals and may even have opposite signs along different directions as is the case for $CaCO_3$.

Thermodynamic Relationships The cubical coefficient of expansion plays an important role in relating the molar specific heat at constant pressure, C_P, (which is usually measured directly in the laboratory) to the molar specific heat at constant volume (which is most often obtained from theory). This relationship, based solely on the laws of thermodynamics is[1]

TABLE 1. LINEAR COEFFICIENTS OF EXPANSION, α, FOR SOME SOLIDS AND CUBICAL COEFFICIENTS OF EXPANSION, β, FOR SOME LIQUIDS AT ROOM TEMPERATURE

	α (/C°)	β (/C°)
Aluminum	25.0×10^{-6}	
Copper	16.8×10^{-6}	
Nickel	12.8×10^{-6}	
Sodium	77.0×10^{-6}	
Mercury		18.2×10^{-5}
Glycerin		48.5×10^{-5}
Water (0–4°C)		-3.2×10^{-5}

$$C_P - C_V = (\beta^2 VT)/X \qquad (3)$$

where T is the absolute temperature and X the compressibility defined by

$$X = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T \qquad (4)$$

To obtain this resuilt we write the first law of thermodynamics (see THERMODYNAMICS):

$$\delta Q = dU + P\,dV \qquad (5)$$

Since

$$C_V = \left(\frac{\delta Q}{\delta T}\right)_V = \left(\frac{\partial U}{\partial T}\right)_V \qquad (6)$$

$$dU = \left(\frac{\partial U}{\partial V}\right)_T dV + \left(\frac{\partial U}{\partial T}\right)_V dT \qquad (7)$$

and

$$dV = \left(\frac{\partial V}{\partial P}\right)_T dP + \left(\frac{\partial V}{\partial T}\right)_P dT \qquad (8)$$

we obtain

$$\delta Q = \left[\left(\frac{\partial U}{\partial V}\right)_T + P\right]\left(\frac{\partial V}{\partial P}\right)_T dP + \left\{C_V + \left[\left(\frac{\partial U}{\partial V}\right)_T + P\right]\left(\frac{\partial V}{\partial T}\right)_P\right\} dT \qquad (9)$$

Thus

$$C_P = \left(\frac{\delta Q}{\delta T}\right)_P = C_V + \left[\left(\frac{\partial V}{\partial T}\right)_P\right]\left[P + \left(\frac{\partial U}{\partial V}\right)_T\right] \qquad (10)$$

By the second law of thermodynamics, we have

$$dS = \frac{dU}{T} + \frac{P}{T}dV \qquad (11)$$

On using Eq. (7) again this becomes

$$dS = \frac{1}{T}\left[\left(\frac{\partial U}{\partial V}\right)_T + P\right]dV + \frac{1}{T}\left(\frac{\partial U}{\partial T}\right)_V dT \qquad (12)$$

Since

$$dS = \left(\frac{\partial S}{\partial V}\right)_T dV + \left(\frac{\partial S}{\partial T}\right)_V dT \qquad (13)$$

one obtains on comparing Eqs. (12) and (13)

$$\left(\frac{\partial S}{\partial V}\right)_T = \frac{1}{T}\left[P + \left(\frac{\partial U}{\partial V}\right)_T\right] \qquad (14)$$

$$\left(\frac{\partial S}{\partial T}\right)_V = \frac{1}{T}\left(\frac{\partial U}{\partial T}\right)_V \qquad (15)$$

Since

$$\frac{\partial}{\partial T}\left(\frac{\partial S}{\partial V}\right)_T = \frac{\partial}{\partial V}\left(\frac{\partial S}{\partial T}\right)_V \qquad (16)$$

we get from Eqs. (14) and (15)

$$\frac{1}{T}\frac{\partial^2 U}{\partial V \partial T} = -\frac{1}{T^2}\left[P + \left(\frac{\partial U}{\partial V}\right)_T\right] + \frac{1}{T}\left[\left(\frac{\partial P}{\partial T}\right)_V + \frac{\partial^2 U}{\partial T \partial V}\right] \qquad (17)$$

or

$$\left(\frac{\partial U}{\partial V}\right)_T = T\left(\frac{\partial P}{\partial T}\right)_V - P \qquad (18)$$

Inserting Eq. (18) into Eq. (10), yields

$$C_P - C_V = T\left(\frac{\partial V}{\partial T}\right)_P \left(\frac{\partial P}{\partial T}\right)_V \qquad (19)$$

Now

$$\left(\frac{\partial P}{\partial T}\right)_V \left(\frac{\partial T}{\partial V}\right)_P \left(\frac{\partial V}{\partial P}\right)_T = -1 \qquad (20)$$

Thus on replacing $(\partial P/\partial T)_V$, the final form of Eq. (19) becomes

$$C_P - C_V = -\frac{T\left(\frac{\partial V}{\partial T}\right)_P^2 V^2}{\left(\frac{\partial V}{\partial P}\right)_T V^2} \qquad (21)$$

or Eq. (3) when the definition of compressibility [Eq. (4)] is employed.

Thus for a substance where β and X are experimentally known C_V may be established from a measurement of C_P.

Grüneisen Relation[2] Grüneisen introduced the parameter $\gamma = \beta V/XC_V$ and on the basis of simple models reached the conclusion that γ is independent of temperature. This implies that the thermal expansion coefficient is proportional to the specific heat and has the same type of temperature dependence. This is true for many substances and has, in fact, been employed as a means for predicting values for C_V at low temperatures. To illustrate the physical basis of the Grüneisen relation, we will work with a crystal model of N oscillators of identical frequency, ν, and each having equilibrium energy, ϵ. In the region of $h\nu \ll kT$, the free energy is given by:

$$F = N\left(\epsilon + 3kT \log \frac{h\nu}{kT}\right) \qquad (22)$$

Since this must be a minimum at equilibrium, we obtain:

$$N\frac{d\epsilon}{dV} = -3NkT\frac{d(\log \nu)}{dV} \qquad (23)$$

To obtain the thermal expansion coefficient, one expands $d\epsilon/dV$:

$$\frac{d\epsilon}{dV} = \left(\frac{d\epsilon}{dV}\right)_{V=V_0} + (V - V_0)\left(\frac{d^2\epsilon}{dV^2}\right)_{V=V_0} \qquad (24)$$

But the compressibility is given by

$$\frac{1}{X_0} = NV_0\left(\frac{d^2\epsilon}{dV^2}\right)_{V=V_0} \qquad (25)$$

and thus

$$\frac{V - V_0}{V_0} = -3NkTX_0\frac{d(\log \nu)}{dV} \qquad (26)$$

Differentiating with respect to T and realizing that $3NkT$ is the thermal energy, we obtain:

$$\frac{\alpha V_0}{C_V X_0} = -\frac{d(\log \nu)}{d(\log V)} \qquad (27)$$

More exact crystal models yield values for

$$\gamma_i = -\frac{d(\log \nu_i)}{d(\log V)}$$

where ν_i is the ith frequency of a set of normal modes of vibration.[3] These and other refinements give rise to modifications of the simple Grüneisen theory.

Source of Thermal Expansion The dynamical basis for thermal expansion is the presence of an anharmonic component for the interaction potential. A qualitative argument for this is based on the property of typical potential energy of atoms in a lattice.[4] Figure 1 represents such a curve and it will be observed that the curve is not symmetrical about r_0, the equilibrium distance between atoms. As the internal energy E increases with an increase in temperature, the average value of r shifts to larger values. Clearly if the potential curve were perfectly parabolic about r_0, we would not have thermal expansion. This argument can be made qualitative as follows.[5] Taking x as the displacement of a lattice atom from its equilibrium neighbor separation, the potential energy has the form

$$V(x) = cx^2 - gx^3 \qquad (28)$$

Then $\bar{x}$, the average displacement using the Boltzmann distribution function becomes

$$\bar{x} = \frac{\int_{-\infty}^{\infty} xe^{-V(x)/kT}\,dx}{\int_{-\infty}^{\infty} e^{-V(x)/kT}\,dx} \qquad (29)$$

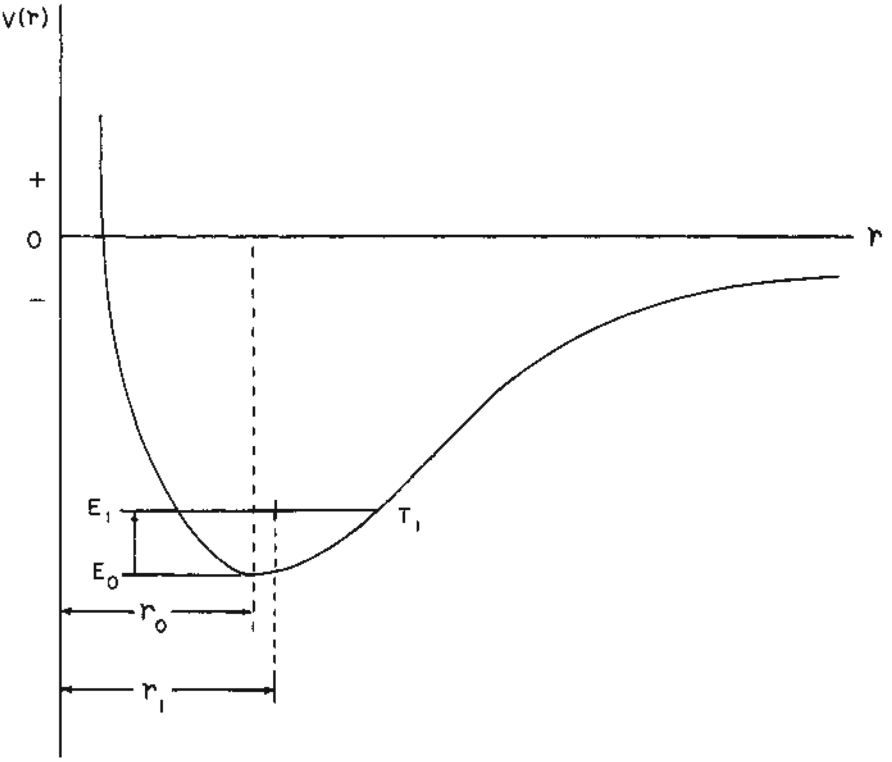

FIG. 1. Potential energy curve for atoms in crystalline solid as a function of interatomic separation.

Assuming that the anharmonic term is much less than the harmonic contribution, we expand $V(x)$ to yield

$$\int xe^{-V/kT}\,dx = \int e^{-cx^2/kT}\left[x + \frac{gx^4}{kT}\right]dx \tag{30}$$

and

$$\int e^{-V/kT} = \int e^{-cx^2/kT}\,dx \tag{31}$$

Both integrals are readily evaluated to give

$$\bar{\bar{x}} = \frac{3kTg}{4c^2} \tag{32}$$

or a constant temperature coefficient for thermal expansion. This simple derivation may be amplified to include specific interaction forces for the atoms of a lattice.[6]

Thermal Expansion and Curie Temperature The Curie-Weiss law for both ferroelectrics and ferromagnets may be shown to be connected with the thermal expansion coefficient.[7] Consider a region where the dielectric constant, ε, is large. If we let N be the cell density and A a constant, the Clausius-Mosotti formula is

$$\frac{\varepsilon - 1}{\varepsilon + 2} = AN \tag{33}$$

Differentiating with respect to T, the temperature, and making use of the assumption that $\varepsilon \gg 1$, one finds that

$$\frac{3d\varepsilon}{\varepsilon^2 dT} = \frac{1}{N}\frac{dN}{dT} = -\beta \tag{34}$$

On integrating between T and θ, the Curie temperature, one obtains

$$\varepsilon = \frac{3/\beta}{T - \theta} \tag{35}$$

which is a typical Weiss law and indicates the Curie constant is of the order of the reciprocal of the thermal expansion. The special electronic structure of ferromagnetic materials also gives rise to anomalous thermal expansion coefficients in the transition region. For some materials β values are depressed and for others β values increase more rapidly with temperature. Both magnetostriction and the variation of the energy of magnetization with the atomic size account for the anomalous behavior of different substances.

F

FALLOUT

The term fallout generally has been used to refer to particulate matter that is thrown into the atmosphere by a nuclear process of short time duration. Primary examples are nuclear weapon debris and effluents from a nuclear reactor excursion. The name fallout is applied both to matter that is aloft and to matter that has been deposited on the surface of the earth. Depending on the conditions of formation, this material ranges in texture from an aerosol to granules of considerable size.

The topographic distribution of fallout is divided into three categories called local (or close-in), tropospheric (or intermediate), and stratospheric (or world wide) fallout. No distinct boundaries exist between these categories. The distinction between local and tropospheric fallout is a function of distance from source to point of deposit, while the primary distinction between tropospheric and stratospheric fallout is the place of injection of the debris into the atmosphere, above or below the tropopause. Whether radioactive debris from a nuclear weapon becomes tropospheric or stratospheric fallout depends on yield, height, and latitude of burst (the height of the tropopause is a function of latitude).

Because air acts as a viscous medium, a drag force is developed to oppose the gravitational force that acts on airborne particulate matter. This makes the velocity of fall dependent on particle size. The larger particles (diameters greater than about 20μm) have a higher rate of settling and create local fallout. Smaller particles injected below the tropopause are carried by prevailing winds over large regions of the surface of the earth and create the tropospheric fallout. Tropospheric fallout particles larger than about 0.1-μm diameter continually mix through the circulating air mass that is in contact with the surface of the earth and gradually settle to the ground, or are washed down by rain or snow. Many smaller particles form nuclei for raindrops. Parts of the tropospheric fallout many remain in the atmosphere for a month or more, long enough to circle the earth several times. The mean residence time above the tropopause of stratospheric fallout is from 5 to 30 months, during which time it completely encircles the earth. It gradually returns through the tropopause, primarily in certain regions where mixing between the two layers is more probable.

The exact characteristics of the radiation associated with fallout depend on the nature of the nuclear processes from which its radioactivity originates. Generally these radioactive nuclides are fission products formed from the fissioning of uranium or plutonium, but, under appropriate circumstances, considerable quantities of radioactivity can be formed through nuclear reactions induced by neutrons that are produced by the weapon or reactor. The radiation problems associated with local fallout are usually those of high-intensity gamma-ray radiation fields resulting from the relatively large quantities of radioactive material that fall back to earth within a few tens of miles from the point of origin. The important radioactive materials consist in this case of short-lived fission products and neutron-induced radioactive nuclides. The hazards of worldwide fallout come more from the problems of the long-lived radionuclides, such as ^{134}Cs, ^{137}Cs, and ^{90}Sr, that can enter the human food chain and ultimately be absorbed by the body.

For a nuclear weapon burst in air, all materials in the fireball are vaporized. Condensation of fission products and other bomb materials is then governed by the saturation vapor pressures of the most abundant constituents. Primary debris can combine with naturally ocurring aerosols, and almost all of the fallout becomes tropospheric or stratospheric. If the weapon detonation takes place within a few hundred feet of (either above or below) a land or water surface, large quantities of surface materials are drawn up or thrown into the air above the place of detonation. Condensation of radioactive nuclides in this material then leads to considerable quantities of local fallout, but some of the radioactivity still goes into tropospheric and stratospheric fallout. If the burst occurs sufficiently far underground, the surface is not broken and no fallout results.

The considerable significance of radioactive fallout became apparent on July 24, 1946, when a nuclear explosive of about the same size as the Hiroshima and Nagasaki weapons was detonated 30 meters below the surface of the lagoon at Bikini atoll. This explosion produced a column one-half mile in diameter consisting of about

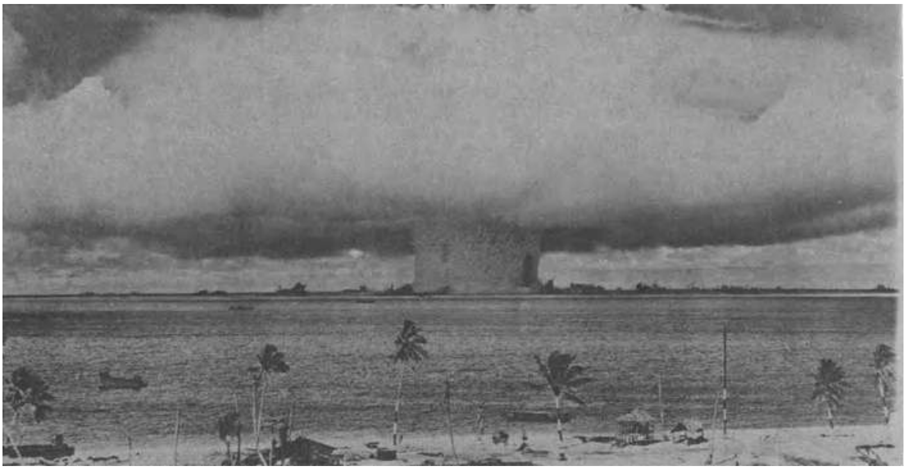

FIG. 1. Nuclear explosion at Bikini Atoll, July 24, 1946.

a million tons of water, as well as a base surge, as illustrated in Fig. 1. Instead of the radioactive debris being lifted by the explosion into the troposphere and stratosphere, as had been the situation for prior nuclear detonations, almost all the radioactivity produced by this underwater explosion was trapped in the water, spread out in a radioactive cloud, and fell as rain. The radioactive material was strongly absorbed by the painted surfaces of a group of ships which had been assembled as a target fleet. It also settled into joints, ventilating systems, almost everywhere. It clung so tenaciously that the paint sometimes had to be removed to reduce significantly the amount of radioactivity. The results were completely unexpected, since most planners had predicted a stronger shock wave to hit the ships than had been experienced from the earlier air detonation, but they greatly underestimated the amount of radioactive contamination that would occur. As a result of this test a large research effort was begun to try to understand the nature of fallout from nuclear detonations and the procedures needed to be followed to decontaminate the regions on which the distributed radioactive material was deposited.

Some type of radioactive fallout has been associated with every near-surface detonation of a nuclear explosive. On one occasion the radiation from fallout debris endangered human health. This was the detonation on March 1, 1954 at Bikini atoll, of a thermonuclear device with a yield equal to that of about 17 megatons (MT) of trinitrotoluene (TNT). The yield was greater than expected and an unexpected shift in wind direction caused significant quantities of radioactive fallout to be deposited over a region extending several hundred miles to the east, over the inhabited atolls of Ailingnae, Rongelap, Rongerik and Utirik and on the Japanese fishing vessel *Lucky Dragon*. The people of these atolls have continued since that time to receive medical examinations on a regular basis. From the information obtained a reasonably thorough knowledge has accrued on the effects of fallout radiation on the health of one small group of individuals.

The aerodynamic principles governing deposition of fallout are the same regardless of the origin of the material which is thrown into the air. Therefore the deposition of any airborne matter should follow the same pattern as equivalent material produced by nuclear explosives. Two reasonably contemporary but very different nonradioactive phenomena which can be used for such comparisons have been the deposition of ash from the eruptions of Mount St. Helens and the deposition of acid rain in the northeastern United States and eastern Canada.

The eruption on May 18, 1980 of Mount St. Helens produced huge quantities of observable airborne particulate matter. This eruption has been determined to have released an energy equivalent to the detonation of about 35 MT of TNT, comparable to the largest nuclear explosions ever detonated. The basic difference between these two types of explosions is that the Mount St. Helens eruption was strictly mechanical, carrying with it several cubic kilometers of debris, considerably more than would be thrown into the air by even a very large nuclear explosion. However, the size distribution of the individual ash particles thrown into the air by the eruption was similar to particle-size distributions of airborne material from surface detonations of high-yield nuclear explosives. Also, the pattern of deposition of the ash was very similar to the expected deposition patterns for fallout from the surface detonation of an 8-MT nuclear weapon in the vicinity of Portland, Oregon, as predicted in 1959 during hearings held by the Joint Committee on Atomic Energy of the Congress of the United States.

The exact pattern of deposition of fallout depends on weather conditions. The eruption of May 18 happened to occur during a period when weather conditions were similar to the conditions assumed for the 1959 study. On the other hand, the eruption of May 25 occurred during a rainy period. Not as many ash particles were thrown aloft during the May 25 eruption as during the May 18 eruption but the number was still more than usually expected from a surface detonation of a nuclear weapon. On May 25 rain mixed with the ash to form mud, which fell locally and not uniformly. However the fallout pattern of this ash was similar to that predicted by Storebø for "rainout" of debris from nuclear explosives, again making the event worthy of study as a possible predictor of effects which could follow the detonation of a nuclear weapon. (See VOLCANOLOGY.)

The series of events which result in acid rain are at the other extreme of the fallout picture for, instead of consisting of particulate matter of finite size, much of the material released from chimneys, smokestacks and motor-vehicle exhausts is composed of individual molecules or groups of molecules of the oxides of sulfur and nitrogen. In the atmosphere these substances go through chemical reactions to form sulfates and nitrates, which are acidic and which dissolve in water and fall as precipitation at distances of 100 to 1000 kilometers downwind from their original source. The mechanical result is a type of fallout not unlike that from an air-burst of a nuclear weapon, during which essentially all matter is vaporized. Although the particulate matter cannot be physically observed, as in the case of the fall of ash from Mount St. Helens, the chemical effects of the acid rain can be observed, for example, in the increased acidity of the lakes of the Adirondack Mountains, where the water of some lakes has become too acidic to support fish life. Similar nuclear-weapon fallout would be observed simply as an increase in radioactivity in the water.

FARADAY EFFECTS*

In 1845, Michael Faraday discovered the first magnetooptical effect[1] when he observed the rotation of the plane of polarization of light as a result of its passage through lead borate glass in a direction parallel to an applied magnetic field B. This is known as the *Faraday effect* or *Faraday rotation* and was important historically because it provided the first concrete evidence for a connection between magnetism and light. Since then many other magnetooptical effects have been investigated–notably cyclotron resonance, magnetic dichroism, and the Voigt and Hall effects–their common linkage being their dependence on various components of the dielectric or conductivity tensor, as well as on the magnetic permeability tensor in the case of magnetic materials. Faraday rotation has now been shown to be a general property of matter and has been observed in a variety of solids (especially semiconductors), liquids, and gases, over a wide range of frequencies.[2] It is often a very useful technique[3,4] for the determination of various quantities such as effective mass m, collision frequency ν, and mobility μ. In fact, not only does it complement cyclotron resonance determinations of m but it is especially useful in determining electron and hole effective masses in solids in cases where cyclotron resonance is unobservable.[5] The latter circumstance occurs when $\nu \gg \omega$, where ω is the angular frequency of the radiation, and corresponds to large damping (since $\tau = \nu^{-1}$, where τ is the damping or relaxation time). Also, since cyclotron resonance occurs when $\omega = \omega_c$, where $\omega_c = (eB/mc)$ is the cyclotron frequency with e being the magnitude of the charge, it is clear that for a typical m value of 10^{-1} m_0 (where m_0 is the free electron mass) and a maximum B value of 100 kG we have resonance at $\omega = 1.77 \times 10^{13}$ s^{-1}, corresponding to a wavelength $\lambda = 326$ μm, i.e., for practical purposes sharp cyclotron resonances typically do not occur for wavelengths smaller than infrared, and in many cases actually no smaller

than microwave. In other words, Faraday rotation may be measured over a far wider range of frequencies and in a far wider range of materials than cyclotron resonance. However, it has the disadvantage of measuring an average effective mass in cases where the effective mass is anisotropic. It is also used to deduce interstellar magnetic field values as well as providing support for the conclusion that there is little or no antimatter in the galaxy. We use cgs units in this article.

A linearly polarized wave can be decomposed into two waves of opposite *circular polarization*, called *right* and *left* (RCP and LCP), which propagate independently. In general, optical rotation occurs in a medium when its refractive indices for right- and left-circularly polarized radiation, n_+ and n_-, are unequal so that the phase velocities c/n_+ and c/n_- are also unequal. In the case of *natural* optical activity, this arises from asymmetry among the atomic layers whereas *Faraday* rotation arises from the anisotropy produced by the magnetic field. The former (which will not concern us here) disappears on reflection back through a sample whereas the latter is doubled. In the case of an absorbing medium, the difference in absorption coefficients for the two components (referred to as *dichroism*) causes the emerging beam to be elliptically polarized.

The Faraday rotation θ is defined to be one-half the phase angle change between the RCP and LCP waves and corresponds to the amount of rotation of the major axis of the transmitted polarization ellipse.[3] For radiation of frequency ω propagating a distance d through the medium along the direction of the magnetic field, the rotation is given by

$$\theta = \frac{\omega d}{2c}(n_+ - n_-) = \frac{\pi d}{\lambda}(n_+ - n_-), \qquad (1)$$

where λ is the wavelength in vacuum. A theoretical evaluation of $n_\pm$ in the case of nonmagnetic materials (magnetic materials will be discussed below) starts with the relation

$$\epsilon_\pm = (n_\pm + ik_\pm)^2, \qquad (2)$$

where k, the imaginary part of the complex refractive index, arises from absorption and $\epsilon_\pm$ is related to the components of the dielectric tensor ϵ_{ij} $(i, j = x, y, z)$ by

$$\epsilon_\pm = \epsilon_{xx} \pm i\epsilon_{xy}. \qquad (3)$$

Thus the problem of calculating θ is reduced to a calculation of ϵ_{ij}. In general, rotation arises due to interaction of the radiation with either free or bound charge carriers. There are five basic frequencies to be considered: the wave frequency ω, the plasma frequency $\omega_p = (4\pi Ne^2/m)^{1/2}$, where N is the number of charge carries per unit volume, the collision frequency ν, the cyclotron frequency ω_c, and ω_0, which refers to either the natural frequency of the bound charges (classical model) or the frequency separation of spectral lines (quantum mechanical model). In a solid there are contributions to θ from both free and bound electrons and also the nuclei but, as a general rule, at optical and infrared frequencies, the dominant contribution to θ is from the free electrons. For low photon frequencies only transitions within the same band (intraband) are of importance in a semiconductor but as we approach the optical region the band to band (interband) effects must be included. A *classical* calculation of ϵ_{ij} is based on the Boltzmann equation or, more frequently although less rigorously, on the Drude model, which assumes that all charge carriers act independently. The Drude model result is often referred to as the *cold-plasma limit* since it corresponds to the result obtained by use of the Boltzmann equation in the limit of extreme degeneracy (zero temperature).
